Abstract

OBJECTIVE: Less aggressive end-of-life (EOL) care has been observed when healthcare professionals discuss approaching EOL and preferences about life-sustaining treatments with nursing home (NH) residents or their families. We performed a comprehensive systematic review to evaluate the association between healthcare professionals-residents and healthcare professionals-family EOL conversations and EOL care outcomes.

DESIGN: Systematic review with meta-analysis.

SETTING AND PARTICIPANTS: Seven databases were searched in December 2017 to find studies that focused on healthcare professionals-residents (without oncologic disease) and healthcare professionals-family EOL conversations and aimed to explore the impact of EOL conversations on resident's or family's EOL care outcomes.

MEASURES: Random effects meta-analyses with subsequent quality sensitivity analysis and meta-regression were performed to assess the effects of EOL conversations on the decision to limit or withdraw life-sustaining treatments. A funnel plot and Eagger test were used to assess publication bias.

RESULTS: 16 studies were included in the qualitative and 7 in the quantitative synthesis.

Healthcare professionals-family EOL conversations were positively associated with the family's decision to limit or withdraw life-sustaining treatments (odds ratio=2.23, 95% confidence interval: 1.58-3.14).

The overall effect of healthcare professionals-family EOL conversations on the family's decision to limit or withdraw life-sustaining treatments remained stable in the quality sensitivity analysis. In the meta-regression, family members with a higher level of education were less influenced by EOL conversations with healthcare professionals when making decisions about limiting or withdrawing life-sustaining treatments. No publication bias was detected (p=0.4483)

CONCLUSIONS/IMPLICATIONS: This systematic review shows that EOL conversations promote palliative care. Structured conversations aimed at exploring NH resident preferences about

EOL treatment should become routine. NH administrators should offer healthcare professionals regular training on EOL conversations, and resident-centered care that involves residents and their families in a shared decision-making process at EOL needs to be promoted.

INTRODUCTION

The increasing number of nursing home (NH) residents and their chronic, progressive decline in the end-stages of disease[1] have led to growing interest in NH end-of-life (EOL) care. Research has revealed a relatively poor quality of EOL care in NHs, with aggressive treatments often being employed, a non optimal management of symptoms and lack of psychological and spiritual care.[2-4] About one-third of NH residents are hospitalized in the last 30 days of life, 60% of whom experience in-hospital death.[5,6]

Discussing EOL issues (treatment goals, advanced care planning, and preferences about life-sustaining treatments) with NH residents and their families is important to ensure patient-centered care.[6,7] EOL conversations enable healthcare professionals to align decisions with NH residents' values, and NH residents whose healthcare professionals are informed of these values and preferences are four times more likely to die in their preferred place.[8] However, healthcare professionals' decision making can be influenced by several factors such as societal values and constraints, training, regional laws, and the policies of the nursing home.[9] Even cultures that favour disclosure and discussion of EOL issues as those of Australia and United States, may have different approaches[10] Sustaining EOL conversations is even more challenging when a common ethno-cultural background lacks.[11]

Because many NH residents experience cognitive decline,[1,12] healthcare professionals depend on family or a designated proxy (surrogate) to guide EOL care. Over 90% of NH residents with late-stage dementia have a surrogate,[3] and around 80% of surrogates must make decisions on aggressive treatments.[13] Indeed, up to 90% of Do-Not-Resuscitate (DNR) directives are put in place by surrogates.[14] Although healthcare professionals recognize the importance of planning a care consistent with the shared goals of NH residents and their families,[15] EOL conversations usually occur only after NH residents' health conditions have worsened,[16] which limits the provision of palliative care and hospice referral.[3,17,18]

Family involvement in EOL conversations results in decreased provision of aggressive care,[4,19] increased families'satisfaction,[2,20] and reduced in-hospital deaths.[4] EOL conversations were

positively associated with Do-Not orders (no feeding tube, no artificial hydration, no hospitalization).[21] EOL hospitalizations are judged especially inappropriate when care can be provided with equal benefit in the NH,[22] and are often inconsistent with residents' preferred EOL treatment and place of death.[23]

No systematic review exists on the impact of EOL conversations on EOL care outcomes. Since social, geographical and cultural contexts may affect sensitivities towards EOL conversations, this systematic review aimed to offer a comprehensive overview on the association between healthcare professionals-NH resident or healthcare professionals-family EOL conversations and EOL care outcomes.

