Running head title: "Hair Analysis for Forensic Toxicology"

Keywords: Hair, Toxicology, Drugs, Mass Spectrometry, Forensic

ABSTRACT

The increasing role of hair analysis in forensic toxicological investigations principally owes to recent improvements of mass spectrometric instrumentation. Research achievements during the last six years in this distinctive application area of analytical toxicology are reviewed. The earlier state of the art of hair analysis was comprehensively covered by a dedicated book (Kintz, 2007a), that represents key reference of the present overview. Whereas the traditional organization of analytical methods in forensic toxicology divided target substances into quite homogeneous groups of drugs, with similar structures and chemical properties, the current approach often takes advantage of the rapid expansion of multiclass and multiresidue analytical procedures; the latter is made possible by the fast operation and extreme sensitivity of modern mass spectrometers. This change in the strategy of toxicological analysis is reflected in the presentation of the recent literature material, which is mostly based on a fit-for-purpose logic. Thus, general screening of unknown substances is applied in diverse forensic contexts than drugs of abuse testing, and different instrumentation (triple quadrupoles, time-of-flight analyzers, linear and orbital traps) is utilized to optimally cope with the scope. Other key issues of modern toxicology, such as cost reduction and high sample throughput, are discussed with reference to procedural and instrumental alternatives.

I I. INTRODUCTION

2

The analysis of biological specimens to detect of various types of drugs is consistently requested 3 4 within forensic investigations as a necessary step to prove exposure to these substances. Although blood and urine remain the matrices of choice to detect recent exposure, hair analysis is gaining 5 6 ever-increasing importance, as its potentials, limitations, and new application areas are progressively uncovered. Although, for most drugs, any evidence of exposure is erased from blood 7 8 and urine a few days (or hours) after their intake because of the natural metabolic and excretion body processes, a minute portion of the same drugs and metabolites is ultimately incorporated 9 10 through several routes (blood capillaries, sweat, and sebum) into the keratin structure of the hair, from which it is hardly removed. This drug-fixing into the hair structure resists hair growth for 11 12 several months and leads to a potential chronological trace of drug exposure, with farther periods corresponding to the hair segments more distant from the hair root. The continuous improvement of 13 14 analytical procedures and instrumental technologies allows one to determine the very small amounts of drugs included into the hair at ever-decreasing concentrations, insomuch as there are currently 15 16 several scientific reporting of drug detection in hair after a single exposure. Progresses in chromatographic and mass spectrometric techniques have both equally contributed to the 17 impressive results achievable nowadays with modern forensic toxicology in hair analysis. 18

19 On the negative side of hair analysis, there are several potential sources of bias that should always be taken into account in order to produce reliable conclusions from experimental results. 20 First of all, hair is not a homogeneous matrix; thus, careful and representative hair sampling is a 21 22 necessary prerequisite of correct analysis. Secondly, the degree of hair incorporation depends on the chemical structure and related properties of the drug, including melanin affinity, lipophilicity and 23 membrane permeability (Kintz, 2012a). Third, adsorption of external substances from the 24 25 environment is occasionally claimed as a source of false-positive results, especially for 26 professionally-exposed subjects and volatile substances, such as, for example, cocaine (LeBeau & Montgomery, 2009). To prevent this inconvenience, preliminary washing of hair samples is always 27 28 recommended to eliminate any possible interfering substances adsorbed onto the external surface of 29 the hair. Segmental analysis and acceptance of cut-off values often rule out the chance that exogenous drug sources might have contaminated the internal keratin structure. Forth, strong 30 31 cosmetic hair treatments, such as the use of oxidants or highly basic coloring, might damage the 32 keratin structure to favor release of incorporated substances to finally lead to false-negative results. 33 Also, repeated shampooing might partly wash out the hydrophilic drugs incorporated into the hair.

Lastly, the use of cosmetic products such as grease, sprays, and gels might also interfere with hair analysis.

A comprehensive review of drug testing in hair was published in a dedicated book edited by Pascal Kintz (2007a). Since then, only one review was published on abused drug analysis in hair samples, in which chapters are organized on the basis of the various classes of substances (Wada et al., 2010). The present review updates Kintz's book, under the perspective of its chapters 10-15 (Kintz, 2007a); namely, under application areas point of view. The studies published before 2006 are only incidentally cited in the present review, whereas extensive coverage of the papers published in the last six years is presented.

43

44 II. APPLICATION AREAS OF MASS SPECTROMETRY TO HAIR 45 ANALYSIS IN FORENSIC TOXICOLOGY

46

47 A. Targeted Drug Screening for Specific Drug Classes

48 Although screening of psychoactive substances in biological specimens might have a variety of objectives, in terms of target chemical classes and purposes of control, legislation of most countries 49 50 make a clear distinction between drugs of abuse, whose use is prohibited in almost all circumstances, and pharmaceutical substances, whose use is permitted under medical control and 51 52 prescription, even though they are occasionally abused. Most routine screening, such as, for example, workplace testing, are addressed to the drugs of abuse only, whereas other psychoactive 53 54 pharmaceuticals are searched in selected subjects and follow anamnestic indications. In particular, 55 detection of the most-common drugs of abuse in hair samples (Kintz, 2007a; Kintz et al., 2006; 56 Pragst & Balikova, 2006; Wada et al., 2010) is increasingly requested for the retrospective 57 withdrawal control of habitual drug abusers, as well as in other toxicological investigations, such as workplace drug testing [EWDTS (European Workplace Drug Testing Society), 2010; Caplan & 58 Goldberger, 2001], driving re-licensing, occasional or pre-natal exposure to drugs (Kintz, 2007b; 59 Falcon et al., 2012), and post-mortem toxicology. Therefore, although hair samples are routinely 60 61 collected and analyzed in forensic and toxicological laboratories, most published methods were implemented to determine class-specific groups of compounds, mainly cannabinoids, 62 63 amphetamines, cocaine, and opiates, even though the analytical procedures have been constantly updated (Kintz, 2007a; Pragst & Balikova, 2006; Wada et al., 2010). 64

66 **1. Classes of drugs**

67

Although the widespread abuse of hashish or marijuana makes the detection of long-term exposure to Δ^9 -tetrahydrocannabinol (THC) by hair analysis extremely important in clinical and forensic contexts, drug inhalation and adsorption from environmental smoke are frequently claimed to justify positive detection of THC and/or its main metabolite. Although a cut-off of 0.1 ng/mg was traditionally recommended, more recently a cut-off of 0.05 ng/mg has been proposed as a suitable level to detect also occasional users (Pragst & Nadulski, 2005) and for confirmation analyses (Cooper et al., 2012).

GC/MS is the technique of choice for THC detection in the majority of published methods, and 75 76 no particular analytical improvement has been proposed recently, except for the increasing role played by headspace solid-phase microextraction (HS-SPME) procedures. Nadulski and Pragst 77 78 developed, validated, and routinely applied to driving-ability examination a new method for cannabidiol (CBD) and cannabinol (CBN) with improved sensitivity (Nadulski & Pragst, 2007). 79 80 The authors used alkaline digestion of 15-30 mg hair aliquots, subsequent liquid-liquid extraction (LLE), automated HS-SPME after in-sample silvlation, and GC/MS-SIM (selected ion monitoring) 81 82 analysis. For THC, a limit of detection (LOD) of 0.012 ng/mg was obtained. A similar procedure 83 without derivatization with 10 mg of hair sample was proposed (Rodrigues de Oliveira et al., 2007), but the reported LOD and LOQ (limit of quantification) values of 0.07 ng/mg and 0.12 ng/mg, 84 respectively, are above the recommended cut-off limits and make the method apparently not 85 appropriate for routine analysis. Emídio et al. developed and validated a method for the 86 determination of THC, CBD, and CBN in hair samples, with HS-SPME combined with GC/MS/MS 87 (ion trap) detection (Emídio et al., 2010). From a 10 mg hair sample, an LOD of 0.031 ng/mg and 88 LOQ of 0.062 ng/mg were obtained; the latter was slightly higher than the cut-off value of 0.05 89 ng/mg. Nonetheless, from 10 hair samples from cannabis users, an average concentration of 0.056 90 91 ng/mg was found; i.e., below the reported LOQ.

Unlike THC, the improvement of existing analytical methods for stimulants, including cocaine 92 93 and amphetamines, in hair samples has been widely investigated recently. Lee et al. used a standard GC/MS procedure, after derivatization with trifluoroacetic anhydride, in order to study the 94 abundance ratio of methamphetamine (MA) and its metabolite amphetamine (AP) in hair and hence 95 aid the positive results interpretation (Lee et al., 2009). High MA concentrations, together with low 96 AP percentage, were related to severe and chronic drug abuse (Lee et al., 2009). In order to 97 facilitate MA and AP analysis in hair, Miyaguchi et al. developed a simple and fast (1 hour) method 98 for sample preparation named MiAMi (micropulverized extraction-acqueous acetylation-99

microextraction by packed sorbent) followed by GC/MS (Miyaguchi et al., 2009). The amount of
hair sample required for qualitative analysis based on full-scan mass spectra was only 5 mg,
whereas 1 mg of a hair specimen was sufficient for amphetamine quantitation. The same group
(Miyaguchi et al., 2007) previously published an extraction method on micropulverized hair for the
HPLC-MS/MS determination of MA and AP, in which only 2 mg of sample were used.

