15 **ABSTRACT**
16

17
18
19 The effects of laser irradiation on Chemically Vapor Deposited graphene is studied by analyzing the
20
21 temporal evolution of Raman spectra acquired under different illumination conditions. It is observed
22
23 that the normalized intensity of the defect-related peak increases with the square root of the time of
24
25 exposure, in a nearly linear way with the laser power density and that the hardness of graphene to the
26
27 radiation damage depends on its intrinsic structural quality. The results suggest that, contrarily to the
28
29 common belief, micro-Raman cannot be considered as a non-invasive tool for characterization of
30
31 graphene.
32
33
34
35
36

37
38
39 The experimental observation are compatible with a model, we have derived from the interpretative
40
41 approach of the Staebler-Wronski effect in hydrogenated amorphous silicon, which assumes that
42
43 photoexcited carrier recombination induces the breaking of weak C-C bonds.

1. Introduction

Metastability of thin films grown either by physical or chemical vapor deposition, has been extensively observed in last decades as a variety of phenomena occurring in numerous materials. Examples can be mentioned like structural changes produced by heating, e.g, agglomeration [1] or the creation of additional defects under electrical or optical stimulation [2].

A phenomenological description of this class of systems considers the configurational ground state as not given by an absolute and isolated minimum of the total potential energy, but rather by a more flexible arrangement of the atoms allowing configurations with different local minima of the potential energy separated by a more or less continuous distribution of barriers. In the case of two configurational energy minima with energy difference ΔE , and separated by a barrier of height V_0 , if the externally applied excitation is $E_{\text{ex}} \geq \Delta E + V_0$, stimulated transitions between the two configurational states become possible, or, if the barrier is thin enough, transition between minima can spontaneously occur by tunneling. A class of phenomena, occurring in both crystalline and amorphous solids, is observed under non-thermal-equilibrium conditions, for example, during illumination which, in some cases, degrades the material properties, whereas a relaxation into the equilibrium ground state and a recovery of its properties is possible, e.g. by annealing [2].

There are, in literature, reports about the healing, or self-healing of graphene defects. Those papers are generally dealing with the employment of thermal treatments [3], aided by the presence of loose C atoms and/or catalyzing metal atoms [4], or by atomic layer deposition of metals [5] or Al_xO_y compounds [6] and their results suggest that the metastability of defects can be encountered also in graphene. This either opens an additional route for improving the properties of the material grown by

1 Chemical Vapor Deposition (CVD) with the aim of large-area production of graphene crystals, or
2
3 allows for tailoring of its properties in a bottom-up fashion. The mechanism can however be studied in
4
5 the opposite way, for example, by intentionally producing defects, and by following their formation
6
7 kinetics.
8
9

10 Raman spectroscopy is considered as one of the best tools to assess the quality and the structural
11
12 properties of graphene [7,8]. The features contained in a typical Raman spectrum of graphene can be
13
14 distinguished in the following way: the first observable peak appears at $\approx 1590 \text{ cm}^{-1}$ and is associated
15
16 with the zone-center in-plane longitudinal optical phonons. This well-known *G* peak is characteristic
17
18 for sp^2 -hybridized carbon-carbon bonds. The second prominent peak is located at $\approx 2700 \text{ cm}^{-1}$. This
19
20 *2D* peak originates from a double-resonance process, which creates an electron-hole pair that
21
22 recombine after two inelastic-scattering events involving phonons with opposite momenta. If defects
23
24 are present, one of the two scattering events can occur elastically and the *D* peak, observed in this
25
26 case, exhibits only half the Raman shift. With intense *D* peaks, a concomitant drop in the intensity of
27
28 the *2D* peak is observed.
29
30
31
32
33

34 Both the wealth of information contained in Raman spectra, and its, in principle, non-destructive
35
36 character (no sample preparation is required, photons are employed) make this technique one of the
37
38 routine characterization tool to characterize graphene and to optimize its synthesis [9]. However, there
39
40 are evidences in literature about the modification of graphene properties induced by intense laser
41
42 irradiation, either in terms of reversible photon-induced doping of the material [10], disassembly of
43
44 graphene monocrystal into a nanocrystalline network [11], or ablation of graphene multilayer till to a
45
46 monolayer [12,13].
47
48
49
50