METHODS

Design

We conducted a systematic literature review according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Table A1, Appendix 1).

Search Strategy

Searches were conducted in seven databases (PubMed, EBSCO CINAHL, EBSCO PsyINFO, Joanna Briggs Institute, Cochrane Database of Systematic Reviews, Scopus, and ISI Web of Knowledge) by an expert librarian (B.M.) for relevant articles published from the databases' inception until 31 December 2017. Searches employed both controlled vocabularies and key words, without temporal or language limits. Search strategies were adapted for each database (Appendix 2). The reference lists of included articles were screened manually to identify potentially relevant publications.

Eligibility Criteria

Original studies were included if published in peer reviewed journals, focused on healthcare professionals-NH non oncologic resident or family EOL conversations and aimed to explore the

impact of EOL conversations on NH resident's or family's EOL care outcomes. Studies that included multiple settings (i.e., home, public hospital, hospice, private hospital, NH) or different populations (i.e., healthcare professionals, NH residents, families) were excluded when it was not possibile to identify the impact of EOL conversations on NH resident or family outcomesin the NH context. Studies using other interventions that promoted less intensive EOL care (e.g., decision aid video) were excluded.

Article Screening and Study Selection

The title and abstract were screened independently by S.G. and I.B. and duplicates were removed. The same investigators then reviewed the full text of the potentially relevant articles. Any disagreement or uncertainty regarding eligibility was addressed through consensus with a third investigator (S.C.).

Quality Assessment of Studies

Study quality was assessed by S.G. and I.B., using an adapted version of Moilanen and collegues' appraisal criteria.[24] This tool has three sets of questions: general, for quantitative and for qualitative papers. We applied general questions (n=13) and questions for quantitative papers (n=8) (Table A2 in Appendix 1). Response options (yes=1, no=0, not relevant=1) were summed to determine the mean quality score (range 0-21), and classified as high ($\geq$19), moderate (16-18), low (13-15), or very low (<13); values with decimals were rounded to the lower integer. Agreement between the investigators was tested using Cohen's Kappa analysis in R v 3.3.3 statistical software[25] and classified as poor (<0.20), fair (0.21-0.40), moderate (0.41-0.60), substantial (0.61-0.8), or almost perfect (>0.8).[26]

Data Collection

Data were entered into a standardized spreadsheet under the following headlines: study characteristics (author, country, year, design, definition of life-sustaining treatments and EOL conversation, subjects

involved and duration of EOL conversation, outcome(s) investigated and assessment tools, data source and time of data collection, number and size of NHs); sample characteristics (number, sex, age, cognitive deficit, nursing home length-of-stay, and advanced directive of NH residents; number, kinship, sex, age, education of family members); narrative summary of findings; and quantitative results (number and proportion of individuals exposed to at least one decision to limit or withdraw life-sustaining treatments).

S.G. and I.B. independently extracted all the data. Disagreements and uncertainties were resolved by consensus with a third researcher (S.C.).

Data Synthesis

Prevalence of decision to limit or withdraw life-sustaining treatments was considered the main EOL outcome. Prevalence was calculated as the proportion of NH residents exposed to at least one decision to limit or withdraw a life-sustaining treatment.

