<b>Abstract:</b>	<p>The dispersion of <i>Scaphoideus titanus</i> Ball adults was studied applying a water solution of cow milk (marker: casein) or chicken egg whites (marker: albumin) onto the canopy of wild grapevine at a distance from vineyards ranging from 5 to 330 m. Yellow sticky traps were placed on the canopy of grapes, and captured insects were analyzed via an indirect ELISA for markers' identification. Data were subject to exponential regression as a function of distance from wild grapevine, and to spatial interpolation (Inverse Distance Weighted and Kernel interpolation with barriers) using ArcGIS Desktop 10.1 software. The influence of rainfall and time elapsed after marking on markers' effectiveness, and the different dispersion of males and females were studied with regression analyses. Of a total of 5417 insects analyzed, 43% were positive to egg; whereas 18% of 536 tested resulted marked with milk. No influence of rainfall or time elapsed was observed for egg, whereas milk was affected by the time elapsed. Males and females showed no difference in dispersal. Marked adults decreased exponentially along with distance from wild grapevine and up to 80% of them were captured within 30 m. However, there was evidence of long-range dispersal up to 330 m. The interpolation maps showed a clear clustering of marked <i>S. titanus</i> close to the treated wild grapevine, and the pathways to the vineyards did not always seem to go along straight lines but mainly along ecological corridors. <i>S. titanus</i> adults are therefore capable of dispersing from wild to cultivated grapevine, and this may affect pest management strategies.</p>

 7 **Abstract**

8 The movement-dispersion of *Scaphoideus titanus* Ball adults ~~from wild to cultivated~~  
 9 ~~grapevine~~ was studied ~~with a novel mark capture technique~~ applying a water solution of  
 10 cow milk (marker: casein) or chicken egg whites (marker: albumin) ~~was applied directly~~ onto  
 11 the canopy of wild grapevine ~~more or less in close proximity (5-350 m) to at a distance from~~  
 12 vineyards ranging from 5 to 330 m; Yellow sticky traps were placed on the canopy of  
 13 grapes, and captured ~~*S. titanus* adults~~ insects were analyzed via an indirect ELISA for  
 14 markers' identification. Data were subject to exponential regression as a function of distance  
 15 from wild grapevine, and to spatial interpolation analyses (Inverse Distance Weighted and  
 16 Kernel interpolation with barriers) ~~were performed using ArcGIS Desktop 10.1 software~~; The  
 17 influence of rainfall and time elapsed after marking on markers' effectiveness, and the  
 18 different ~~dispersal patterns~~ dispersion of males and females were ~~also studied~~ with regression  
 19 analyses. Of a total of 5417 insects analyzed ~~for egg~~, 43% were positive to egg; whereas 18%  
 20 of 536 tested ~~were milk-resulted marked with milk~~ positive. No influence of rainfall or time  
 21 ~~since the marker's application~~ elapsed was observed for egg ~~marked specimens~~, whereas milk-  
 22 ~~marked were was~~ affected by the time elapsed. Males and females showed no difference in  
 23 dispersal. Marked adults decreased exponentially along with distance from wild grapevine  
 24 and up to 80% of them were captured within 30 m; However, there was evidence of long-  
 25 range dispersal up to 350-330 m. The interpolation maps showed a clear clustering of marked

33

### Introduction

34 The nearctic leafhopper *Scaphoideus titanus* Ball (Hemiptera: Cicadellidae) was introduced  
35 into Europe in the late 1950s (Bonfils & Schvester, 1960) and is now widespread in many  
36 European countries from Portugal to Bulgaria (COST Action FA0807). This species is a  
37 grapevine specialist, and develops on both wild and cultivated grapevine (*Vitis* spp.). It is  
38 univoltine and overwinters in the egg stage, which is laid under the bark of wood 2-yr of age  
39 or more (Vidano, 1964); eggs start to hatch in the middle of May and nymphs (which include  
40 five instars) are present until the end of July, whereas adults usually appear at the beginning  
41 of July and are observed up to the middle of October (Vidano, 1964). *S. titanus* is an  
42 important pest, as it is the main vector of grapevine's Flavescence dorée (FD), a disease  
43 caused by 16SrV phytoplasmas (subgroups C and D) (Malembic-Maher *et al.*, 2011). Nymphs  
44 from the 3<sup>rd</sup> instar on acquire phytoplasmas by feeding on infected plants (acquisition access  
45 period, AAP), and following a latency access period (LAP) of 4-5 weeks they become adults  
46 and able to transmit FD to healthy plants (IAP) (Bressan *et al.*, 2005). Since FD is a cause of  
47 great economic losses, insecticidal sprays against *S. titanus* are mandatory in Italy: active  
48 ingredients include neonicotinoids, organophosphates, etofenprox, and natural pyrethrum,  
49 the latter in organic farming (Lessio *et al.*, 2011a). However, there are still many ecosystems  
50 suitable to *S. titanus*' survival such as untreated vineyards, organic farming vineyards, cast-  
51 away vineyards, and woods or uncultivated areas colonized by wild grapevine (mainly from

Formatted: Superscript

52 | overgrown rootstocks: *Vitis rupestris*, *V. riparia* × *berlandieri*, etc.): ~~T~~he easiest way to  
53 | assess the threat of these areas to viticulture by serving as reservoirs for this leafhopper vector  
54 | is to apply mark-release-recapture (MRR) or mark-capture (MC) techniques.