51 For these reasons, when the laser light is focused down to the diffraction limit, as in micro-Raman
52
53 instruments, possible sample damage can occur, as reported in the case of exfoliated material [11]. The
54
55 assessment of the technique in the case of CVD graphene is then necessary, otherwise information

10 11 12 13 **2. Experimental** 14 15

16 The synthesis of graphene was performed by CVD, using a 99.8% Cu foil (Alpha Aesar N°13382)
17 as a catalyst and CH₄ as precursor gas in a vacuum chamber of a Rapid Thermal Annealing apparatus
18 [13]. The Cu foil was initially cleaned with acetic acid at 60°C, sonicated in acetone and ethanol and
19 then inserted in the reactor chamber, encapsulated in between two oxidized silicon wafers. The
20 encapsulation of the Cu foil produces a closed environment, which increases the quality of graphene,
21 by promoting a lower number of nucleation centers and, consequently, larger graphene domains [14].
22
23 After a first step of 5 minutes in H₂ atmosphere to remove residual Cu oxide, 30 sccm of CH₄ and 20
24 sccm of H₂ were introduced in the chamber for 5 minutes at constant temperature of 1025 °C and
25 pressure of 6.7 mbar. The obtained graphene was then transferred on a Si substrate with 300 nm SiO₂,
26 using PMMA as a supporting layer [15]. The graphene layer on the back-side of the Cu foil was
27 etched with O₂ plasma, before dipping the sample in a 1M FeCl₃ solution for Cu removal. After
28 several washing steps in H₂O, PMMA/graphene structure was picked up with the Si/SiO₂ target
29 substrate with Au/Pd markers that were prefabricated by optical lithography. PMMA was removed by
30 acetone.

19 **3. Results and discussion**

20
21 Fig. 1a shows the Raman spectrum of the CVD graphene, collected in macro- configuration with a
22
23 laser ($\lambda=532\ \text{nm}$, wavelength) spot of $d=100\ \mu\text{m}$ diameter and a laser power at the sample $P=11.7\ \text{mW}$
24
25 (power density, $\Psi \approx 150\ \text{W}/\text{cm}^2$) for $T_{\text{integ}}=60\ \text{s}$ integration time. The spectrum is compared with a
26
27 typical one from micro-Raman of exfoliated graphene [11], to highlight the similar quality, apart from
28
29 the slightly higher D peak in the CVD case. Considering the spatial averaging character of the macro-
30
31 tool, this encouraging result suggested us to perform micro-Raman investigation to select the best
32
33 areas, which reasonably should show an even better quality.
34
35
36
37
38

39 Quite surprisingly, most of the micro-Raman spectra collected in a standard configuration ($\lambda=532\ \text{nm}$,
40
41 $d=2\ \mu\text{m}$, $P=2\ \text{mW}$, $\Psi \approx 6.4 \cdot 10^4\ \text{W}/\text{cm}^2$, $T_{\text{integ}}=45\ \text{s}$), show a D peak more pronounced than the macro-
42
43 case. The spectrum resulting from mathematical averaging of ~ 1400 acquisitions collected by the
44
45 micro- tool on a $40 \times 30\ \mu\text{m}^2$ area shows a more pronounced D peak, related to defects, than the
46
47 corresponding macro- one, as evidenced in Fig. 1b. According to Krauss et al. [11], these preliminary
48
49 results indicate that additional defects are created when focusing the laser down to a micrometer-sized
50
51 spot. It seems, in addition, that the application of the Raman technique to CVD graphene (instead of
52
53 exfoliated), is harmful to the sample, despite the employment of lower power ($64\ \text{kW}/\text{cm}^2$ against [11]
54