An LC-MS/MS method that used electrospray ionization (ESI) and a triple quadrupole 105 instrument was developed and validated by Chèze et al. to determine AP, MA, 3,4-106 methylenedioxyamphetamine (MDA), 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy"), 107 3,4-methylenedioxyethamphetamine (MDEA), and N-methyl-1-(3,4-methylenedioxyphenyl)-2-108 butanamine (MBDB) at low concentration levels, in hair, blood, and urine (Chèze et al., 2007). 109 110 With 20 mg of decontaminated hair, the experimental LODs ranged from 0.3 pg/mg for MBDB to 6.3 pg/mg for MDA, where the recommended cut-off limit for amphetamines is 200 pg/mg (Cooper 111 112 et al., 2012). The same study reported a real forensic case, in which the high sensitivity of the LC-ESI-MS/MS method was exploited to detect MDMA in a hair sample, after a single oral dose 113 114 administration to an unaware victim (Chèze et al., 2007). Another recent study reported the development of an LC-MS/MS method for the simultaneous determination of a large set of 115 116 amphetamine-like anorectics and their metabolites in hair samples (Lee et. al., 2012). The procedure 117 was used to analyze the diffusion of anorectics abuse in Korea. The hair incorporation of MA and AP following controlled administration of MA to seven volunteers was recently studied (Polettini et 118 al., 2012). For these amphetamines, significant dependence (i.e.; linear direct correlation) of drug 119 incorporation on hair melanin content was clearly demonstrated. 120

Besides MALDI-imaging techniques, several traditional methods were recently proposed to determine the most common stimulant drug (i.e., cocaine) in hair samples. The suggested cut-off concentration is 500 pg/mg for cocaine and 50 pg/mg for its main metabolite, benzoylecgonine (BZE) (Cooper et al., 2012). A GC/MS analytical method to quantify cocaine and its main metabolite BZE in hair samples was proposed (Barroso et al., 2008). Despite the simple instrumentation utilized, the method proved to be sensitive and specific, and allowed one to detect 20 and 15 pg/mg of cocaine and BZE, respectively, from only 20 mg of sample.

Improved sensitivities were obtained with LC-MS/MS methods. Moore et al. developed and validated an LC-MS/MS procedure for the analysis of cocaine and its metabolites (BZE, cocaethylene, and norcocaine) in hair with an atmospheric pressure chemical ionization (APCI) source and a triple quadrupole (QqQ) mass analyzer (Moore et al., 2007). For all analytes, the LOQs (50 pg/mg) and LODs (25 pg/mg) made the method suitable for routine forensic analysis.

A simple and fully validated procedure for the qualitative and quantitative determination of 133 opiates in hair was presented (Barroso et al., 2010a). This paper describes a GC/MS method for the 134 analysis of codeine, morphine, 6-monoacetylmorphine (6-MAM), 6-acetylcodeine, and tramadol in 135 20 mg hair samples. The presence of the screened analytes was demonstrated in several real cases, 136 among which it was proven that tramadol is occasionally abused by opiate addicts. A combination 137 of opiates, cocaine and metabolites was simultaneously screened with an LC-ESI-MS/MS method 138 (Huang et al., 2009). This method was fully validated and used in the analysis of 79 authentic hair 139 samples, and demonstrated that a multiresidue approach might screen different classes of drugs at 140 141 the same time.

The objective of cost reduction of workplace drug screening with a multiresidue UHPLC-MS/MS strategy was explicitly cited in a recent study (Di Corcia et al., 2012). Thirteen analytes, including opiates, cocaine, amphetamines, THC, buprenorphine, methadone, and a few metabolites, were simultaneously screened in hair samples. A simple sample preparation combined with multiclass analysis and fast chromatographic separation allowed one to obtain high sample throughput, together with excellent sensitivity and selectivity; the procedure is valuable for large sample workload and reduced costs of analysis (Di Corcia et al., 2012).

149

150 **2. New instrumental set-up**

151

A new and original study, aimed to the direct detection of MA in hair samples, used imaging 152 mass spectrometry (IMS) to perform micro-segmental analysis (Miki et al., 2011). In practice, a hair 153 shaft was affixed to a carbon tape and manually cut lengthwise to produce micro-incisions at 154 extremely close range with a razor and a microscope. After matrix deposition, IMS was obtained by 155 matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) and MALDI-Fourier 156 transform ion cyclotron resonance (FTICR) mass spectrometers. IMS produced a barcode-like 157 image of methamphetamine on the longitudinal sections of the hair shafts, obtained from a 158 methamphetamine chronic abuser, to indicate the periods and sequence of single MA intake (Miki 159 et al., 2011). This innovative approach appears to be very promising in the forensic context, as soon 160 as the hair sample preparation can be automated. 161

A MALDI hybrid triple quadrupole linear ion trap (QqQ_{LIT}) instrument, equipped with a high repetition rate laser, was recently proposed to perform MS imaging on a single hair, for cocaine consumption monitoring (Porta et al., 2011). The QqQ_{LIT} technology was exploited to simultaneously achieve target quantification with selected reaction monitoring (SRM) mode of operation and sensitive MS³ acquisition for confirmatory analysis. MS imaging of intact single hair

sample offers much higher resolution than segmental LC-MS/MS analysis, and only depends on the 167 distance between two adjacent laser shots. However, the minimal 0.1 mm resolution allowed by the 168 laser and corresponding to a theoretical average hair growth of less than 12 h, has currently little 169 significance in forensic investigations, beacuse the complex nature of keratin incorporation 170 mechanisms and the heterogeneous physiology of hair growth might provide a much larger bias on 171 chronological assessment. Single washed hair samples were fixed onto a stainless steel MALDI 172 plate with a double-sided adhesive foil, and the MALDI matrix was manually sprayed. First, an 173 imaging profile of cocaine and metabolites was acquired in the SRM mode over the whole hair 174 length, taking into account that highly selective transitions should be chosen to compensate for the 175 absence of chromatographic separation. Secondly, MS/MS and MS³ experiments were performed 176 for confirmatory identification. The entire analytical workflow is represented in Figure 1 (Porta et 177 al., 2011). An experimental LOD of 5 ng/mg allows for cocaine detection in the hair of chronic 178 179 abusers, but not after a single administration. Moreover, scaling down to single-hair analysis makes the choice of representative sampling crucial, unless a further source of uncertainty and bias is 180 181 introduced.

In order to detect all cocaine metabolites, including the highly polar ecgonine methyl ester 182 183 (EME), Quintela et al. developed and validated a hydrophilic interaction liquid chromatography 184 (HILIC) method to be coupled to tandem mass spectrometry (Quintela et al., 2010). With as little as 10 mg of specimen, experimental LODs were better than or equal to 1 pg/mg. The recognition of 185 ultra-trace amounts, at low pg/mg of hair, appears to be crucial for EME detection, because this 186 metabolite has a very low incorporation rate into the hair shaft (Quintela et al., 2010). Recently, 187 Thibert et al. adopted a clean-up process for hair extracts based on molecularly imprinted polymers 188 (MIP) selective for cocaine and BZE, followed by LC-MS/MS analysis (Thibert et al., 2012). An 189 LOD lower than 70 pg/mg was reached for both molecules, slightly above the suggested cut-off 190 191 value for BZE (Cooper et al., 2012).

192 A fast, but only qualitative, screening method to detect cocaine and its metabolites from hair samples used MALDI-TOF technology (Vogliardi et al., 2009). The whole hair sample preparation 193 194 for MALDI analysis turned out to be significantly more rapid and simpler than for GC/MS, and data acquisition in MALDI analysis is, in turn, much quicker than in GC/MS. Thus, the MALDI 195 technique shows clear advantages over the traditional approach, when fast screening of a large 196 number of sample is required, as the same authors subsequently demonstrated by validating and 197 testing the new method on 304 real hair samples (Vogliardi et al., 2010). High throughput and fit-198 199 for-purpose principles both find neat application in this well-designed example of fast cocaine 200 screening in hair samples.

201

202 B. Non-Targeted Drug Screening

Most of the methods cited in the preceding chapter are specific for a class of drugs. The highlyfocused objective of these analytical investigations allows one to optimize sample treatment, cleanup, and chromatographic conditions in order to maximize recoveries and to meet the acceptance criteria of sensitivity and specificity that lead to accurate quantification for confirmation. However, their applicability in general drug screening for acute intoxication and autopsic analysis appears limited. In practice, these class-specific procedures find useful application when the target analytes can be predicted in advance; for example, in heroin overdose fatalities.

In the daily activity of forensic laboratories, it is quite frequent that the target analytes cannot be 210 foreseen, so that a wide range or "general" screening of abused drugs is commonly required, as it 211 212 occurs in most acute intoxications and post-mortem investigations. Whenever a multitude of candidate substances might represent the cause of intoxication or death, several analytical 213 procedures are likely to be used on the collected biological specimen, with a direct impact on time, 214 costs, and efficiency. For this reason, comprehensive screening procedures of multiclass drugs are 215 progressively introduced into the analytical practice, even if the method conditions should 216 compromise on absolute performances, in terms of recovery, sensitivity, selectivity, and accuracy, 217 due to the presence of target analytes with widely different physico-chemical properties. 218

Even though hair is not the preferred biological matrix to ascertain acute intoxication, hair analysis is frequently commissioned to complete the circumstantial evidences; i.e., to ascertain whether the victim formerly abused drugs or whether any drug was administered to him/her earlier. To meet the high demand for drug screening in hair samples, toxicology laboratories are forced to update their procedures in order to target an ever-increasing number of drugs, but also to achieve rapid, simple, and sensitive testing with reduced sample preparation and fast instrumental processing so as to increase the overall sample throughput.

226

1. Methods based on GC separation

228

Cordero and Paterson developed and validated a GC/MS protocol to simultaneously quantify fourteen compounds, including some amphetamines, opiates, cocaine and metabolites, diazepam, and metabolite (Cordero & Paterson, 2007). A two-step derivatization with *N*-methyl-bis trifluoroacetamide (MBTFA) and *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) + 1% trimethylchlorosilane (TMCS) was used. Due to the general availability of GC/MS instrumentation in toxicology laboratories and the good analytical performances obtained in this study, this method

might find useful application in a variety of clinical and forensic investigations. An interesting 235 evolution of the preceding method was developed by Aleksa et al., that used an HS-SPME-GC/MS 236 to improve the protocol sensitivity (Aleksa et al., 2012). Seventeen drugs of abuse, including 237 opiates, cocaine, amphetamines, and opioids, were reacted with the same derivatizing agents 238 described above, and were detected at LOD levels of 130-200 pg/mg. The method was validated 239 with only 5-10 mg of hair, and was especially useful for newborn, when sample availability is 240 limited. Among the wide screening protocols to detect common panels of abused drugs, only few 241 comprehensive methods include THC, regardless of the instrumental technique used. Merola et al. 242 243 developed a new procedure with HS-SPME and GC/MS to provide concomitant determination of 244 several drugs of abuse, including THC, but not opiates (Merola et al., 2010). A different approach 245 and derivatizing agent, namely heptafluorobutyric anhydride (HFBA), was used (Wu et al., 2008a) to develop a GC/MS method for the simultaneous determination of amphetamines, opiates, 246 247 ketamine, and their metabolites at LODs of 30-80 pg/mg. The same group (Wu et al., 2008b) improved selectivity and sensitivity to reach the low pg/mg level with electron capture negative 248 chemical ionization (NCI) to detect the same derivatives. 249

TOF mass analyzers have also been used for broad drug screening in hair samples that take 250 251 advantage of their full-scan and high-resolution capabilities. In an original study, Guthery et al. developed a GC×GC-TOF-MS procedure to provide a comprehensive qualitative drug screening of 252 hair samples (Guthery et al., 2010). The hair extracts were subjected to derivatization with N-253 254 methyl-N-(tert-butyldimethyl)trifluoroacetamide (MTBSTFA), which efficiently reacted with a broad range of multiclass analytes, including opiates, opioids, cocainics, and benzodiazepines. The 255 2D chromatographic plot obtained from GC×GC separation offers an extremely clear depiction of 256 257 the drug content profile, as Figure 2 demonstrates (Guthery et al., 2010).