55 | Marking methods used in entomology include fluorescent dusts (Garcia-Salazar & Landis,  
56 | 1997; Takken *et al.*, 1998; Skovgard, 2002), radioisotopes ([Hagler & Jackson, 2001](#)), and  
57 | immunomarking (Hagler & Jackson, 2001; Jones *et al.*, 2006; Hagler & Jones, 2010). In  
58 | mark-release-recapture (MRR) experiments, insects (obtained under laboratory conditions or  
59 | captured in the field) are marked, released at a certain point in the field, and then recaptured,  
60 | usually by means of traps. However, there are many drawbacks in applying MRR methods,  
61 | both generally and especially concerning *S. titanus*. First of all, it isn't possible to mark and  
62 | release a quantity of insects as large as the effective population in the field; ~~M~~oreover, the  
63 | number of marked individuals recaptured is generally small, up to 8–10% (Zhou *et al.*, 2003;  
64 | Lessio *et al.*, 2008). In addition, the marker may affect the insects' flight behaviour to some  
65 | extent, and it is sometimes difficult to obtain a large quantity of insects, especially with  
66 | species like *S. titanus* that have just one generation per year [and an obligatory diapause](#) and  
67 | therefore ~~cannot are difficult be to~~ reared continuously under lab conditions. The possibility  
68 | of applying a marker directly on the host plants overcomes these problems, and ~~it~~ is possible  
69 | since the development of ELISA mark detection techniques. The first immunomarking  
70 | [method](#) available was based on vertebrate proteins, such as chicken or rabbit immunoglobulin  
71 | G (IgG) (Hagler, 1997; Blackmer *et al.*, 2004, 2006), but it hasn't been much used because it  
72 | is too expensive. The development of low-cost markers, such as food proteins like cow milk,  
73 | soy milk, or chicken egg whites, widened the possibility of using mark-capture techniques in  
74 | entomology on large-scale experiments (Jones *et al.*, 2006). A recent study compared the  
75 | performances of so-called first (IgGs) and second (food proteins) generation markers, and  
76 | found that egg whites have a longer persistence than IgGs, whereas no difference was  
77 | observed in the insects' mortality (Slosky *et al.*, 2012). For these reasons (the need to mark

78 field-born insect populations, low cost and high reliability of the markers), we decided to  
79 apply this novel large-scale mark-capture technique to track the movements of *S. titanus*  
80 adults from wild to cultivated grapevine in Northwestern Italy. As markers, we used cow milk  
81 and chicken egg whites (see materials and methods for details).

## 83 **Materials and methods**

### 84 **Large scale field marking and sampling of *S. titanus***

85 Field studies were conducted during 2010– and 2011 in the district of Portacomaro (AT),  
86 Piedmont, Italy (~~44.97029–44.94596 °N, 8.24774–8.26120 °E~~). We set up four experimental  
87 sites, called A, B, C and D; each site consisted of one or two vineyards (A-1 and A-2 for site  
88 A, etc.) ~~more or less in close proximity which disted from 5 to 330 m from~~ woods colonized  
89 by wild grapevine (WGV). All the vineyards were subject to insecticidal sprays: vineyard B  
90 received two sprays with Etofenprox on the 26 June and 25 July, whereas all others were  
91 sprayed with Thiamethoxam and Chlorpirifos-methyl on the first and second date,  
92 respectively. In the middle of June, before the first spray, we assessed the presence of *S.*  
93 *titanus* nymphs by visual inspection according to a sequential sampling plan with a fixed-  
94 precision level of 75%, based on Green's equation (Lessio & Alma, 2006) (Table 1).

95 As markers we used albumin (pasteurized chicken egg whites: Eurovo SRL, S. Maria in  
96 Fabiano Lugo, RA, Italy, approximate cost 5.00 €/lt.), and casein (sterilized Ultra High  
97 Temperature, UHT cow whole fat milk: by Centrale del latte di Torino, Italy, approximate  
98 cost 0.50 €/lt.), henceforth referred to as egg and milk, which have a greater reliability  
99 compared to soy milk (Jones *et al.*, 2006). The markers were used as tap water solutions at a  
100 ratio (volume/volume) of 10 and 20% for egg and milk, respectively; ~~Nowe didn't use any~~  
101 water softener and/or wetting agent was used, as they don't significantly improve insect  
102 marking in the field (Boina *et al.*, 2009). The markers were applied every 10–20 days from 8<sup>th</sup>  
103 July to 10<sup>th</sup> September (Table 1) using a hand jet sprayer with a 15 l tank, at ~~an approxa-~~ rate

104 | of 4000 l/100-m<sup>2</sup>, directly onto WGV. When two separate WGV stands were present in the  
105 | same site, we applied a different marker on each of them; otherwise, we applied only egg,  
106 | which is more detectable than milk (Jones *et al.*, 2006). The daily amount of rainfall (mm)  
107 | was recorded from a meteorological station nearby set at the same distance (2 km) from each  
108 | of the experimental sites.  
109 | Yellow sticky traps (cm 20 × 30) were placed in the vineyards at a distance of 15–20 ± 2 m  
110 | from each other on the vine row, and 5-6 ± 0.5 m between rows, depending on plot size (for  
111 | larger plots, we increased the distances in order to cover evenly the whole plot size), and  
112 | directly on stands of WGV, at a distance of 15–20 ± 2 m from each other (Table 1; Figs. 3-6)  
113 | to capture marked *S. titanus* adults; each trap was geo-referenced with a Garmin® GPS  
114 | receiver and the distance between traps was confirmed by measuring with a graduated tape.  
115 | Eight to 19 days after each marker's application, captured adults were carefully removed from  
116 | the traps directly in the field using a wooden toothpick (using a new one every time to prevent  
117 | cross-contamination), placed into sterilized 1.5 ml microcentrifuge tubes (one insect/tube),  
118 | and stored at -20° C before analyses. The traps were placed at the beginning of July and  
119 | replaced after each insect removal up to the middle of October, which represents the window  
120 | of *S. titanus* adults' presence in North-western Italy (Lessio & Alma, 2004b).