1 400 kW/cm²) and energy (3.8 MJ/cm² against [11] 12 MJ/cm²) densities. Actually, Tiberj et al. [10]
2
3 reported about photo-induced doping as directly connected to the substrate preparation, evidencing
4
5 that, when graphene is transferred onto Si/SiO₂ substrates used as-received and without any cleaning,
6
7 the doping of graphene flakes remains constant for all the entire laser power range. Doping from
8
9 adsorbates has to be considered as an alternative origin for spectral changes in Raman spectra, the
10
11 most evident being the blue-shift of the *G* band [11,16]. Raman *G-mode* softening and shifting with
12
13 illumination time have been observed by Krauss et al. [11] and ascribed to laser heating as presumably
14
15 responsible for the dopant removal. In all our experiments, however, we did not observe any variation
16
17 in the intensity and position of the Raman *G-mode*, both with time and illumination power density, as
18
19 discussed in the following. This confirms the conclusions of Tiberj et al. [10], since we transferred
20
21 graphene onto as-received substrates, and suggests a negligible amount of adsorbates onto the
22
23 graphene surface.
24
25
26
27
28
29

30 In order to elucidate the effect of the degradation of graphene quality induced by laser irradiation, we
31
32 performed micro-Raman spectroscopy studies using different laser power densities, which have been
33
34 reduced to 50% ($\Psi = 32$ kW/cm²), 80% (51 kW/cm²), and 90% (58 kW/cm²) by means of neutral
35
36 density filters.
37
38
39

40 Fig. 2 shows maps of the I_D/I_G Raman peak intensity ratio from two graphene regions (16 μm x 16
41
42 μm): maps a) and b) are collected in the first region at power levels increasing from 80% to 100%, and
43
44 d) and e) in the second one at power levels decreasing from 100% and 80%, respectively. The
45
46 acquisition time for each point was $T_{\text{Integ}}=45$ s. The differential maps displayed in c) and f) evidence
47
48 the different damaging effects of the second exposure. The role played by the laser power in the
49
50 formation of additional defects is evident, since the damage induced by the second exposure is higher
51
52 in the case of increasing power level (first region). However, both cases show that defective graphene
53
54 is more prone to further degradation. This indirectly agrees with the results of Krauss et al. [11], who
55
56
57
58
59
60
61
62
63
64
65

1 needed to employ one order of magnitude higher power density to produce defects in exfoliated
2
3 graphene, where the Raman D mode is generally very weak, indicating a low concentration of pristine
4
5 defects.
6

7
8 CVD graphene is polycrystalline, being formed of grains with characteristic dimensions ranging from
9
10 tens of nm up to hundreds of μm , depending on the deposition conditions. Raman spectroscopy is
11
12 often employed to estimate the average grain dimension, which correlates well with the I_D/I_G intensity
13
14 ratio [17]. This reasoning bases on the observation that most of the defects are located at grain
15
16 boundaries.
17
18

19
20 There is another Raman feature, the D' peak, located at $\approx 1600\text{ cm}^{-1}$, and ascribed to states lying at the
21
22 zigzag boundaries, whereas the D peak, is associated to armchair boundaries [17]. In all our
23
24 investigations, however, the D' peak has never been observed, suggesting a higher formation energy
25
26 for this kind of defects. This is in agreement with theoretical calculations of formation energy of
27
28 armchair and zigzag boundaries in graphene nano-ribbons [18] Actually, it is found that the formation
29
30 of armchair boundaries requires an energy about 2.3 eV per atom, 1 eV per atom less than the case of
31
32 zigzag boundaries. This is due to substantial lattice relaxation which takes place on the armchair edge,
33
34 with a bond length of the edge C atoms of 0.123 nm. In contrast, the lattice relaxation at the edge
35
36 atomic site does not take place for the zigzag edges and a bond length of 0.138 nm is calculated. A
37
38 similar situation could be envisaged in the case of topological defects, say, pentagons, where the
39
40 formation of armchair-related defects would require a smaller energy. It is worth noting that the
41
42 formation energy of armchair edges is not too far from the energy of impinging photons in a
43
44 conventional Raman apparatus employing green light, and, consequently, to the energy released to the
45
46 lattice by non-radiative recombination of a photo generated electron-hole pair.
47
48
49
50
51
52
53