258

259 2. Methods based on LC separation

260

261 Although the latter GC/MS methods proved suitable to test simultaneously several classes of drugs of abuse, the need to further expand the assortment of target substances within the same 262 protocol, without the necessity of derivatization, made the highly flexible LC-MS/MS approach to 263 multiclass screening more profitable and more widely used than GC/MS. An LC-APCI-MS/MS 264 method was developed, validated, and applied for the retrospective multi-parameter evaluation and 265 distribution of eleven drugs of abuse in hair samples (Klis et al., 2007). Subsequently, ESI was 266 more extensively utilized than APCI, as in a validated LC-MS/MS method (Miller et al., 2008) that 267 was aimed at the simultaneous quantification of amphetamines, opiates, cocaine and metabolites, 268

and diazepam and metabolites (17 compounds) in post-mortem hair samples. The use of an ion trap 269 mass spectrometer was suggested (Bucelli et al., 2009) to screen 16 drugs of abuse in human hair. 270 Despite the flexibility of ion traps to provide an easy switch between full-scan and MS/MS or MSⁿ 271 modes of data acquisition, the method was not expected to provide accurate quantitative 272 273 determinations, and needs further validation and a more extended panel before it might find widespread application in forensic laboratories. Di Corcia et al. proposed a simple sample 274 extraction and direct injection into a UHPLC-MS/MS system to avoid solid-phase and liquid-liquid 275 extraction and to achieve fast and simultaneous detection of the most common drugs of abuse, 276 277 including THC, in hair samples (Di Corcia et al., 2012). Lendoiro et al. developed and validated an 278 LC-MS/MS multiclass screening method for the simultaneous detection of 35 substances, including 279 THC, and the other most common drugs of abuse (opiates, amphetamines, cocaine, LSD, ketamine 280 and scopolamine) and pharmaceuticals (benzodiazepines, antidepressants and hypnotics) (Lendoiro 281 et al., 2012). For the entire range of investigated molecules, LODs were 0.2-50 pg/mg and achieved better cut-offs than Society of Hair Testing (SOHT) recommendations. In the screening mode of 282 283 operation, only one SRM transition per compound was used, but the same procedure could be transformed into a confirmation method with addition of further target-specific SRM transitions 284 285 (Lendoiro et al., 2012). Confirmatory analysis of ketamine and norketamine was the objective of a 286 recent study that used molecularly imprinted solid-phase microextraction (MISPE) followed by LC-287 MS/MS (Harun et al., 2010).

An effective method to check for the presence of a wide set of drugs in hair samples was 288 proposed (Nielsen et al., 2010), to validate an analytical method for the simultaneous screening and 289 quantification of 52 common drugs and pharmaceuticals in hair with the novel UHPLC-TOF-MS 290 technology. The panel of compounds was very broad because it included common drugs of abuse, 291 benzodiazepines, analgesics, antidepressants and antipsychotics. The authors underlined, however, 292 293 that the TOF instrument was less useful than a triple quadrupole on low-mass molecules, such as 294 amphetamines, due to the presence of high background noise and the consequent lack of sensitivity and linearity (Nielsen et al., 2010). Similar broad drug screening, based on accurate mass 295 296 measurements with LC-TOF-MS, was also achieved (Pelander et al., 2008). Also in this study, the 297 potential to conduct a comprehensive screen (35 targeted analytes) was clearly demonstrated; however, the authors recommended more-specific instrumentation for target confirmation analyses. 298 299 More recently, an automated screening method for the simultaneous identification and quantitation 300 of 30 compounds (including most drugs of abuse, but also a few anabolic steroids, β -agonists and other pharmaceuticals) in hair samples was proposed with fast LC-TOF-MS (Domínguez-Romero 301 et al., 2011). Progressive instrumental upgrading and method refinement provided improved 302

sensitivity with TOF mass spectrometers to allow the detection of the target compounds in the low
 pg/mg range (LODs ranged from 5 pg/mg to 50 pg/mg).

General screening of unknown drugs in hair samples was performed with LC combined with a 305 quadrupole time-of-flight mass spectrometer (LC-QTOF-MS) (Broecker et al., 2012). Systematic 306 307 collection of CID (collision-induced dissociation) spectra from quadrupole-selected protonated molecule used a data-dependent acquisition mode to create a wide dataset to allow the retrospective 308 investigation of potentially toxic substances present in the hair sample. These CID spectra were 309 compared with an accurate-mass CID spectral library created by the authors that contained more 310 311 than 2500 toxicologically relevant substances (Broecker et al., 2011; Niessen, 2011). For 24 tested illegal drugs and benzodiazepines, significantly low LODs (3-15 pg/mg) were observed. The 312 313 method was applied to hair samples from 90 death cases to reveal 212 substances altogether, even if only partial agreement with the positive identifications from urine and blood analysis was found, 314 315 with many unexpected drugs detected and many reported drugs not detected in hair (Broecker et al., 316 2012). A similar approach was also applied to hair samples (Liu et al., 2010) with an in-house 317 spectral library of about 800 substances for the identification of unknown drugs. In this case, the hybrid QqQ_{LIT} mass spectrometer produced low-resolution CID spectra from mass-selected 318 319 precursor ions, with good sensitivity provided by the ion-accumulation capability of ion trap.

320

321 3. Other methods

322

Besides GC and LC, capillary electrophoretic methods were also occasionally used to separate 323 324 drugs extracted from hair samples and to introduce them into the mass spectrometer. Capillary zone electrophoresis was combined with TOF analysis (CZE-TOF-MS) to detect four amphetamines, 325 ephedrine, opiates, cocaine, and metabolites in hair samples. The method proved suitable for 326 qualitative screening of all drugs below the prescribed cut-off limits, but was not fully satisfactory 327 for accurate quantification, possibly due to the lack of deuterated internal standards (Gottardo et al., 328 2007; Gottardo et al., 2012). Also, another method, cation-selective exhaustive injection and 329 330 sweeping micellar electrokinetic chromatography, proved compliant with the cut-off values in hair (Lin et al., 2007); however this method and the preceding study represented isolated proposals with 331 no further application in common laboratory practice. 332

Quite uniquely, Jackson et al. proposed to eliminate the chromatographic separation with an ambient ionization technique, defined as low temperature plasma (LTP) ionization, to analyze biological specimens, including urine, saliva, and hair extracts (Jackson et al., 2010). The method was tested on 14 drugs that belonged to different classes (amphetamine, BZE, cannabidiol, caffeine,

ephedrine hydrochloride, heroin, 337 cocaine, codeine, diazepam, ketamine, methadone, methamphetamine, morphine, and THC) with a linear ion trap mass spectrometer in the positive-ion 338 mode. However, LOD values were rather high [ng/mL (i.e., 10 ng/mL) to the mg/mL 339 340 concentrations] and only one real hair sample was analyzed that showed the presence of cocaine. 341 The main focus of the study was on the potential of LTP ionization and its compatibility with miniaturized and portable instrumentation for on-site screening analysis. 342

343

344 C. Rape Drug Detection and Segmental Analysis

Drug-facilitated crime (DFC) is a general term that involves the administration of a drug to 345 perpetrate a variety of crimes, including rape or other sexual assault, robbery, money extortion, as 346 well as the deliberate maltreatment of elderly persons or children under the influence of 347 psychotropic substances [UNODC (United Nations Office on Drug and Crime), 2011]. In most 348 DFCs, the victims are subjected to violence or nonconsensual acts while they are incapacitated by 349 350 the effects of a drug, often unknowingly ingested. Psychoactive substances used in DFCs might alter the victim's degree of consciousness, state of awareness, judgment, and memory. Such 351 substances can make the victim vulnerable and unable to fight off the attacker, or are used to sedate 352 the victim in order to facilitate his/her transport by the perpetrator. The drugs used for these 353 354 criminal purposes include benzodiazepines, hypnotics, sedatives and anesthetics, drugs of abuse (such as cannabis, ecstasy, LSD, or heroin), miscellaneous drugs (e.g., scopolamine), and, most 355 356 frequently, ethanol (Kintz, 2007b). The ideal substance to be dispensed to perpetrate a crime is the one that is readily available, easy to administer, able to rapidly impair consciousness, and produce 357 358 anterograde amnesia (LeBeau & Montgomery, 2010).

Among DFCs, a drug-facilitated sexual assault (DFSA) occurs when a person is subjected to 359 unwilling sexual acts while incapacitated or unconscious, due to the effects of ethanol, drugs, and/or 360 other intoxicating substances (generally called "rape drugs"). It is highly unlikely that the specific 361 362 drug used in a DFSA could be determined only by symptoms because the depressant effects of most 363 of these drugs are similar. This factor makes crucial identification of the administered drug in the 364 victim's biological specimen (Negrusz & Gaensslen, 2003). It is well-known that sexual assaults are significantly under- and late-reported. Evidently, any delay to report a DFSA implies that the 365 victim's biological fluids (i.e., blood and urine) are not timely collected, hence rendering more 366 difficult the toxicologists' task to identify the incapacitating agent (LeBeau & Mozayani, 2001). 367 Whenever the natural metabolic processes have eliminated the drug from biological fluids 368 (typically, urine and blood), hair is the most helpful specimen to be investigated (Negrusz et al., 369 370 2000; Villain et al., 2004; Negrusz et al., 2001; Scott, 2009; Parkin & Brailsford, 2009).