121

122

### Laboratory analyses

123 | An indirect ELISA was performed to detect protein markers acquired by the leafhoppers;  
124 | when egg and milk were used in the same sampling site, insects were analyzed so as to detect  
125 | both markers at once. Commercially available antibodies for chicken egg albumin (RAE,  
126 | (rabbit anti egg) (C6534, Sigma-Aldrich, St. Louis, MO, USA) and bovine casein (SAC,  
127 | Sheep anti casein) (antibodies-online GmbH, Aachen, Germany) were used. The secondary  
128 | antibodies used for the chicken egg albumin and bovine casein assays were peroxidase  
129 | conjugated donkey anti-rabbit IgG (H + L) (DAR) (31458; Pierce Biotechnology, Rockford,

130 IL, USA) and peroxidase conjugated rabbit anti-sheep IgG (H + L) (RAS) (31480; Pierce  
131 Biotechnology, Rockford, IL, USA), respectively.

132 Reagents included: TBS-EDTA (Tris Buffered Saline, pH 8.0 plus 0.3 g/l sodium  
133 ethylenediamine tetra acetate) (Sigma-Aldrich, St. Louis, MO, USA); PBS-BS (Phosphate  
134 Buffered Saline + 20% Bovine Serum) (Sigma-Aldrich, St. Louis, MO, USA); PBSS-BS 20  
135 (Phosphate Buffered Saline + 20% Bovine Serum + 1300 ppm Silweet L-77) (Silwet,  
136 Chemtura Manufacturing, Manchester, UK)); PBSS-BS 30 (Phosphate Buffered Saline + 30%  
137 Bovine Serum + 1300 ppm Silweet L-77); PBST (Phosphate Buffered Saline + 0.09% Triton  
138 X-100) (Triton-X-100; Sigma-Aldrich, St. Louis, MO, USA), PBS-SDS (Phosphate Buffered  
139 Saline + 2.3 g/l Sodium dodecyl sulfate), sulphuric acid (H<sub>2</sub>SO<sub>4</sub>) 2N; and immuno-pure ultra  
140 TMB substrate (Pierce Biotechnology, Rockford, IL, USA).

141 For the chicken egg assay, the primary antibody was diluted 1:4000 (2 µl in 8.0 ml) in PBSS-  
142 BS20, while the secondary antibody was diluted 1:6000 (1.4 µl in 8.4 ml) in PBSS-BS20.

143 For the casein assay, the primary antibody was diluted 1:500 (16 µl in 8.0 ml) in PBSS-BS30,  
144 while the secondary antibody was diluted 1:1500 (5.4 µl in 8.1 ml) in PBSS-BS20. The  
145 following protocol, slightly modified after Jones *et al.* (2006), was applied: 1 ml TBS-EDTA  
146 was added to the 1.5 ml microcentrifuge tube with the insect, vortexed for 2–4 seconds and  
147 left in stand-by mode for 3 minutes. From each tube, three 80 µl aliquots (replicates) were  
148 retrieved and placed in individual wells of a 96-well microplate (Nunc Polysorp, Nalge Nunc,  
149 Naperville, IL, USA) (to minimize contamination during washings, the 6 wells closest to the  
150 negative and blank controls were left empty); the micro-plate was then covered with  
151 aluminium foil and incubated at 37°C for 2 hrs. (at the end of this step, the leafhoppers were  
152 sexed by observing the external genitalia with a stereomicroscope and then discarded). The  
153 plate was then emptied and washed 5 times with 300 µl PBST using a LT-3000 micro-plate  
154 washer (Labtech International Ltd, Uckfield, UK); then 300 µl PBSS-BS (for egg) or 300  
155 µl PBS-BS (for milk) were added, and the plate was incubated at 37°C for 1 hr. Afterwards, it

156 was washed 2 times with 300  $\mu$ l PBST, and 80  $\mu$ l of the first antibody (RAE for egg, SAC for  
157 milk) were added and the plate was incubated at 37°C for 30 min. The plate was then  
158 emptied, washed 5 times with 300  $\mu$ l PBST, 80  $\mu$ l of the second antibody (DAR for egg, RAS  
159 for milk) was added, and the plate was incubated at 37°C for 2 hrs. After incubation, the plate  
160 was washed 3 times with 300  $\mu$ l PBS-SDS and 3 times with 300  $\mu$ l PBST. Then 80  $\mu$ l TMB  
161 were added and the plate was incubated at room temperature (25°C) in the dark on a shaker  
162 for 10 min. The reaction was then stopped by adding 80  $\mu$ l of 2N H<sub>2</sub>SO<sub>4</sub> and the plate was  
163 scanned with a LT-4000 micro-plate reader (Labtech International Ltd, Uckfield, UK) at  
164 wavelengths of  $\lambda=450$  nm and 492 nm (reference standard).