54
55 A systematic analysis of defect evolution with time by employing different laser energies can provide
56
57 a deeper insight into the nature of these metastable defects. However, this study is beyond the scope of
58
59
60
61
62
63
64
65

1 this work, which is focused on the analysis of the kinetics of these defects during laser irradiation

2
3 The distribution of the I_D/I_G intensity ratios extracted from a Raman map is asymmetrical and well
4 described by a log-normal function as shown in Fig. 3. Here, two distributions, arising from maps
5 collected at two power densities (80% and 100%, respectively) onto two different, but adjacent areas,
6 are displayed. Increasing the laser power results in a broader distribution shifted towards higher values
7 of I_D/I_G . On the other hand, it is worth noticing that the I_{2D}/I_G intensity ratio is always symmetrically
8 distributed.
9

10
11 A log-normal distribution is the result of a process in which a variate obeys the law of proportionate
12 effect, i.e. the change of the variate at any step of the process is a random proportion of the previous
13 value of the variate [19]. Therefore, the random evolution of the I_D/I_G ratio, induced by laser
14 irradiation, can be expressed as a percentage of the number of defects, with a proportionality factor
15 depending on the laser power. This indirectly corroborates the evidence that defects existing in
16 pristine material act as seeds for propagating laser induced ones.
17

18
19 In order to study the kinetics of defect formation in CVD graphene we have analysed the evolution of
20 the Raman spectra obtained by focusing the laser ($\Psi=64$ kW/cm², $d=2$ μ m,) onto three points of the
21 sample, which showed similar pristine I_D/I_G ratio but different I_{2D}/I_G . The laser irradiated these points
22 for 2 hours and spectra were acquired at fixed intervals of 10 min with integration time of $T_{\text{Integ}}=45$ s.
23 The I_D/I_G intensity ratio is found to monotonically increase with the square root of time. Fig. 4a shows
24 a typical trend.
25

26
27 This dependence suggests that the rate of formation of new defects is higher at the first stage of
28 illumination, and gradually decreases. All the investigated spots on the sample surface display this
29 $K \cdot t^{1/2}$ dependence, but with different values of the proportionality factor K , indicating a different
30 reactivity to the damaging action of the laser beam. Maps in Fig. 2 suggest that such reactivity is
31 strongly reduced in regions where pristine defects are absent, meaning that $K \approx 0$, there. This
32
33
34

55
56
57
58
59
60
61
62
63
64
65

1 observation is corroborated by Fig. 4a, in which the slopes of the linear fits (in the $t^{1/2}$ scale) increase
2
3
4 with the value of the initial I_D/I_G peak ratio.

5
6 We found additional dependence of the K slope on the I_{2D}/I_G intensity ratio. In Fig. 4a, data relevant to
7
8 regions with $I_{2D}/I_G \approx 4$, show different slopes (vs. $t^{1/2}$) because of the different initial defect
9
10 concentrations. However, their linear behaviors are remarkably steeper than the linear trend of data
11
12 relevant to $I_{2D}/I_G = 2$. This evidence suggests that samples with larger I_{2D}/I_G ratios are generally more
13
14 prone to photon damage, or, in other words, that bilayer graphene is more laser radiation hard.
15
16 Furthermore, the proportional factor K is function of the power density Ψ . This fact is evidenced by
17
18 the I_D/I_G time evolution resulting from the illumination of the same spot of the sample at successive
19
20 different power levels (namely 50%, 80%, 90%, and 100%) for the same time interval, obtaining this
21
22 way the data displayed in Fig 4b. Here the colored bar chart refer to the right axis and indicates the
23
24 different powers, whereas the quantity I_D/I_G (left axis) is plotted against the square root of time for the
25
26 four cycles, evidencing the change in slope due to different Ψ values.
27
28
29
30
31
32