Toxicology laboratories are frequently asked to analyze hair from victims in order to reveal 371 allegedly administered drugs. Further information is furnished by segmental analysis to generally 372 provide chronological setting. Head hair should be collected at least four weeks after the alleged 373 374 assault [UNODC (United Nations Office on Drug and Crime), 2011]. Since the average growth rate of human scalp hair is about 1 cm/month, administration of a single dose can be confirmed by drug 375 detection in the corresponding segment, with no presence in the preceding and subsequent 376 segments. The expected concentration in hair is generally in the low pg/mg range for most drugs 377 (Kintz, 2007b; Villain et al., 2005). Therefore, the use of highly sensitive instrumental techniques is 378 379 mandatory in the investigation of DFCs (Kintz et al., 2005; Chèze et al., 2005).

380

1. Methods based on LC-MS/MS with triple quadrupoles

382

383 The analytical strategy generally starts with a comprehensive screening for benzodiazepines and other drugs commonly involved in DFCs (Parkin & Brailsford, 2009). In recent years, several 384 385 methods have been proposed for the simultaneous analysis of a large series of pharmaceuticals and drugs with LC-MS/MS with triple-quadrupole instruments. Hegstad et al. developed a multiclass 386 387 LC-MS/MS method to screen several drugs of abuse on 20 mg of hair, which included 7-388 aminonitrazepam, 7-aminoclonazepam, 7-aminoflunitrazepam, oxazepam, diazepam, alprazolam, and two benzodiazepines-like z-drugs (zopiclone and zolpidem) (Hegstad et al., 2008). Similarly, 389 Irving and Dickson described an LC-MS/MS procedure to detect sedatives in hair and nail samples 390 (Irving & Dickson, 2007). Nine benzodiazepines, three metabolites, and zopiclone and its 391 metabolite were selected and detected at low level in 50 mg specimen, with LODs that ranged from 392 0.02 pg/mg for zopiclone to 6.00 pg/mg for temazepam. This procedure was applied to the analysis 393 of a hair sample collected 17 months after the occurrence of a DFSA: zopiclone and its metabolite 394 395 were both detected in different hair segments at concentrations below 7 pg/mg (Irving and Dickson, 396 2007). Our group developed an LC-MS/MS method to detect 14 pharmaceuticals, including 10 benzodiazepines, ketamine, scopolamine, zopiclone, and zolpidem with LODs that ranged from 0.2 397 398 pg/mg for ketamine and zolpidem to 4.0 pg/mg for flunitrazepam (Salomone et al., 2012a). The 399 method was applied to a real case of segmental analysis of the hair from two women, and showed conclusive discrimination between occasional and therapeutic administration (Salomone et al., 400 2012a). An interesting study of high-resolution segmental analysis on single hairs was developed to 401 investigate the history of a multiple poisoning case with clozapine (Thieme & Sachs, 2012). From 402 1-2.5 mm segments of a single hair, a highly-specific LC-MS/MS procedure allowed to detect as 403 little as 30 fg (1 pg/mg) of clozapine and its metabolite norclozapine. The collection of hair samples 404

after a 165 days interval, combined with the subsequent comparison of drug concentration profiles,
provided an accurate estimation of hair growth rate for the selected individuals (Thieme & Sachs,
2012).

Another LC-MS/MS method was proposed and validated (Xiang et al., 2011) for the 408 409 quantitative determination of 18 benzodiazepines in 20 mg of hair. LODs ranged from 0.2 pg/mg for estazolam to 5 pg/mg for 7-aminoclonazepam, 7-aminonitrazepam, α -hydroxytriazolam, and α -410 hydroxymidazolam. This method determined the distribution of estazolam after single dose intake 411 in hair segments of healthy volunteers: estazolam concentrations ranged between 0.56 pg/mg and 412 413 2.60 pg/mg. Two real cases were studied with the same method, where the victims of DFCs were 414 exposed to clonazepam: the presence of this drug was found in several hair segments from victim 415 #1, and ranged from 1.63 pg/mg to 15.47 pg/mg, and in two segments from victim #2 at 1.31 pg/mg and 11.93 pg/mg concentrations. The metabolite 7-aminoclonazepam was found in hair segments at 416 417 considerably higher concentrations than the parent drug to demonstrate the opportunity to include also the main metabolites in the benzodiazepine-screening procedure (Xiang et al., 2011). Similarly, 418 419 Kim et al. established and validated an analytical method to simultaneously detect 27 benzodiazepines and metabolites plus zolpidem in hair with LC-MS/MS (Kim et al., 2011). The 420 421 absolute LODs ranged from 0.005 ng (zolpidem) to 0.5 ng (bromazepam and chlordiazepoxide). 422 The protocol was successfully applied to five forensic cases of either DFCs or benzodiazepines abuse, together with a study on drug incorporation into the hair of rats. As model for human hair, it 423 was proved that rat-hair pigmentation does not have any significant effect on the degree of 424 benzodiazepines (and metabolites) deposition in hair. As a matter of fact, the incorporation rates of 425 other classes of drugs proved to depend on the hair pigmentation, to create ethnic discrimination 426 (Gambelunghe et al., 2007; Polettini et al. 2012). The panel of screened compounds was expanded 427 further by Lendoiro et al., who recently presented a target multi-analyte LC-ESI-MS/MS screening 428 method to detect 35 licit and illicit drugs, including THC, in 50 mg hair samples (Lendoiro et al., 429 430 2012). Among the screened substances, zolpidem, zopiclone, and 12 benzodiazepines were detected at LODs that ranged from 2 pg/mg (7-aminoflunitrazepam, flunitrazepam, lorazepam, 431 432 lormetazepam, nordiazepam, and diazepam) to 10 pg/mg (oxazepam, clonazepam, and tetrazepam). 433 Analysis of seventeen hair specimens from various forensic cases demonstrated the method applicability: several illicit and prescription drugs were tentatively identified, and subsequently 434 confirmed with two SRM transitions in place of one (Lendoiro et al., 2012). In all the cited LC-435 MS/MS procedures, triple-quadrupole instruments were used, and proved the efficiency of this 436 instrument for wide multi-analyte screening. Similar LC-MS/MS configuration was also used in 437 confirmation methods specifically designed to determine acepromazine (Gaulier et al., 2008), 438

diazepam, nordiazepam and tetrazepam (Laloup et al., 2007), sildenafil (Kintz et al., 2009), and
gamma-hydroxybutyrate (Stout et al., 2010) in hair samples, with the purpose to investigate DFSA
cases.

442

443 2. High-resolution mass spectrometers

444

Mass spectrometers other than triple quadrupoles were used for wide-range screening and 445 confirmation analysis. Mass analyzers with high-resolution capability and accurate mass detection, 446 447 such as TOF-MS and FTICR-MS, are particularly suited for *a-posteriori* reevaluation of the 448 presence of drugs not considered in a preliminary target analysis. UHPLC-TOF-MS and UHPLC-449 MS/MS were both used in the development of a specifically validated confirmation protocol, aimed to quantification of triazolam in an emblematic case of DFC (Stybe Johansen and Dahl-Sørensen, 450 451 2012). In the hair segments (2 cm) that corresponded to the period of the alleged assaults, the presence of triazolam was revealed at a concentration of 1.0 pg/mg. A wider range of analytes was 452 453 covered in a high-resolution mass spectrometric (HRMS) drug screening with TOF-MS (Pelander et al., 2008). The authors initially developed an analytical strategy for the comprehensive screening of 454 455 drugs and doping agents in urine, but afterward the applicability of the method to other matrices, 456 such as keratin, was also studied. Although the potential of the LC-TOF-MS approach to obtain a comprehensive drug screening in the hair of drug addicts was clearly proved, the study did not 457 clarify whether the method sensitivity was high enough to detect drug traces from single intake. A 458 UHPLC-TOF-MS screening procedure previously cited (Nielsen et al., 2010) targeted 52 analytes, 459 among which 13 benzodiazepines and metabolites plus zaleplon, zolpidem, and zopiclone. For the 460 screened molecules, homogeneous LODs were obtained that ranged from 10 pg/mg for diazepam 461 and zolpidem, to 40 pg/mg for 7-aminoflunitrazepam and lorazepam. The method was applied to 15 462 autopsy hair samples. In most strands, several benzodiazepines were identified. Although accurate-463 mass analysis provided comparable selectivity to multiple SRM transitions from a triple-quadrupole 464 instrument, the authors recommended positive findings to be confirmed with an additional method 465 466 (Nielsen et al., 2010).