165 As positive standards, we used adults of *Euscelidius variegatus* (Kirschbaum) (Hemiptera:  
166 Cicadellidae) reared on oat (*Avena sativa* L.) under laboratory conditions. Potted plants of  
167 either oat or broad bean (*Vicia faba* L.) were sprayed with the markers using a hand vaporizer,  
168 and then placed into insect-proof cages (cm 20  $\times$  20  $\times$  40) made of mesh and Plexiglas in a  
169 climatic chamber (T=23  $\pm$  2 °C, RH=60%, L:D=16:8 h). In each cage (placed in the climatic  
170 chamber) we put ~~some~~ 90 *E. variegatus* adults; 7 days later, the leafhoppers were removed,  
171 killed by freezing, and preserved at -20° C before analyses; some untreated leafhoppers were  
172 used as negative controls, and extraction buffer alone was the blank control.

173 Each sample (=insect) was associated with 3 values of optical density (ODS) for each  
174 wavelength. The mean ODS at 450 was subtracted from the mean at 492: ODS<sub>(450-  
175 492)</sub>=ODS<sub>450</sub>-ODS<sub>492</sub>; and the same equation was applied to the optical densities of the  
176 negative control: ODN<sub>(450-492)</sub>=ODN<sub>450</sub>-ODN<sub>492</sub>; and blank: ODB<sub>(450-492)</sub>=ODB<sub>450</sub>-ODB<sub>492</sub>.  
177 Finally, we obtained the corrected (blanked) optical density for each sample as:  
178 ODCS=(ODS<sub>450-492</sub>)-(ODB<sub>450-492</sub>), and of the negative control as ODCN=(ODN<sub>450-492</sub>)-  
179 (ODB<sub>450-492</sub>). A sample was considered marked when the ODCS was greater than the mean  
180 ODCN added plus 4 times its standard deviation (SD): ODCS>ODCN+4SD, providing  
181 additional protection against false positives (Jones *et al.*, 2006).

182

183

### Data analyses

184 The ~~movement-dispersion~~ of *S. titanus* adults from WGV to the vineyards was studied by  
185 fitting an exponential model:  $N(r) = a \exp(-br)$ , where  $N$  is the percentage of marked  
186 individuals caught at the minimum distance  $r$  from the treated area ( $5 \pm 1.5$  m step), weighted

187 by the number of traps displayed at the same distance  $r$  ~~(being  $P_i$  the number of positive~~  
188 ~~specimens captured on the total number of traps  $t_i$  placed at the  $i^{th}$  minimum distance  $r$  from~~  
189 ~~treated WGV, we have the grand total  $T = \sum P_i/t_i$ ; and subsequently, we calculated  $N = P_i/T$  as~~  
190 ~~the percentage of marked individuals per trap at the  $i^{th}$  distance  $r$ );~~  $a$  is a scaling parameter

191 that estimates the number of *S. titanus* collected at  $r = 0$ ; and  $b$  is the spatial scale parameter  
192 that models the rate of variation in insects captured. ~~The choice of an exponential model was~~

193 ~~made to verify if marked *S. titanus* would decrease at increasing distances from the source~~  
194 ~~(treated WGV) following an exponential decay pattern.~~ For ~~the same reason, for~~ each

195 regression, we calculated the median dispersal index  $r_{0.5}$  ~~(that is, the distance where 50% of~~  
196 ~~the marked individuals are found)~~ using the negative half-life equation:  $r_{0.5} = \ln(2)/b$

197 (Northfield *et al.*, 2009).

198 In order to assess differences in dispersal between genders, regression equations were  
199 obtained separately for females and males and the homogeneity of the regression test was

200 evaluated (Sokal & Rohlf, 1995). The influence of rainfall ~~occurred~~ and time ~~elapsed between~~  
201 ~~since~~ the marker's application ~~and insect sampling~~ (independent variables) on the percentage

202 of positive individuals captured on traps placed within the treated points (dependent variable)  
203 was studied by applying a weighted least square (WLS) linear regression, using the total

204 number of insects captured as the weight variable ~~(Sokal & Rohlf, 1995)~~. All regression  
205 analyses were carried out with the SPSS 20.0® statistical package (<http://www.spss.it>).

206 ~~percentage-All percentage~~ data were previously arcsin square root transformed.

207 To individuate the pathways of *S. titanus* adults from WGV to vineyards, spatial interpolation  
208 of the marked insects captured was performed applying Inverse Distance Weighting (IDW)  
209 and Kernel interpolation with barrier (KB), both available in the ArcMap toolbox of ArcGIS  
210 Desktop 10.1 (<http://esri.com>). The choice of these two models rather than others was made in  
211 order to detect a movement pattern of *S. titanus* based solely on line of sight distances  
212 between sampling points (IDW), to another one that might be influenced by the presence of  
213 breaklines (KB). The IDW is a deterministic method, based on the Euclidean distance  
214 between sampling points (Bartier & Keller, 1996). It is easy and rapid to use, and is  
215 appropriate for aggregated data, as it highlights the hot spots (Tillman *et al.*, 2009). The  
216 generic IDW equation is:  $z_{x,y} = \sum z_i w_i / \sum w_i$ , where  $z_{x,y}$  is the value to be estimated,  $z_i$  is the  
217 control value for the  $i^{th}$  sample point, and  $w_i = (d_{x,y,i})^{-\beta}$  is the weight that states the  
218 contribution of each  $z_i$  in determining  $z_{x,y}$ , where  $d$  is the distance between sampling points  $z_{x,y}$   
219 and  $z_i$ , and  $\beta$  is defined by the user (the larger the value of  $\beta$ , the smaller the reciprocal  
220 influence of the sampling points; in this research we chose  $\beta=2$ , which is the most widely  
221 used). Kernel interpolation is used to determine the “utilization distribution” (UD) of a  
222 resource by an animal (Sheather & Jones, 1991; Benhamou & Cornélis, 2010). The ~~kernel~~  
223 Kernel density estimate  $f^{\wedge}_h$  of an univariate density  $f$  based on a random sample  $X_1, \dots, X_n$  of  
224 size  $n$  is:  $f^{\wedge}_h(x) = n^{-1} \sum h^{-1} K[h^{-1}(x-X_i)]$ , where  $K$  is the kernel function and  $h$  is the  
225 bandwidth, a smoothing parameter (Sheather & Jones, 1991). Kernel interpolation with  
226 barriers (KB) is a variant that uses a non Euclidean distance rather than a line of sight  
227 approach, so that the shortest distance between two points within the defined search  
228 neighbourhood is used to connect them; in this case, we used as Kernel function the  
229 exponential equation, which was used during the regression analysis (whereas no transfer  
230 function is needed to apply the IDW method)as kernel function, whereas the bandwidth was  
231 calculated as a default by ArcMap. Barriers were crops or natural vegetation stands between  
232 treated WGV and vineyards; however, they were considered partially open, as some