33 To summarize, our experiments provide evidence that the density of defects induced by laser
34
35 irradiation follows a general behavior, which appears in Raman spectroscopy through the dependence
36
37 on the I_D/I_G ratio:

- 38 i) On the initial values of the defect density in pristine conditions.
- 39
- 40 ii) On the square root of the time exposure at fixed laser power density.
- 41
- 42
- 43
- 44
- 45 iii) On the electron-hole pair photogeneration rate G (which is proportional to the power density Ψ) in
46
47 a nearly linear way.
48
49

50 A thermal mechanism, related to the sample heating at the laser spot, could be envisaged to explain
51
52 the photo-induced formation of defect. The well-defined dependence, summarized above, of the I_D/I_G
53
54 ratio on the experimental parameters is however difficult to explain in the framework of a simple
55
56 thermal model. Actually, sample heating can be monitored through the spectral evolution of the
57
58
59
60
61
62
63
64
65

1 Raman modes (the G peak above all), with time and power density [20]. As displayed in Fig. 5, no
2
3 appreciable shift is observed for such feature either with time or with laser intensity, suggesting a
4
5 temperature rise on the light spot of some tens °C [20]. Basing on these consideration, the thermal
6
7 origin for the defect creation can be ruled out.
8
9

10 All the experimental findings can be included in the following expression instead:
11
12
13

$$14 \quad N_d(t_{ill}) - N_d(0) = \text{const} \cdot G^\kappa \cdot t_{ill}^{1/2} \quad (1)$$

16 where it is assumed that the density of defects $N_d(t_{ill})$ is proportional to the I_D/I_G intensity ratio, t_{ill} is
17 the laser exposure time, $N_d(0)$ is the pristine defect density, and the constant is actually
18 position-dependent. According to eq. (1), the results of the fits in Fig. 4b can be plotted against Ψ , by
19 considering the photogeneration rate G as proportional to the laser power density Ψ (see point iii). The
20 inset shows that a power law with exponent κ close to unity (1.0 ± 0.2) could be envisaged, albeit with
21 a relatively large uncertainty, as after-effect of the indirect nature of the measurement. It has to be
22 noticed, however, that illumination cycles repeated on other sample spots yielded approximately the
23 same power law. Consequently, eq. (1) can be considered as descriptive of the kinetics of defect
24 formation in CVD graphene under intense illumination and suggests a lack of reciprocity between
25 intensity and time. Actually, doubling the integration time and halving the laser power during a Raman
26 measurement is not equivalent to the opposite in terms of laser-induced disassembly of graphene.
27 According to eq. (1), the first approach seems less detrimental to the sample's quality, meaning that
28 employing lower power densities is a safer strategy. In order to investigate if there is a safety limit to
29 the power density value, we reduced it down to the lowest limit for our apparatus, $\Psi = 19 \text{ kW/cm}^2$, with
30 $T_{\text{integ}} = 600 \text{ s}$, in order to yield spectra with acceptable S/N ratio. These conditions are obviously
31 unpractical for acquiring Raman maps, but allow following the time evolution of defects on a single
32 spot. We observed an increase for the I_D/I_G intensity ratio of 30% for the first 120 min of illumination,
33
34
35

65

1 with the same trend of eq. (1). Possible departures from this trend could be observed with Raman
2 instruments with superior optical quality employing lower laser power levels or by excitation with less
3 energetic photons. In this case, however, the scaling of the Raman cross section with the inverse
4 fourth power of the excitation photon energy, requires, in principle, longer integration times.
5
6

7
8 Eq. (1) is reminiscent of a relationship proposed by Stutzmann et al. [2] to explain the kinetics of
9 transition of metastable defects occurring in hydrogenated amorphous silicon (a-Si:H) under
10 illumination, the so-called Staebler-Wronski effect.
11

12 There are, however, important differences: in the a-Si:H case the power law of defect evolution is
13 cubic, and not quadratic as in eq. (1); differently from our case, in that model $N_d(0) \ll N_d(t_{ill})$ and is
14 generally negligible; last, the relationship from Stutzmann et al. [2] is a simplified version of a more
15 complex model, and is obtained for low injection rates.
16