Orbitrap technology was also used for HRMS multi-target screening of hair samples (Vogliardi et al., 2011). The purpose of this study was to develop and validate a specific method based on LC-HRMS for the simultaneous detection in 50 mg hair strands of 28 benzodiazepines (and metabolites) registered in the Italian market. The "z-drugs" were not included, despite the fact that zolpidem is significantly prescribed among the Italian population. The use of a hybrid linear ion trap-Orbitrap mass spectrometer yielded LODs from 0.5 pg/mg (clotiazepam) to 10 pg/mg

(delorazepam). The validated procedure was applied to hair samples from suspected benzodiazepine 473 consumers and showed its suitability for screening and identification of the target compounds. 474 Indeed, the potential of such an instrument includes full-scan exact-mass measurement of 475 protonated molecule ions and CID fragment ions, isotopic pattern recognition, and ion ratio 476 477 determination between molecular and fragment ions. Recently, the same group developed and validated an analogous method to detect 28 substances that belonged to several drug classes: 478 cocaine, amphetamines, opioids, benzodiazepines, antidepressant, and hallucinogens. Although a 479 mass spectrometric approach similar to the one previously described was applied, a new and faster 480 481 extraction process on micropulverized hair allowed reliable identification and quantification of the target drugs on as little as 2.5 mg of hair samples (Favretto et al., 2012). The combined use of full-482 scan HRMS and CID offered the possibility of retrospective analysis to detect previously untargeted 483 substances. 484

485

486 D. Biomarkers for Alcohol Abuse

An important goal of forensic toxicology and clinical medicine is to identify appropriate 487 biological markers of ethanol consumption to evaluate harmful drinking and to ascertain alcohol 488 abstinence (Pragst & Balikova, 2006). The determination of direct ethanol metabolites, such as 489 ethyl glucuronide (EtG), ethyl sulfate (EtS), fatty acid ethyl esters (FAEEs), and 490 phosphatidylethanol (PEth), in different biological matrices currently represents the most-valid 491 strategy to provide unbiased evidence of chronic alcohol abuse. Among direct biomarkers, FAEEs 492 and EtG can be detected in a variety of matrices, including hair (Pragst & Balikova, 2006), and 493 494 allow one to gain information on alcohol consumption for several months. Hair analysis proved very useful to monitor ethanol use/abstinence, workplace testing, driving license reissue/renewal, 495 child custody, divorce proceeding, withdrawal treatment (Politi et al., 2006), and post-mortem or 496 pre-natal alcohol exposure investigation (Bendroth et al., 2008; Pragst & Yegles, 2008), even if the 497 straightforward interpretation of analytical results has been fiercely questioned and warning about 498 499 possible intra- and inter-individual variability has been raised (Tagliaro et al., 2011).

According to the Society of Hair Testing, analysis of the proximal 3 cm hair segment is recommended in order to avoid partial loss of the analytes. The suggested cut-off values that support a diagnosis of chronic excessive alcohol consumption are 30 pg EtG/mg scalp hair, and 0.5 ng FAEEs/mg scalp hair, respectively; both measured in the 0-3 cm proximal segment (Kintz, 2012b). Figure 3 shows the effectiveness of the 30 pg EtG/mg cut-off value (horizontal line) to discriminate harmful drinkers (red dots) from low-risk drinkers and non-drinkers (yellow and green dots), whereas the cut-off value (vertical line) commonly adopted for an esteemed indirect biomarker, such as carbohydrate-deficient transferrin (CDT), proved to have reasonable specificity
but largely insufficient sensitivity, that led to about 50% false negative results (Pirro et al., 2011a).

509 In contrast to other forensic applications, a very small number of direct alcohol biomarkers represent for toxicologists the target analytes in hair samples, essentially FAEEs and EtG. 510 Consequently, considerable effort has been devoted to their extraction procedures and instrumental 511 arrangements, in order to obtain continuously improving analytical performances and, above all, 512 minimal LOD and LOQ values. In particular, the refinement of existing methods was addressed to 513 (i) increase the laboratory throughput, with a reduction of sample preparation steps, analysis-time, 514 515 and costs, (ii) increase the sensitivity and detection capability, so as to accurately quantify minute 516 biomarkers hair concentrations (in the pg/mg range), especially to ascertain alcohol abstinence, (iii) 517 improve the method validation protocols in order to consider all potential sources of bias and uncertainty and assure highly reliable analytical results. Under such circumstances, quite traditional 518 519 instrumentations, such as triple-quadrupole mass spectrometers in the SRM mode, combined with either GC or HPLC, were almost uniquely utilized, because they assure sensitive and accurate 520 521 quantification of few pre-determined target analytes.

522

523 **1. FAEE determination in hair samples**

524

Due to the relatively high volatility and hydrophobicity of FAEEs, HS-SPME-GC/MS is the 525 526 suggested method-of-choice for the routine determination of ethyl myristate (E14), ethyl palmitate (E16), ethyl stearate (E18), and ethyl oleate (E18:1) in hair extracts (Kintz, 2012b). Among over 20 527 ethyl esters detected in hair, these four selected analytes were found to best reflect harmful drinking 528 (Pragst et al., 2001). In brief, deuterated internal standards are added to decontaminated hair 529 samples, and subsequently extracted overnight with a heptane-dimethylsulfoxide mixture. The 530 hydrocarbon layer is evaporated and the residue dissolved into a phosphate buffer, on which HS-531 532 SPME is executed. The SPME fiber is analyzed with GC/MS in the electron impact (EI) ionization mode under SIM conditions. 533

Over time, laboratories interested in testing for FAEEs adopted the protocol (Pragst et al., 2001), with small changes for in-house revalidation of the method and to optimize the experimental conditions, to determine E14, E16, E18 and E18:1, with the purpose to better clarify the reliability, limitations, and potential of FAEE biomarkers in hair to ascertain harmful drinking. Later, Pragst and Yegles presented an updated procedure, with detection limits ranging between 0.003-0.01 ng/mg, as determined on 30 mg of hair (Pragst & Yegles, 2008).

Kulaga et al. investigated the potential effect of hair pigmentation on FAEEs incorporation into 540 541 the keratin matrix, and used, for the first time, hair collected from rats as a model matrix for FAEE production and hair inclusion (Kulaga et al., 2009). As expected for neutral and lipophilic 542 molecules such as FAEEs, they concluded that FAEE concentration in hair does not depend on hair 543 pigment. However, they noted that FAEE hair concentration in rats was much lower than that 544 typically observed in humans, at comparable dosage, but still measurable with the analytical 545 protocol adopted. Gareri et al. used the same analytical method to study the potential bias from use 546 of ethanol-containing hair-care products on FAEE concentration measured on hair of a non-547 548 compliant female population (Gareri et al., 2011). From the comparison of FAEE and EtG 549 concentrations in the same hair samples, they concluded that use of hair-care products that contain 550 ethanol (even at low percentage; i.e., less than 10% by volume) might affect FAEE levels in real 551 hair samples, with experimental values from approximately 0.5 to 5.0 ng/mg, to possibly produce 552 false non-compliant outcomes (Gareri et al., 2011). Süsse et al. considered the experimental results from as many as 1872 hair samples from forensic cases (Süsse et al., 2012). They deduced that (i) 553 554 the use of hair spray might affect (increase) detected FAEEs, but not EtG, hair concentrations; (ii) conversely, bleaching and dying hair treatments might affect (decrease) EtG, but not FAEEs, hair 555 556 concentrations, whereas (iii) hair gel, hair wax, oil, and grease have apparently no influence on 557 FAEEs and EtG.

Süsse et al. reported a method with detection limits ranging from 0.008 to 0.026 ng/mg, as 558 measured on 20-50 mg hair samples (Süsse et al., 2010). These analytical features allowed the same 559 authors to accurately measure the basic levels of hair FAEEs in strict teetotalers: the results showed 560 that 20% of abstainers (N=242) presented total a FAEE concentration that exceeded the cut-off 561 562 values of 0.5 or 1.0 ng/mg, as a function of the examined hair length (Süsse et al., 2012). In contrast, Albermann et al. reported total a FAEEs concentration lower than 0.2 ng/mg for 74% of 563 drivers who self-claim as abstinent (N=160), whereas only 9% of these samples showed a FAEE 564 concentration that exceeded 0.5 ng/mg, among which some true-positive cases (Albermann et al., 565 2011). 566

Lately, Hastedt et al. updated and revalidated the HS-SPME-GC/MS method originally developed by Pragst et al. (Hastedt et al., 2012; Pragst et al., 2001). Better detection limits were achieved (0.004-0.014 ng/mg), although an expanded time to complete the chromatography cycle was needed (over 30 min) than in the original method.

571 On the other hand, Caprara et al. and Kulaga et al. described a different analytical strategy to 572 quantify a larger number of FAEEs in neonatal human and animal hair samples, with ethyl 573 heptadecanoate as the internal standard (Caprara et al., 2006; Kulaga et al., 2006). They adopted

solid-phase extraction (SPE) in place of SPME to isolate FAEEs from hair extracts, followed with 574 575 either GC/MS or GC/MS/MS in the chemical ionization (CI) mode, with isobutene as the ionizing gas. Unlike EI, which typically leads to an extensive, but nearly identical, fragmentation patterns for 576 577 all FAEEs, CI virtually generates only the protonated molecule ion, which is distinctive for each ethyl ester. MS/MS performed in an ion-trap device clearly adds specificity to the method. In 578 choosing CI rather than EI for the analysis, good detection limits were achieved (<2.4-6.6 pg/mg), 579 only recently outperformed, as reported above. FAEE-analysis profile was also expanded to six, 580 rather than four esters, by adding ethyl laureate (E12), and ethyl palmitoleate (E16:1), and 581 582 cumulative analysis of all commonly occurring FAEEs in biological matrices was suggested to provide a more effective way to identify neonates with suspected pre-natal exposure to ethanol 583 584 (Caprara et al., 2006; Kulaga et al., 2006).

By taking advantage of the preceding experiences, Zimmermann and Jackson proposed a 585 586 globally revisited analytical method to determine five FAEEs (E12, E14, E16, E18, and E18:1) in human hair, and aimed to combine high sample throughput with analytical performances 587 588 (Zimmermann & Jackson, 2010). Instead of extensive washing procedures and an overnight extraction, followed by a 20 or 40 min-long GC/MS analysis, they proposed a method that required 589 590 a total analysis-time of less than 1 hour, including a 15-minute sonication-extraction procedure, 591 followed with HS-SPME-GC/MS/MS, performed with a quadrupole ion trap. Positive-CI combined 592 with MS/MS provided high selectivity and detection capability, despite a total chromatography 593 cycle time of only 9 min. The limits of detection ranged from 0.002 to 0.030 ng/mg (Zimmermann & Jackson, 2010). More recently, Politi et al. developed a sensitive (LOQ = 0.01 ng/mg for each 594 FAEE) analytical protocol for FAEE determination in hair, based on the widespread SPE and GC-595 EI-MS techniques (Politi et al., 2011). These techniques are affordable by any toxicology laboratory 596 - a key feature to make this determination routine. Four ethyl esters (E14, E16, E18, and E18:1) 597 were chromatographically separated in about 16 min. Faster chromatographic analysis is prevented 598 599 by the need to obtain well-separated peaks and no interferences, because FAEEs share most EI fragment ion signals. 600

601

602 2. EtG determination in hair samples

603

EtG is a polar substance with a relatively low molecular weight. Due to these attributes, a singlestage of MS analysis is generally insufficient to comply with the low detection limits in the pg/mg range required for its determination in a complex keratinic matrix. Either GC/MS/MS after derivatization or LC-MS/MS are the methods of choice for EtG determination in hair samples; both are capable to minimize the background interferences and to achieve the optimal detection capability and high specificity, required in toxicological and forensic applications. The limitations of the simple GC-EI-MS approach for EtG determination in hair samples is indirectly demonstrated by a recently developed method, which barely reaches an LOD of 100 pg/mg with as much as 100 mg of hair in the SIM acquisition mode (Álvarez et al., 2009). This LOD value is considerably higher than the established cut-off limit to evidence alcohol use disorders (Kintz, 2012b).