Formatted: Font: Italic

233 movement within non-grapevine ecosystems may occasionally occur. The obtained  
234 interpolation maps were tested for accuracy via cross-validation: we calculated the mean  
235 prediction error:  $ME = [\sum_{j=1,n} (\hat{x}_i - x_i)/n]$ , and the root mean square error:  $RMSE = \sqrt{[\sum_{j=1,n}$   
236  $(\hat{x}_i - x_i)^2/n]}$ , where  $\hat{x}_i$  is the predicted value,  $x_i$  the observed value, and  $n$  the sample size. Both  
237 *ME* and *RMSE* are given in the same units of measure of the data: an ideal model should have  
238 a *ME* equal 0, and a *RMSE* as small as possible. While *RMSE* gives an estimate of the error as  
239 a whole, *ME* mainly provides an estimate of the bias: that is, positive and negative *ME* values  
240 indicate that the model over or underestimates the data, respectively. (Rhodes *et al.*, 2011).

## Results

243 In total, 1675 and 3901 *S. titanus* adults were captured in 2010 and 2011, respectively. The  
244 flight peak occurred between the first ten days of August and the beginning of September. We  
245 analyzed 4881 insects by detecting egg alone (1664 in 2010 and 3217 in 2011), and screened  
246 536 for both egg and milk (all in 2011). ~~The total net percentages Without considering~~  
247 ~~differences in sites and position of traps, of~~ egg-positive individuals were 32 and 55% in 2010  
248 and 2011, respectively (mean 43%). In 2010, the rate of egg-marked adults captured on WGV  
249 and in vineyards ranged from 36 to 44% and 9 to 68%, respectively (Fig. 1A). ~~However,~~  
250 the minimum value of 9% refers to vineyard C-2, placed at a minimum distance of 220 m  
251 from the treated WGV, where few insects were captured. In vineyard B (minimum distance  
252 from WGV:  $D_{min}=6$  m), although many insects were captured, there were few marked  
253 specimens (<40%) ~~probably because of a high residential population of *S. titanus*; in fact,~~  
254 ~~pest management in this site was different from (and probably less effective with respect to)~~  
255 ~~the others~~ (Table 1). In 2011, we found 46–78% and 38–68% of egg-marked adults in WGV  
256 and vineyards, respectively (Fig. 1B). Milk was only used in site D in 2011 on one stand of  
257 WGV ( $D_{min}=110$  m), whereas a second stand ( $D_{min}=120$  m) was sprayed with egg: 97  
258 (18%) of the 536 tested leafhoppers were milk-positive, and 82 of them were captured on

259 milk-sprayed WGV; 206 (38%) were egg-positive, and 131 were captured on egg-treated  
260 WGV (Fig. 1B); finally, 58 (11%) of them were positive for both egg and milk at the same  
261 time. The optical density values of positive specimens calculated on 5 plates chosen at  
262 random (mean  $\pm$  s.e.) were  $0.67 \pm 0.09$  for egg, and  $0.56 \pm 0.19$  for milk; positive reference  
263 standards (*E. variegatus* maintained on treated broadbean or oat) scored  $2.26 \pm 0.03$  for milk  
264 and  $2.28 \pm 0.06$  for egg, whereas negative controls (untreated *E. variegatus*) were  $0.01 \pm 0.00$ .  
265 Rainfall occurred eight times both in 2010 (min. 1.4 mm, max. 35 mm, total amount 125  
266 mm), and 2011 (min. 0.4 mm, max. 31 mm, total amount 67 mm). No influence of either  
267 rainfall or time between applications was observed on the rate of egg-marked *S. titanus*; on  
268 the other hand, milk-marked specimens were negatively related to time (Table 2).

269 The sex ratio (M/F) was generally female biased, both for total (0.39–0.55) and marked  
270 (0.35–0.99) individuals; site C in 2010 represents an exception; it was investigated only from  
271 the first week of August on, and the sex ratio was 0.08 for both total and marked insects. Egg-  
272 marked specimens ranged from 33 to 66% for males, and 18–54% for females; whereas milk-  
273 marked males and females were 17% and 19% of the total captured, respectively. The  
274 homogeneity of regression test between the distribution of marked males and females as a  
275 function of distance of capture from the treated point was never significant within different  
276 experimental sites and years (Table 3). Therefore, the exponential models were fitted to the  
277 experimental data (and the subsequent median dispersal indexes calculated) without taking  
278 gender into account.