17 The recombination, if non-radiative, provides the energy necessary for breaking the associated weak
18 bonds. Then, the process involved is the electron-hole recombination at band-tail states, which are
19 metastable defects related to weak (elongated, distorted) bonds of the a-Si:H network.
20

21 The last argument can be extended to the case of CVD graphene, considering its polycrystalline
22 nature. Defects in graphene are known to be spatially located mainly at grain boundaries, where it is
23 reasonable that covalent bonds of neighboring C atoms are weaker: one C atom on the border shows
24 only two, reasonably weaker, saturated bonds, whereas pentagons, or heptagons are more likely to be
25 present [4]. Then, the density of weaker, metastable bonds (WB) is reasonably higher in proximity of
26 pre-existing defects. This argument simply explains the observation that CVD graphene is more prone
27 to laser damage than exfoliated one, and different portions of the same sample are resistant to the laser
28 damage in different fashions.
29

30 There is a general agreement about the enhancement of the D mode and the concurrent softening of
31 the $2D$ mode in highly defective graphene [11]. We argue that Raman scattering at metastable bonds

60
61
62
63
64
65

1 occurs through the $2D$ transition, and involves two photons with energy $\hbar\Omega'$, which is in principle
2
3 different from the phonon energy $\hbar\Omega$, exchanged in the $2D$ Raman scattering at stable bonds. By
4
5 analogy with the case of folded graphene, where the Fermi velocity is lowered by a few percent [16],
6
7 such reduction can also occur in the case of elongated/distorted bonds. This means that Dirac's cones
8
9 are somewhat broadened at those sites. Moreover, there are theoretical studies showing how breaking
10
11 of the honeycomb symmetry can lead to distorted Dirac's cones, as in the case of Graphynes [21-22].
12
13 It can be noted, in passing, that a larger distortion of the Dirac's cone on defect sites has been
14
15 proposed to keep into account for the elastic scattering, which is at the origin of the D mode [23].
16
17
18
19
20

21 The occurrence of $2D$ transitions at distorted Dirac's cones, with different exchanged phonon
22
23 energies, is in agreement with the observation that in defective regions the $2D$ mode is generally
24
25 broader. Then, Raman technique allows the monitoring of defect evolution as a balance between D
26
27 and $2D$ transitions. Defects creation tends to enhance the D mode, and to shunt the $2D$ transition, by
28
29 opening additional electron-hole recombination pathways through photogenerated defects. Actually,
30
31 Fig. 6 displays the correlation between the D and $2D$ peak intensities obtained on different portions of
32
33 the graphene sample at two different laser powers, evidencing that photogeneration of defects reduces
34
35 the intensity of the competitive $2D$ transitions. This explains the self-limiting trend of the defect
36
37 formation by photogeneration.
38
39
40
41
42
43
44

45 The above argument can be invoked to explain the better stability of bilayer graphene, as evidenced in
46
47 Fig. 4. It is well known, in fact, that the $2D$ structure in bilayer graphene is more complex, being the
48
49 convolution of 4 different peaks, originating from 4 transitions occurring through the energy
50
51 sub-bands of such system. Then, more pathways are available for electron-hole recombination. The
52
53 weight of a specific recombination process responsible for bond-breaking is then reduced.
54
55
56