Although the simplicity and progressively increasing performances of ESI make the LC-MS/MS 614 approach prevalent nowadays, several highly-efficient GC/MS/MS methods have been recently 615 616 developed and updated to fulfill the legal requisites entailed by regulations of many countries. Paul et al. proposed and validated a GC/MS/MS procedure, with EI, triple-quadrupole mass 617 618 spectrometer, and SRM (Paul et al., 2008). The instrumental analysis followed water extraction, SPE purification, and derivatization with N,O-bis[trimethylsilyl]trifluoroacetamide (BSTFA). An 619 620 LOD of 5 pg/mg was obtained, and the chromatography cycle was 7.30 min (Paul et al., 2008). A modified protocol was reported by the same group in 2011, in which the SRM transitions for GHB 621 622 were added to the same analytical protocol, so as to detect EtG and GHB within a single chromatographic procedure. This combination is of importance in the investigation of drug-623 624 facilitated crimes, because GHB and alcohol are frequently combined substances used to perpetrate 625 these offences (Paul et al., 2011).

Large-volume injection (LVI) GC-EI-MS/MS was proposed to increase the sensitivity in hair EtG determination. The authors suggested that, upon optimization of streaming volume, purge time, programmable temperature vaporization (PTV) temperature, injection volume, and other experimental parameters, the detection capability can be improved by at least 1–2 orders of magnitude, as compared to the traditional approach (Shi et al., 2010). Even so, they estimated an LOD value of 5 pg/mg, with 20 mg of hair, as in the method previously cited (Paul et al., 2008).

NCI with methane was proposed as an alternative to EI within a GC/MS/MS protocol in order 632 to improve analytical sensitivity (Kharbouche et al., 2009). A high cross-section for electron capture 633 was induced by double derivatization of EtG with perfluoropentanoic anhydride. The choice of two 634 635 selective SRM transitions allowed high specificity in the analyte identification, despite the fast GC protocol. The estimated LOD value for EtG was 3 pg/mg, with 30 mg hair. This analytical protocol 636 was adopted to analyze rat hair samples, so as to evaluate any potential hair-pigmentation effect on 637 EtG incorporation into the keratin matrix. No statistically significant differences were observed 638 between pigmented and non-pigmented hair (Kharbouche et al., 2010). The same group also 639 evaluated the possible effect of hair-care products on EtG incorporation (Sporkert et al., 2012). 640

A similar GC-NCI-MS/MS approach was also proposed (Agius et al., 2010), but the final EtG 641 642 enrichment was performed with HS-SPME, after derivatization with heptafluorobutyric anhydride. HS-SPME injection yielded further clean-up in the headspace extraction and accumulation of the 643 644 derivatized analyte on the fiber, with a significant decrease of the LOD value: 0.6 pg/mg, with 10 mg hair (Agius et al., 2010). No further improvements were recorded with nonafluorobutyrric 645 anhydride for EtG derivatization instead of heptafluorobutyric anhydride. A similar LOD value (0.7 646 pg/mg) was also achieved (Kerekes et al., 2009), from 20-30 mg of hair, although NCI was 647 followed by single MS detection, with two monitored ions in the SIM acquisition mode. The EtG 648 649 concentration was in hair collected from several parts of the body for the same subjects determined 650 and compared (Kerekes et al., 2009).

Even though the GC/MS/MS procedures for EtG determination in hair proved to be accurate and highly sensitive, especially when electron capture was used, most toxicology laboratories currently prefer LC-MS/MS, because the sample-purification steps are easier and no derivatization is needed. These simplifications substantially contribute to reduce the work and time for sample processing - a crucial aspect in laboratories with high sample load.

Although the first LC-MS/MS method dates back to 2002, the real bloom of analytical 656 657 procedures based on LC separation and ESI started in 2007. ESI is commonly used in the negative ion mode because of the acidic nature of EtG. Among the large variety of proposed methods, 658 different sample-preparation steps, amounts of analyzed hair, and chromatographic conditions were 659 adopted that yielded excellent selectivity and LOD values between 1 and 10 pg/mg. The proposed 660 methods proved highly reliable to support evaluation of harmful drinking (Morini et al., 2009; 661 Marques et al., 2010; Pirro et al., 2011a; Agius et al., 2012); monitor total abstinence (Kronstrand et 662 al., 2012); study hair-treatment effects that possibly lead to partial disappearance of EtG from the 663 keratin matrix (Morini et al., 2010); and evaluate the effect of individual and external parameters on 664 665 EtG accumulation and persistence in hair, so as to define the boundaries and to exclude conditions for its use as a biomarker of ethanol consumption (Pragst et al., 2010, Süsse et al., 2012; Hastedt et 666 al., 2012; Cabarcos et al., 2012; Pirro et al., 2011b). Almost all these methods made use of triple-667 668 quadrupole instruments to monitor SRM transitions between the deprotonated molecule ion of EtG $(m/z \ 221)$ and two fragment ions $(m/z \ 75, \ 85)$. For EtG determination in hair samples, a detailed list 669 of MS conditions used in the cited articles is presented in Table 1. Conditions for GC and LC 670 methods are reported. 671

The major critical point of hair EtG determination with LC-ESI-MS/MS methods is the possible occurrence of matrix effects (Matuszewski et al., 2003; Peters & Remane, 2012), especially when a non-polar stationary phase is used for LC separation; i.e., EtG eluted quickly. In any case, matrix effects need to be carefully evaluated during method development and validation (Lamoureux et al., 2009; Tarcumnicu et al., 2010; Cabarcos et al., 2012). Several authors proposed to modify previously developed analytical protocols in order to improve sample clean-up (essentially with SPE) and consequently reduce ion-suppression and increase the signal-to-noise ratio. Politi et al. reported an extreme case, in which SPE clean-up proved useful to decrease ion suppression and identify EtG traces in three hair segments of a known alcoholic, 27 years after his death (Politi et al., 2008).

Carbon-blend SPE columns, based on porous graphitic material, are suitable for the extraction 682 683 of EtG from complex matrices such as hair (Lamoureux et al., 2009). Besides, the use of silica HPLC columns, in place of reversed-phase columns, allows one to elute EtG with a mobile phase 684 685 that contain a high percentage of organic solvent and low percentage of water, to improve ESI efficiency (Lamoureux et al., 2009). An alternative strategy, proposed previously, made use of post-686 687 column addition of acetonitrile to the eluate. For the same goal, the use of HILIC coupled to mass spectrometry was proposed and successfully applied for the analysis of EtG in hair (Kintz et al., 688 689 2008; Tarcumnicu et al., 2010). Recently, Albermann et al. proposed a modification of their method for EtG determination in hair, aimed to solve occasional chromatographic problems during routine 690 691 work (Albermann et al., 2012). The new method used an LC column with stationary phase 692 composed of 100% porous graphitic carbon, instead of the reversed-phase LC column previously used (Albermann et al., 2010). However, the new method led to a longer analysis-time and slightly 693 694 higher LOD value (1.7 pg/mg) than previously reported (1 pg/mg).

695

696 E. Antidoping Analysis

697 In amateur and professional sport, the artificial enhancement of the athletic performance with drugs 698 or forbidden practices is subjected to systematic control. Doping controls in sport events are managed by the World Anti-Doping Agency (WADA), through tests of urine or blood sample 699 700 collected from athletes in and out of competition. Hair analysis is currently not accepted as an 701 alternative to urine and blood analysis for doping control (WADA, 2012) for several reasons, 702 including its heterogeneous nature, the uncertainty on mechanisms that regulate drug incorporation, 703 and alleged diversity in occurrence and extent of these mechanisms among different ethnic groups 704 (Kintz, 2007a). However, it is evident that hair analysis would be of practical significance in several 705 circumstances, because it provides complementary information with respect to urine and blood 706 testing (Gaillard et al., 2000; Kintz, 2003). In fact, urine and blood analyses detect recent drug 707 intake, but cannot distinguish between chronic use or single exposure, whereas hair analysis can 708 offer this distinction (Kintz, 2007a). Indeed, doping agents are partially excreted in the sweat and incorporated into growing hair, and remain stable for long periods of time. Thus, hair testing might offer a large detection window to allow long-term detection of prohibited drugs and a retrospective estimation of the intake period. This opportunity appears to be particularly important to detect out-of-competition doping treatments; for example, in the athletes who use anabolic substances during the training period and interrupt their intake long before the start of competition (Kintz et al., 2000).