279 | Exponential regression analyses provided a ~~good~~significant fit of marked *S. titanus* adults as  
280 | a function of the minimum distance from the treated point, although in site D we obtained low  
281 |  $R^2$  values; the subsequent median dispersal indexes ranged from 14 to 70 m within the  
282 | different experimental plots (Table 4). The cumulative distribution functions show how the  
283 | main captures (80%) occurred within 20–30 m from WGV (Fig. 2A, B:); however, there was  
284 | also evidence of long-range dispersal up to ~~350~~320 m (Fig. 2C, D). In site A, captures

285 decreased asymptotically after 25–30 m, although a slight increase was observed between 65  
286 and 70 m (Fig. 2A), whereas in site B (investigated only during 2010) they were almost  
287 constant with increasing distance (Fig. 2B). In site C, in 2010 there was a clear point break  
288 (increase) at a distance of 30 m, and thereafter captures didn't increase anymore; but this site  
289 was only observed from the beginning of August in 2010. In the second vineyard (C-2),  
290 further from the treated zone, only a single marked specimen was captured. In 2011, the trend  
291 was smoother with a constant decrease in captures up to 60 m (maximum distance of the first  
292 vineyard, C-1, from WGV); up to 10% of the total marked insects were found in the second  
293 vineyard (C-2) (Fig. 2C). In site D, 70% of the egg-marked adults were captured on treated  
294 WGV and a cumulative 30% in the vineyard, at a 120–160 m distance, without any clear  
295 break point; on the other hand, only 60% of the milk-marked specimens were captured at the  
296 treated point, and 40% were found in the vineyard at a distance of 100–220 m (Fig. 2D).

297 On the whole, both IDW and KB interpolation methods showed a clear clustering of marked  
298 adults on the edges of the experimental vineyards. In many cases, when WGV was distributed  
299 along two edges, the clustering was much more evident if the European grapevine's rows  
300 were parallel rather than perpendicular to the edge, e.g. sites A (Fig. 3), and C, concerning the  
301 first vineyard (C-1) close to WGV (Fig. 5). Site B, only studied in 2010, shows almost the  
302 same pattern (Fig. 4); however, these results should be considered carefully because of the  
303 small size of the vineyard. In site D, egg and milk-marked individuals showed almost the  
304 same pattern independent of the interpolation method used (Fig. 6), ~~suggesting how an~~  
305 ~~ecological corridor may exist between the two areas colonized by WGV~~. On the other hand,  
306 in site C long distance dispersal from the WGV to vineyard C-2 had a different pattern  
307 depending upon the interpolation method used: IDW produced a more uniform map, whereas  
308 KB showed how the possible ecological corridors are displaced along the rows (Fig. 5). On  
309 the whole, the cross-validation results showed lower ~~ME and~~ RMSE values for KB rather  
310 than for the IDW (with the exception of sites B and D, concerning egg-marked specimens).

311 ~~indicating a better interpolation power of the first model compared to the second interpolation~~  
312 ~~method; the only exception was represented by egg-marked specimens in site D. The ME was~~  
313 ~~generally positive for KB (overestimation) and negative (underestimation) for IDW, however~~  
314 ~~KB always had a lower absolute value (the only exception was represented by egg-marked~~  
315 ~~specimens in site D)~~ (Table 5). Insects marked with both egg and milk were too few in  
316 number to perform cross-validation.

317

318

### Discussion

319 The marking method proposed, used in large-scale application on *S. titanus*, was quite reliable  
320 with egg, as up to 78% of the insects captured on the traps placed into the treated wild  
321 grapevine (WGV) were marked; on the other hand, milk had a poorer performance (22%).  
322 These data are in accord with Jones *et al.* (2006), who obtained roughly 70% and 23% of  
323 marked *Cydia pomonella* L. in apple orchards treated with egg and milk, respectively;  
324 whereas Boina *et al.* (2009) obtained higher rates of *Diaphorina citri* Kuwayama marked  
325 with egg (88%) and milk (80%). In our research, one of the main problems was to properly  
326 treat the WGV canopy, as it develops up to 6 m above ground level in certain places and is  
327 sometimes very dense and difficult to reach. In order to study the movement of *S. titanus*  
328 during the entire period of the adults' presence in the field, we applied the markers constantly  
329 but sometimes with a longer window of time between application and the insects' removal  
330 from traps; otherwise, it would become too time-consuming. We found a higher rate of  
331 positive individuals in 2011, probably because of a smaller amount of rainfall; ~~However,~~  
332 concerning egg, there was no influence of rainfall or time after the marker's application on the  
333 rates of positive individuals; ~~On the other hand,~~ the time between application and removal  
334 did affect the rate of milk-marked *S. titanus*. In other researches, the rate of marked  
335 individuals decreased along with time after application and the amount of (simulated) rainfall  
336 (Jones *et al.*, 2006; Boina *et al.*, 2009). Under laboratory conditions, a residue egg-treatment

Formatted: Font color: Auto

337 on true bugs remained 68–100% positive up to 10 days after marking, and 27–88% positive  
338 from 11 to 20 days after marking (Hagler & Jones, 2010). In addition, direct egg treatment of  
339 *Hippodamia convergens* Guérin-Méleville allowed detection of egg proteins on 100% of the  
340 individuals up to 26 days after marking (Sloski *et al.*, 2012). The problem with marking plants  
341 is that insects must come into contact with the marker before it dries up or is washed off. In  
342 addition, direct marking of *S. titanus* adults would not be reliable because of the difficulty in  
343 obtaining a very large number of specimens, and we couldn't release this leafhopper in the  
344 vineyards as it is subject to compulsory pest management. However, our data set (30–50% of  
345 egg-marked specimens out of more than 5000 captured) seemed large enough to analyse and  
346 interpret the movement patterns of this leafhopper vector.