57 In order to elaborate a simplified interpretative model of the kinetics of metastable defect creation,
58
59
60
61
62
63
64
65

partially borrowed by Stutzmann et al. [2], let us consider the basic set of equations describing generation/recombination phenomena in graphene:

$$\frac{dn}{dt} = G - \beta \cdot n \cdot p - \alpha_n \cdot n \cdot N_d, \quad (2a)$$

$$\frac{dp}{dt} = G - \beta \cdot n \cdot p - \alpha_p \cdot p \cdot N_d, \quad (2b)$$

$$\frac{dN_d}{dt} = \gamma \cdot n_{WB} \cdot p. \quad (2c)$$

n, p are the electron, hole concentrations in the conduction and valence band, respectively. Assuming that the material is nearly intrinsic, at the illumination levels of the experiment n and p represent the photo-generated electron and hole concentrations, respectively, being $p \gg p_0$ and $n \gg n_0$, where the subscript “0” indicates the carrier concentration in dark conditions and in pristine material. β accounts for the direct band to band recombination and $\alpha_{n,p}$ are the probabilities of recombination transitions in centers relevant to defects with density N_d . Equation (2c) accounts for the creation of new defects by the interaction of a small fraction of electrons in the conduction band (with density n_{WB}) with metastable and weak bonds.

The complete solution of the set of equations (2) is beyond the scope of this work; however, some approximations can be adopted to interpret our experiments. First, we can assume that the increase of defects density is a very slow process with respect to the carrier kinetics, occurring in a much longer time scale than the carrier generation/recombination processes. In this case, eqs. (2a,b) can be solved separately from the equation involving the defect kinetics (eq. 2c). Therefore, the quasi-steady state approach (i.e. $dp/dt=0$ and $dn/dt=0$), leads to the following coupled expressions for n and p :

$$\begin{cases} n = \frac{G}{\beta \cdot p + \alpha_n \cdot N_d} \\ p = \frac{G}{\beta \cdot n + \alpha_p \cdot N_d} \end{cases} \quad (3)$$

At the illuminating time scale, we can account for the evolution of defects by assuming that n_{WB}

1 electrons undergo a pure monomolecular recombination:
 2
 3

$$4 \quad \frac{dn_{WB}}{dt_{ill}} \approx \frac{d}{dt_{ill}} \left[\frac{G}{\alpha_n \cdot N_d} \right] = -\frac{G}{\alpha_n} \left[\frac{1}{N_d} \right]^2 \cdot \frac{dN_d}{dt_{ill}} \quad (4)$$

5
 6
 7 By inserting eqs. (4) in eq. (2c), we obtain:
 8
 9

$$10 \quad \frac{d^2 N_d}{dt_{ill}^2} = \gamma \cdot \frac{dn_{WB}}{dt_{ill}} \cdot p \approx -\gamma \cdot p \cdot \frac{G}{\alpha_n} \cdot \left[\frac{1}{N_d} \right]^2 \cdot \frac{dN_d}{dt_{ill}} \quad (5)$$

11
 12 The solution of this equation is
 13
 14

$$15 \quad [N_d(t_{ill})]^2 - [N_d(0)]^2 = 2 \cdot \gamma \cdot p \cdot \frac{G}{\alpha_n} \cdot t_{ill} \quad (6)$$

16
 17 For high injection level, i.e. assuming
 18
 19

$$20 \quad G \gg \frac{\alpha_n \cdot \alpha_p}{\beta} \cdot (N_d)^2 \quad (7)$$

21
 22 a pure *n-p* bimolecular transition occurs and the hole concentration in the valence band is given by the
 23
 24 following expression:
 25
 26

$$27 \quad p \approx \left(\frac{\alpha_n}{\alpha_p \cdot \beta} G \right)^{\frac{1}{2}} \quad (8)$$

28
 29 Finally, by inserting eq. (8) in eq. (6), we obtain:
 30
 31

$$32 \quad [N_d(t_{ill})]^2 - [N_d(0)]^2 = 2 \cdot \gamma \cdot \left(\frac{G^3}{\alpha_p \cdot \alpha_n \cdot \beta} \right)^{1/2} \cdot t_{ill} \quad (9)$$

33
 34 Although based on simplified hypotheses, eq. (9) justifies the phenomenological expression given by
 35
 36 eq. (1) and gives the time evolution of degradation of metastable bonds into defects N_d . Of course, the
 37
 38 formation of new defects leads to the formation of new weak bonds at neighboring sites, leading to a
 39
 40 progressive disassembly of the graphene sheets [11].
 41