The need for equal conditions for all athletes and the freedom for them to make use of whatever 714 cosmetic treatment, including complete body shaving, prevented any official use of hair analysis in 715 doping controls. For example, the incorporation rates of prohibited drugs was proved to depend on 716 the hair pigmentation, to possibly lead to unequal conditions in doping control, and consequently 717 ethnic discrimination (Gambelunghe et al., 2007). In addition, hair washing, discoloring, and tinting 718 719 appear to influence the drug concentration measured in hair, as well as their distribution within the 720 hair longitudinal axis (Kintz, 2003). Nevertheless, the potential of hair analysis for antidoping 721 purposes is so strong that several analytical methods were developed in the past to detect doping agents in hair specimens (Kintz, 2007a). 722

723 In the last five years, a limited number of analytical methods was additionally developed, with the main objective to measure anabolic androgenic steroid (AASs) level in human hair with gas or 724 725 liquid chromatography coupled to high-resolution mass spectrometry or tandem mass spectrometry 726 (Anielski, 2008; Gambelunghe et al., 2007; Deshmukh et al., 2010). A complex challenge was 727 addressed to exploit hair analysis to distinguish between natural production of endogenous steroids (e.g., testosterone) and exogenous uptake of the same steroids (Shen et al, 2009; Pozo et al, 2009, 728 729 Deshmukh et al. 2012). AASs represent the most frequently detected class of substances in out-ofcompetition doping testing, because they are widely abused to increase strength and lean body 730 mass, and also lead to reduced recovery periods (Thieme et al., 2000; Pozo et al., 2009; Deshmukh 731 et al. 2010). AASs are also utilized to speed up muscle growth in cattle and horses (Gaillard et al., 732 1999; Anielski, 2008). AAS detection in hair specimens is more widely accepted in animals than in 733 734 humans; it still receives a considerable interest in the scientific research, as demonstrated recently (Nielen et al., 2011) in which hormone and veterinary drug screening and, in general, forensic 735 736 investigations can benefit from the recent developments in desorption electrospray ionization 737 (DESI) mass spectrometry (Takáts et al., 2004). DESI allowed bovine hair analysis with very limited sample preparation: after rapid ultrasonic liquid extraction, a few microliters of supernatant 738 were deposited onto a glass or PTFE surface, and dried, before DESI analysis. Full-scan and MS³ 739 experiments with a linear ion trap MS were used to detect estradiol benzoate, testosterone 740 741 cypionate, and testosterone decanoate to demonstrate the general feasibility of rapid screening and detection of anabolic steroid intact esters. Quite high levels (300–800 g/kg) of steroid esters are
generally present in hair samples from controlled and illegally treated animals (Nielen et al., 2011).

Anielski published a method to detect anabolic steroids and their esters in hair material (Anielski, 2008). After hair extraction (sonication, methanol, 4h, 50°C) and LLE raw purification, a refined sample clean-up procedure was carried out with HPLC. The residue was subsequently derivatized, and the trialkylsilyl steroid derivatives were analyzed with GC/HRMS and GC/MS/MS to yield LOD values between 0.1 and 5.0 pg/mg. The method was successfully applied to real samples to detect testosterone propionate in the hair of treated horses. Unlike a urine specimen, the parent drugs instead of their metabolites are more frequently detected in hair samples.

751 The goal to determine the natural occurrence of anabolic steroids in hair, and their biological 752 variability within selected populations of individuals, led Shen et al. to develop a specific GC/MS/MS method to simultaneously identify testosterone, epitestosterone, androsterone, 753 754 etiocholanolone, and dehydroepiandrosterone (DHEA) (Shen et al., 2009). After alkaline digestion (NaOH, 1N, 10 min, 90°C), LLE extraction with diethylether was carried out. The extracts were 755 756 derivatized with a MSTFA/iodotrimethylsilane/dithioerythritol mixture (10:5:5, v/v/w) and analyzed with GC/MS/MS/SRM. The method was fully validated and applied to 80 subjects (39 757 758 males, 30 females, 11 children). The sensitivity of the method (LODs between 0.1 and 0.2 ng/mg) proved sufficient to determine the physiological concentration ranges for the selected endogenous 759 steroids in the three populations, so as to address the interpretation of non-compliant results from 760 761 alleged steroid abuse (Shen et al., 2009).

An analogous GC/MS/MS method was previously developed for the simultaneous determination of methyltestosterone, nandrolone, boldenone, fluoxymesterone, cocaine, and benzoylecgonine, and was applied to hair samples from seven athletes with reported AAS abuse (Gambelunghe et al., 2007). All anabolic steroids included in the procedure could be detected with a 10 pg/mg detection limit. Methyltestosterone, nandrolone, boldenone, and fluoxymesterone were detected in real samples between 12 pg/mg and 37 pg/mg.

A specific LC-MS/MS method was developed for the clinical determination of testosterone 768 769 undecanoate in hair samples (Pozo et al., 2009). After decontamination and incubation in a tris(2-770 carboxyethyl)phosphine hydrochloride solution (1.5h, 50°C) within an ultrasonic bath, a double LLE with n-pentane was performed. The reconstituted residue was injected into an LC-MS/MS 771 triple-quadrupole mass spectrometer with APCI source. The proposed fragmentation pattern of 772 testosterone undecanoate is shown in Figure 4. The method was applied to hair samples from three 773 774 patients treated with testosterone undecanoate and led to detected concentrations of 0.4, 1.6 and 8.4 775 pg/mg.

The group of Naughton and coworkers recently published two sensitive LC-MS/MS methods 776 for the detection of various steroids in human hair samples. In the first study, nandrolone and 777 778 stanozolol were determined in human hair for the first time (Deshmukh et al., 2010). After alkaline digestion (NaOH, 1M, 15 min, 95°C) and LLE with n-pentane, the extracts were injected into a 779 780 UHPLC system interfaced to a triple-quadrupole mass spectrometer with ESI source. From 20 mg aliquots of hair, LOD values of 0.5 pg/mg for stanozolol and 3.0 pg/mg for nandrolone were 781 obtained. The method was successfully applied to 19 hair samples previously tested positive with 782 ELISA (enzyme-linked immunosorbent assay) screening to reveal seven false-positive results and 783 784 to confirm one sample positive to nandrolone (14.0 pg/mg) and eleven samples positive to stanozolol (concentration range 5.0+86.3 pg/mg). The second study used a similar experimental 785 approach to develop a highly sensitive LC-MS/MS method to determine testosterone and 786 epitestosterone in hair samples (Deshmukh et al., 2012). The natural abundance ratio of these 787 steroids (T/E) is significantly modified by any exogenous intake of testosterone. Low LOD values 788 (0.1 pg/mg and 0.25 pg/mg for testosterone and epitestosterone, respectively, from 50 mg of hair) 789 790 allowed the determination of physiological testosterone and epitestosterone levels on 75 real samples, which ranged from 0.70 to 11.81 pg/mg in males and 0.33 to 6.05 pg/mg in females 791 792 (testosterone); from 0.63 to 8.27 pg/mg in males and 0.52 to 3.88 pg/mg in females 793 (epitestosterone).

794

795 III. FUTURE TRENDS OF HAIR ANALYSIS

796

797 A. New Designer Drugs

In the last years, forensic laboratories have been challenged worldwide with the puzzle to detect 798 799 a variety of new psychoactive substances. These compounds, occasionally called either designer drugs or legal highs, have little or no previous history of medicinal use. Amphetamine derivatives, 800 801 with backbone molecular structures of piperazine and cathinone, initially represented the main group of designer drugs. Almost at the same time, another wide group of compounds, known as 802 803 synthetic cannabinoids, appeared on the black market. A very rapid proliferation of new psychoactive substances of these and other classes followed in recent years. Although most of the 804 latest drugs act as central nervous system (CNS) stimulants, their assorted chemical structures range 805 from derivatives of pipradrol, ketamine, phencyclidine, arecoline, aminopropylbenzofuran, ring-806

substituted aminoindans, thiophenyl bioisosteres of methamphetamine, as well as compounds
structurally related to cocaine (King & Kicman, 2011).

809 Reference standards for most designer-drugs metabolites are not yet commercially available. 810 That lack of standards poses a serious and longstanding challenge to toxicological laboratories to develop analytical procedures to detect their presence in a variety of biological matrices. 811 Nevertheless, several analytical methods were developed to determine some of these new 812 psychoactive substances and/or their metabolites in either blood or urine (Moran et al., 2011; 813 Grigoryev et al., 2011; Dresen et al., 2011; Teske et al., 2010; Wintermeyer et al., 2010; Beuck et 814 815 al., 2011; Kraemer et al., 2009; Sobolevsky, Prasolov, & Rodchenkov, 2010). On the other hand, 816 only very few studies have been published to date that describe protocols for the detection of these 817 substances in hair samples.

In a Letter to the Editor, Torrance and Cooper reported the detection of mephedrone in hair 818 819 samples at 4.2 and 4.7 ng/mg concentration with a ISO/17025 accredited method, but details on the analytical method used and comments or interpretations of results were not included (Torrance & 820 821 Cooper, 2010). A specific and accurate method for mephedrone detection with GC/MS was proposed (Martin et al., 2012). The study reported that 67 real hair samples were analyzed - 10 were 822 823 found positive, with mephedrone concentrations from 0.2 to 313.2 ng/mg; 8 of them were below 6 824 ng/mg. As for amphetamines, it is deduced that mephedrone concentrations in hair are likely in the ng/mg, not pg/mg, at least in the cases of repeated abuse (Martin et al., 2012). Detection of 825 826 piperazine-like compounds was meticulously described (Barroso et al., 2010b). This study was the first to report the development and validation of an analytical method for the determination of three 827 828 phenylpiperazines in hair samples. Trimethylsilyl derivatives were determined with GC/MS, and the method was applied to autoptic samples and samples collected from subjects under psychiatric 829 evaluation. 830

The first multiclass screening for synthetic cannabinoids in hair samples was published recently 831 (Salomone et al., 2012b). In this study, a UHPLC-MS/MS procedure was developed and validated 832 to determine the possible presence of five synthetic cannabinoids (i.e., consistently present in the 833 834 black market during the period considered: JWH-018, JWH-073, JWH 200, JWH-250, and HU-210) in 179 real hair samples collected from previously proven Cannabis consumers (Figure 5). The 835 fourteen (7.82%) samples found positive to at least one synthetic cannabinoid demonstrated 836 significant diffusion among drug abusers. Concentrations of synthetic cannabinoids ranged from 837 0.50 to 730 pg/mg. Although the published screening was limited to relatively few compounds, its 838 UHPLC-MS/MS approach makes further method expansion feasible, so as to include new 839 840 substances that are continuously introduced into the black market.

841

842 **B. Future Trends Driven by Instrumental Developments**

843

After years of pioneering studies, hair analysis for toxicology applications represents nowadays a reliable and well-established means of forensic investigation. The Society of Hair Testing periodically meets to exchange scientific experiences, establish new protocols, and draw up consensus documents to carefully guide conclusions and legal judgments on the basis of experimental results from hair analysis.