347 *S. titanus* adults are therefore capable of both short and long range dispersal from wild  
348 (WGV) to cultivated grapevine. This behaviour was previously theorized both in Italy (Pavan  
349 *et al.*, 2012), and in the US (Beanland *et al.*, 2006) by comparing captures in traps placed at  
350 different distances from potential *S. titanus* sources: the results of our mark-capture  
351 experiments clearly demonstrate how these movements actually occur. The majority of  
352 individuals seem to cover short distances: when WGV is close to the edge of the vineyards,  
353 up to 80% of the marked individuals are captured within 30 m. However, long distance flight  
354 is also possible: *S. titanus* captures on the local scale are spatially related up to 200 m,  
355 whereas at greater distances they seem to depend on local factors, mainly pest management  
356 strategies (Lessio *et al.*, 2011b). The results of this research confirm this aspect, as some  
357 movement occurred up to more than 200 m. In vineyard B, although many insects were  
358 captured, there were few marked specimens (<25%) probably because of a high residential  
359 population of *S. titanus*; in fact, pest management in this site was different from (and probably  
360 less effective with respect to) the others. Concerning site D, in the vineyard, the majority of  
361 marked adults was captured in the North-West corner, suggesting how the infestation may  
362 have mainly occurred from the second uncultivated area, treated with milk; however, this area

363 may also have recruited adults from other areas, as suggested by the double-marked  
364 individuals, and milk-marked adults being captured in the egg-treated zone and vice versa. On  
365 the whole, the Kernel with barriers (KB) interpolation method showed smaller errors (RMSE  
366 and absolute ME values) compared to inverse distance weighting (IDW): the first model,  
367 which derives partially from the exponential regression (used as a transfer function in the  
368 Kernel interpolation process) is therefore more accurate than the latter (due to lower RMSE  
369 values), and its overestimation of observed data (ME>0) has a lower absolute value than the  
370 underestimation given by IDW (ME<0). These differences suggest~~ing~~ how the movement  
371 patterns of *S. titanus* adults may not depend solely upon their distance from sources but also  
372 upon ecological corridors or natural barriers. It seems therefore that this leafhopper is less  
373 likely to perform direct long-distance flights, whereas it rather moves along more roundabout  
374 pathways. *S. titanus* adults have a crepuscular flight activity, which makes them not rely on  
375 the wind for dispersal (Lessio & Alma, 2004b), and this may be in accord with an active  
376 wandering movement rather than a passive wind-borne transport. Moreover, marked adults  
377 were generally clustered along the same row of cultivated grapevine rather than on different  
378 rows; this is in accord with the fact that they move mainly along the same row, and captures  
379 on the same row are more spatially related (Lessio *et al.*, 2009b). Males and females showed  
380 no differences in dispersal from wild to cultivated grapes. Usually, males of *S. titanus* start to  
381 fly earlier than females, however, in the late part of the season the presence and flight activity  
382 of females is increased, whereas males tend to decrease (Lessio *et al.*, 2009a). This long-range  
383 dispersion of females may have a consequence during the next year, resulting in a higher  
384 population of *S. titanus* in vineyards because of egg-laying.

385  
386 Because WGV may also host 16SrV phytoplasmas (Lessio *et al.*, 2007), incoming *S. titanus*  
387 adults may also be capable of transmitting FD to cultivated grapevine: in fact, symptomatic  
388 grapes are often clustered at the edges, consistent with *S. titanus* coming in from outside

Formatted: Font: Italic

389 (Pavan *et al.*, 2012). Within this frame, pest management strategies against *S. titanus* in NW  
390 Italy should be revisited, as the main problem seems to be represented by adults entering the  
391 vineyards in the late part of the season; at present, PM focuses on a first spray against nymphs  
392 at the end of June, a second one against adults at the middle-end of July, and a further one  
393 sometime after harvest (Lessio *et al.*, 2011a). It is perhaps necessary to change this calendar,  
394 using a more persistent active ingredient in the late part of the season to protect grapes from  
395 inoculation; for instance, neonicotinoids are much more efficient than organophosphates in  
396 preventing transmission (Saracco *et al.*, 2008).

397 Other strategies should be directed toward avoidance: the first action to be applied should be  
398 to erase WGV as a source of *S. titanus*; however, such an action must not be done when adults  
399 (both males and females) are present, as it may cause an increase of their movement onto  
400 European grapevine. The same problem occurs when dealing with *Hyalesthes obsoletus*  
401 Signoret, the vector of Stolbur phytoplasmas causing Bois Noir (Weber & Maixner, 1998),  
402 which lives on weeds and only occasionally feeds on grapes as an adult (Alma *et al.*, 1987): if  
403 weeds are erased, adults are compelled to move onto grapevine; for example, in Israel, where  
404 *H. obsoletus* has two generations per year, the second generation is more likely to move to  
405 grapes if its host plant is harvested or dries up because of summer heat (Orestein *et al.*, 2003).