42
 43 The derivation of eq. (9) resembles the approach adopted by Stutzmann et al. [2] to model the SW
 44
 45 effect in the low illumination condition. However, it is worth to underline that our model is based on
 46
 47 the assumption of high injection conditions, defined by eq. (7), which determines a dominant

1 bimolecular recombination and, consequently, an almost constant hole concentration (eq. 8). This
2
3 accounts for the $G^{3/4}$ dependence in eq. (9), which is not far from the estimation of κ , as calculated
4
5 from the fit in Fig. 4(b). On the other hand, the time evolution of defects is assumed to be exclusively
6
7 determined by a small fraction of photogenerated electrons $n_{WB} \ll n$, which undergo a pure
8
9 monomolecular recombination mediated by defects.

16 **4. Conclusions**

17
18 In conclusion, a model for the kinetics of defect formation in CVD graphene under illumination is
19
20 proposed. The model assumes that electron-hole recombination involving weak bonds can provide
21
22 enough energy to convert metastable bonds into defects and well describes the experimental
23
24 observations. The kinetics is self-limiting, confirming that the D and $2D$ are competing transitions for
25
26 carrier recombination. From a more applicative point of view, it is shown that irregularities in the
27
28 graphene atomic network make it prone to be damaged by photons, i.e. damaging the mechanically
29
30 exfoliated material requires a photon flux one order of magnitude larger than CVD. For this reason,
31
32 great care must be employed when performing Raman characterization of CVD graphene. In
33
34 particular, there is no reversibility between the time of spectrum integration and the laser power. It is
35
36 then advisable to reduce the latter, eventually increasing the former. Last, the technique can be
37
38 fruitfully employed for graphene structuring, taking advantage from the possibility of monitoring *in*
39
40 *situ* the evolution of the process.

Figure Captions

Figure 1 a) A comparison between Raman spectra from exfoliated (top) and CVD (bottom) graphene samples. The latter is acquired by a macro-Raman tool with spot size of 100 μm . b) Enlargement of the low energy region of Raman spectra of a CVD sample acquired with a macro-tool (bottom) and a microscope with laser spot size of about 2 μm (top), which is the result of averaging ~ 1400 spectra from a 42 μm x 32 μm map.

Figure 2 a) and b): I_D/I_G Raman peak intensity ratio maps of the same region from CVD graphene taken at increasing laser power, 80% and 100%, respectively. c) shows the difference between the I_D/I_G intensity ratios in b) and a), [b)-a)]. Figs. d) and e) show maps from another region, taken at decreasing power, 100% and 80%, respectively; their difference [e)-d)] is shown in f). The two color bars pertain to a), b), d), e) maps and to the corresponding differences in c) and f), respectively. Scale bar is 4 μm .

Figure 3 Histograms of the I_D/I_G intensity ratio from two Raman maps taken on separate regions of a CVD graphene sample at 80% and 100% laser power levels. Inset: the same for the I_{2D}/I_G intensity ratio.

Figure 4 a) The characteristic dependence of the I_D/I_G intensity ratio vs. square root of time. Triangles and circles indicate data collected from two different sample spots displaying typical monolayer Raman features, whereas squares refer to a sample bilayer region. b) Behavior of the I_D/I_G peak ratio vs. $t^{1/2}$ (left axis) measured at four successive laser power densities (Ψ), which are represented by the colored bar chart (right axis). The slope of the linear fit of the four sets of data are shown in the inset as function of the laser power density (log-log scale). The slope, in the log-log scale, is $\kappa \approx (1.0 \pm 0.2)$.

Figure 5 Behavior of the Raman shift of the G peak as function of laser illumination time, at three successive laser power values.

Figure 6 The correlation between the I_D/I_G and the I_{2D}/I_G peak ratios from two graphene regions irradiated at 80% (red circles) and 100% (blue circles) power levels. The two larger markers represent the 1st, 2nd (median) and 3rd quartiles of the two clouds of data, evidencing that sample irradiation enhances the D peak at the expenses of the $2D$ one.