849 Whereas instrumental sensitivity and overall method specificity have been for years key issues 850 of experimental studies and analytical method developments, the latest instrumentation for sample 851 treatment, chromatographic separation, and mass spectrometric detection substantially fulfills these requirements, and frequently provides LOD and LOQ values largely better (i.e., lower) than the 852 853 expected drug concentrations in hair. Indeed, various sources of individual variability, including genetic polymorphisms, metabolic disorders, diet, use of cosmetics, and environmental exposure, 854 855 are likely to represent more-important causes of bias and incorrect reporting than insufficient sensitivity and specificity. For example, the LOD for EtG in hair will soon break the 1 pg/mg limit 856 857 and will open up a reflection on the possible origins of this alcohol metabolite other than ingestion 858 of alcoholic beverages. Moreover, the chance of external contamination of hair samples and extracts grows with increasing method sensitivity, in turn becoming a major concern during the 859 860 experimental method validation.

Other issues, basically linked to one another, are becoming increasingly important in forensic 861 862 hair analysis. These issues are: multiresidue and multiclass potential, high throughput, and costs of analysis. Capability of simultaneous multiclass analysis is essential in broad drug screening of 863 unknown analytes, because in most acute intoxications and post-mortem investigations the ingested 864 substance cannot be anticipated; however, this feature also contributes to dramatically decrease the 865 866 number of analysis for each sample, with a resultant cost lowering. Modern UHPLC-MS/MS instruments with triple-quadrupole analyzers can already simultaneously detect more than one 867 868 hundred substances in just a few minutes, and QuEChERS-like procedures to extract hair samples are rapidly spreading within toxicology laboratories. This trend will be probably pursued further in 869 the near future, up to new limits in terms of speed and number of target analytes, so as to manage 870 hundreds of samples per day. Automatically-driven high-resolution MS/MS instruments, 871 sequentially generating data-dependent CID product-ion spectra, will provide true general unknown 872 873 screening and will allow retrospective inquiry of previously acquired data. Improvements in mass analyzers that will lead to enhanced sensitivity and mass resolution at high scanning rate will 874

possibly make these instruments preferable to triple quadrupoles for general unknown screeninganalysis.

877 High throughput and costs of analysis are strictly connected to one another. Hair analysis is still 878 an expensive determination that prevents its generalized application to workplace and driving 879 license testing, even if it is evident that drivers and, for example, workers who carry fire-arms should not be habitual drug consumers. The analysis costs are due to the labor-intensive hair-sample 880 treatment and the difficulty to test all drugs of abuse at once. Further development of direct MS 881 methods of analysis, such as DESI or MALDI-TOF, combined with simplified sample handling, 882 883 could possibly provide very fast and cheap drug screening of hair samples in the future. Even if the sensitivity of these instrumental approaches is still low, quite high cut-off values could be accepted 884 885 whenever the scope of the screening is to single out only the chronic drug consumers. Also, MSimaging techniques require significant improvement, in terms of hair sample handling and 886 887 instrumental sensitivity, before generalized application can be found in the chronological assessment of drug intake. 888

889 The scientific literature reports no studies on the application of isotope-ratio mass spectrometry (IRMS) to hair analysis to discriminate the natural vs. exogenic origin of substances present therein. 890 891 The substances of interest might include doping agents, such as steroids, as well as a common rape drug; i.e., gamma-hydroxybutyric acid. The reasons for this lack can be found again in the limited 892 sensitivity of the technique, the restricted sample availability, the complexity of its purification, and 893 894 that specificity provided by mass selection is lost in the combustion process. The chance of using IRMS to detect the illegal administration of drugs over extended periods of time, as it might occur 895 for androgenic steroids, will possibly push some scientific efforts in this direction in the near future. 896

In general, the recent major improvements of MS and chromatographic instrumentation have 897 driven forensic toxicology toward previously inconceivable results. Among these studies, it is 898 899 impressive to note that hair analysis can nowadays provide evidence of a single administration of 900 drugs. The continuous enhancement of MS sensitivity progressively reduces the amount of hair sample needed for the chemical analysis, and extends the chance to investigate newborn children, to 901 902 detect pre-natal drugs exposure. The scientific goal to gain toxicological information from a single 903 hair has already started, in a worthy competition with forensic genetics. Further unexpected developments of MS instruments are likely to have immediate impact also in the investigations of 904 905 forensic toxicology, and in particular in hair analysis.

TABLE 1. Comparison of MS conditions for EtG determination in hair samples

	6-MAM	6-monoacetylmorphine		
	AASs	Anabolic Androgenic Steroids		
	AP	Amphetamine		
	APCI	Atmospheric Pressure Chemical Ionization		
BSTFA BZE CBN		N,O-bis[trimethylsilyl]trifluoroacetamide		
		Benzoylecgonine		
		Cannabinol		
	CDB	Cannabidiol		
	CDT	Carbohydrate-Deficient Transferrin		
	CI	Chemical Ionization		
	CID	Collision-Induced Dissociation		
	CNS	Central Nervous System		
	CZE	Capillary Zone Electrophoresis		
	DESI	Desorption Ionization Mass Spectrometry		
	DFC	Drug Facilitated Crime		
	DFSA	Drug Facilitated Sexual Assault		
	DHEA	Dehydroepiandrosterone		
	E12	Ethyl laureate		
	E14	Ethyl myristate		
	E16	Ethyl palmitate		
	E16:1	Ethyl palmitoleate		
	E18	Ethyl stearate		
	E18:1	Ethyl oleate		
	EI	Electron Impact		
	ELISA	Enzyme-Linked ImmunoSorbent Assay		
	EME	Ecgonine Methyl Ester		
	ESI	Electrospray Ionization		
	EtG	Ethyl Glucuronide		
	EtS	Ethyl Sulfate		
	FAEE	Fatty Acid Ethyl Esters		
	FTICR	Fourier Transform Ion Cyclotron Resonance		
	GC	Gas Chromatography		
	HFBA	Heptafluorobutyric Anhydride		
	HILIC	Hydrophilic Interaction Liquid Chromatography		
	HPLC	High Pressure Liquid Chromatography		
	HRMS	High Resolution Mass Spectrometry		
	HS-SPME	Head Space Solid-phase MicroEstraction		
	IMS	Imaging Mass Spectrometry		
	IRMS	Isotope-Ratio Mass Spectrometry		
	LC	Liquid Chromatography		
	LLE	Liquid-Liquid Extraction		
	LOD	Limit of Detection		
	LOQ	Limit of Quantification		

TABLE 2. Abbreviations and acronyms used in this article.

TABLE 2. (Continued)

LVI	Large Volume Injection
LTP	Low Temperature Plasma
MALDI	Matrix-Assisted Laser Desorption Ionization
MBDB	N-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine
MBTFA	N-methyl-bis trifluoroacetamide
MDA	3,4-methylenedioxyamphetamine
MDEA	3,4-methylenedioxyethamphetamine
MDMA	3,4-methylenedioxymethamphetamine
MiAMi	Micropulverized Extraction Aqueous Acetylation Microextraction
MIP	Molecularly Imprinted Polimers
MISPE	Molecularly Imprinted Solid-Phase MicroExtraction
MS	Mass Spectrometry
MSTFA	N-methyl-N-trimethylsilyltrifluoroacetamide
MTBSTFA	N-methyl-N-(tert-butyldimethyl)trifluoroacetamide
NCI	Negative Chemical Ionization
PEth	Phosphatidylethanol
PTV	Programmable Temperature Vaporization
QqQ	Triple quadrupole mass spectrometer
QqQLIT	Hybrid triple quadrupole linear ion trap mass spectrometer
QuEChERS	Quick Easy Cheap Effective Rugged Safe
SIM	Selected Ion Monitoring
SOHT	Society of Hair Testing
SOHT	Society of Hair Testing
SPE	Solid-phase Extraction
SRM	Selected Reaction Monitoring
THC	Δ^9 -tetrahydrocannabinol
TMCS	Trimethylchlorosilane
TOF	Time of Flight
UHPLC	Ultra High Performance Liquid Chromatography
WADA	World Anti-Doping Agency

FIGURE CAPTIONS

FIGURE 1. MALDI-MS analytical workflow for single hair analysis. The whole process from sample preparation to SRM relative quantitation and MS/MS and MS³ confirmatory analyses takes approximately 2 h, including the analysis of multiple samples (Porta et al., 2011; reproduced with permission, American Chemical Society, copyright 2011).

FIGURE 2. GC×GC contour plot (TIC) obtained for a hair sample. (1) Cotinine; (2) meconin; (3) mesocain; (4) tropacaine; 5.EDDP; (6) phenazocine; (7) hydroxycotinine-TBDMS; (8) methadone; (9) quaalude; (10) norcocaine; (11) cocaine; (12) cocaethylene; (13) codeine; (14) diazepam; (15) benzoylecgonine-TBDMS; (16) acetylcodeine; (17) cinnamoylcocaine; (18) diacetylmorphine; (19) codeine-TBDMS; (20) morphine-TBDMS; (21) 6-MAM-TBDMS; (22) Papaverine; (23) morphine-di-TBDMS (Guthery et al., 2010; reproduced with permission, Elsevier, copyright 2010).

FIGURE 3. Concentration of head hair EtG (pg/mg) versus %CDT for 175 patients clinically classified as non-drinkers (A, green dots, N=65), social drinkers (S, yellow dots, N=51), and active heavy drinkers (H, red dots, N=59). The data are reported on a logarithmic scale. Horizontal and vertical lines divide the plane into four quadrants (I-IV) that identify the number of true and false positive (or negative) results in each category: For heavy drinkers (red dots): I. True-positive results; II. false-negative results for CDT only; III. false-negative results; IV. false-negative results for head hair EtG only (Pirro et al., 2011; redrawn with permission, Springer, copyright 2011).

FIGURE 4. Proposed fragmentation pattern for testosterone undecanoate (Pozo et al., 2009; reproduced with permission, John Wiley and Sons, copyright 2009).

FIGURE 5. SRM chromatogram of a blank hair sample fortified with the target compounds: (1) JWH-200, (2) JWH-250, (3) JWH-073, (4) CBD, (5) JWH-018, (6) CBN, (7) HU-210, (8) THC, (ISTD) JWH-018-*d9* (Salomone et al., 2012; reproduced with permission, John Wiley and Sons, copyright 2012).