406 Another means of preventing leafhoppers from entering the vineyard may be the use of insect-  
407 proof fences (nets). These devices were successfully used in Israel against some Diptera  
408 (Vernon & MacKenzie, 1998; Päs & Vernon, 1999; Bomford *et al.*, 2000). A five metres  
409 high screen barrier was successfully evaluated in Californian citrus orchards and nurseries  
410 against *Homalodisca vitripennis* (= *coagulata*) (Say), a vector for *Xylella fastidiosa* causing  
411 Pierce's disease (Blua *et al.*, 2005). Such a protective device against *S. titanus* should be at  
412 least 2.5 m, as high as the flight boundary layer of this leafhopper (Lessio & Alma, 2004a).  
413 Moreover, the screen should be provided with an overhang to avoid insects double crossing it  
414 by walking on it (Bomford *et al.*, 2000). On the other hand, plantation of trees had

415 inconsistent effects in limiting invasion into vineyards by *Graphocephala atropunctata*  
416 (Signoret), another vector for *X. fastidiosa* (Daugherty *et al.*, 2012).

417 In conclusion, the presence of wild grapevines in vine growing areas must be addressed with  
418 an integrated pest management strategy that includes: area-wide sprays and use of suitable  
419 active ingredients to prevent such transmission as much as possible; avoidance of new vine  
420 plantations in regions with a high presence of WGV; destruction of WGV whenever possible,  
421 which would decrease the pathways available to this leafhopper; and the development of new  
422 tools such as physical barriers to avoid the entrance of *S. titanus* adults into vineyards from  
423 outside.

424

425

### Acknowledgments

426 We are grateful to Edoardo Sala and Francesca Martina for the help given in field collections  
427 and laboratory analyses. Meteorological data were kindly provided by “Regione Piemonte  
428 Direzione Agricoltura, Settore Fitosanitario - Sezione Agrometeorologica”. This work was  
429 realized within the frame of the “FLADO” research project, supported by “Regione Piemonte,  
430 Servizi di Sviluppo Agricolo”.

Sites consisted of vineyards and stands of wild grapevine. All vineyards (Vin.) were treated with Thiametoxam (approx. 26 June) and Chlorpirifos-methyl (approx. 25 July), except vin. B that was treated twice with Eiofenprox on the same dates; S<sub>v</sub>: size of vineyards, in m<sup>2</sup>; Y<sub>p</sub>: year of planting; Y<sub>s</sub>: year of study; STN: density of *S. titanus* nymphs /5 leaves per plant in the vineyard, calculated with a sequential sampling plan (Lessio & Alma, 2006). D<sub>min.</sub>: minimum distance in metres from stands of wild grapevine (WGV); N<sub>WGV</sub>: number of traps on stands of WGV (in site D there were 2 separate stands of WGV); N<sub>v</sub>: number of traps in vineyards; N<sub>m</sub>: number of markers' application during the season, \*: egg; \*\*: milk; AP: application period of markers during the season.

Dependent variable: rate of marked *S. titanus* (previously arcsin square root transformed) collected on traps placed on wild grapevine (WGV) at each observation, without considering differences between experimental sites; N: number of observations during the season; T: number of traps observed; independent variables: rainfall occurred (mm) and time elapsed (days) ~~from-between~~ marker's application on WGV and insects' collection; weight variable: total insects captured (marked + unmarked) on traps placed on WGV at each observation.

Table 3. ~~H~~Sex ratios observed, and ~~h~~homogeneity of regression test for exponential regression of marked *S. titanus* males and females ~~*S. titanus*~~ captured at different distance from wild grapevine (WGV).

year	site	males		females		Sex ratio (m/f)		Homogeneity of regressions		
		total	marked	total	marked	total	marked	F	df	P
2010	A*	276	115	549	188	0.50	0.61	1.10	1, 21	0.31
	B*	255	85	4065	86	0.06	0.99	0.05	1, 7	0.83
	C*	12	4	151	51	0.08	0.08	0.81	1, 21	0.38
2011	A*	755	455	1377	739	0.55	0.62	0.17	1, 21	0.68
	C*	298	197	761	406	0.39	0.49	1.88	1, 23	0.18
	D*	150	92	386	171	0.39	0.54	0.18	1, 11	0.68
	D**	150	25	386	72	0.39	0.35	2.84	1, 11	0.12

Dependent variable: rate of marked *S. titanus* males and females (marked/total) previously arcsin square root transformed; independent variable: distance from treated WGV. \*: egg; \*\*: milk; df: degrees of freedom.

Table 4. Results of exponential regression of marked *S. titanus* adults as a function of minimum distance from wild grapevine (WGV).

year	site	intercept	slope	R <sup>2</sup>	P	r <sub>0.5</sub>
2010	A*	8.27	0.05	0.56	<0.05	13.86
	B*	9.51	0.03	0.48	<0.05	23.10
	C*	73.43	0.04	0.61	<0.05	17.33
2011	A*	55.69	0.05	0.80	<0.05	13.86
	C*	4.19	0.02	0.84	<0.05	34.66
	D*	29.13	0.01	0.34	<0.05	69.31
	D**	6.2	0.01	0.12	<0.05	69.31

Dependent variable: percentage of marked *S. titanus* captured during the whole season at the same minimum distance from treated wild grapevine (WGV), weighted by the number of traps placed at the same distance per trap; independent variable: minimum distance from treated wild grapevine (WGV) (see text for details). \*: egg; \*\*: milk; r<sub>0.5</sub>: mean dispersal index (in metres).

Formatted: Right: -0.12"

Table 5. Results of cross-validation analysis on the interpolation maps of marked *S. titanus* adults.

year	site	interpolation method	ME	RMSE
2010	A*	IDW	-1.27	7.85
	A*	KB	0.70	6.51
	B*	IDW	-1.06	5.58
	B*	KB	0.70	5.73