We performed a meta-analysis to assess the association between healthcare professionals-family EOL conversations and the main EOL outcome (only one study[27] assessed healthcare professionals-NH resident EOL conversations), using odd ratios (ORs) with 95% confidence intervals (CIs). We used a random-effects model with unrestricted maximum likelihood using the sample size as a weighting factor. Heterogeneity, assessed using the Cochran Q test via a Mantel-Haenszel test based on the pooled OR, was suggested if Q>degrees of freedom and confirmed if p≤0.10, and by means of the I^2 statistic as proposed by Higgins and Thompson. I^2 values of 0-24.9%, 25-49.9%, 50-74.9%, and >75% were considered as none, low, moderate, and high heterogeneity, respectively.[28] A funnel plot and Eagger test were used to assess publication bias. ORs were plotted on a logarithmic scale against the corresponding standard error for each study. In the absence of publication bias, one would expect studies of all sizes to be scattered equally to the right and left of the line, showing the pooled estimate of natural log OR.[29]

Additional data were requested from authors. Two[21,30] did not answer: one study[30] was excluded since no explicit data on the decision to limit or withdraw life-sustaining treatments after EOL conversation was available; the second study[21] provided individual figures for each life-sustaining treatment, thus the most frequent DNR decision (90%) was used.

We performed a sensitivity analysis based on study quality according to Moilanen's appraisal criteria[24] and a meta-regression in case of heterogeneity. We combined the data regarding family member's kinship (child *vs* others), sex (male *vs* female), age, education (graduate or postgraduate *vs* lower education), and multi-healthcare professionals EOL conversation (yes *vs* no) in a meta-regression to identify factors associated with the decision to limit or withdraw life-sustaining treatments. Results were considered statistically significant at 2-tail $p<0.05$. All analyses were carried out in R v 3.3.3 statistical software.[25]

Results

Review Process

A total of 1,958 articles were identified. After removal of duplicates and screening, of the 19 articles included in the full-text review, 14 met our inclusion criteria. Two additional articles were included from the reference lists of selected articles (Figure 1).

Please, insert figure 1 here

Characteristics of Included Studies

Ten studies were conducted in the United States (54,149 NH residents; 1,910 family members), four in Europe (1,141 NH residents; 275 family members), one in Canada (208 NH residents; 208 family members), and one in Asia (201 NH residents; 201 family members). All but one study[27] were conducted after 2000 (Table 1). The main aim of each study is reported in Table A3 (Appendix 1).

Studies involved a median of 20 NHs (range 1[19-21]-1,201[31]). Eleven studies were cross-sectional,[2,13,14,27,30-36] four prospective,[4,19,20,37] and one retrospective[21] (Table 1).

Please, insert here table 1.

Most studies assessed the decision to limit or withdraw life-sustaining treatments:[4,13,14,19,21,27,30,36] six explored the prevalence of in-hospital death,[2,4,16,21,31,33] five assessed family satisfaction with EOL care,[2,19,20,32,35] two described the quality of dying,[33,37] and one assessed family well-being[34] (Table 1). Data were collected from medical records (n=9),[4,13,14,19-21,27,34,35] family interviews (n=8),[2,13,19,20,27,34-36] family questionnaires (n=5),[14,30,32,33,37] healthcare professionals questionnaires (n=4),[30,31,33,37] healthcare databases (n=2),[21,31] or NH resident interviews.[27] Data from healthcare professionals were collected between <5 [4] and 82 days after the resident's death.[33] Data collection from families ranged from the time of the resident's EOL[13,14,19,20,27,34,35] to 23.8 month after the resident's death[36] (Table 1).

Ten studies were classified as high quality, two as moderate quality and four as low quality (Table A2, Appendix 1).

Subjects Involved in End-of-Life Conversations

Families were always involved in EOL conversations, while NH residents only in six studies.[4,21,27,30,31,33] Family members were mostly adult children (range 55.2%-75.5%),[2,14,19,20,32,34-37] nieces/nephews (range 9.2%-14.4%),[20,21,32,34,35] and spouses (range 3.9%-19%)[2,19-21,32,34-37] (Table 1). EOL conversations were managed exclusively by the physician[4,14,27,34,37] or nurse,[32] or by multiple healthcare professionals (i.e., physician, nurse, healthcare aide, social worker, physical therapist).[2,19-21,30,33,35] Three studies did not specify the healthcare professionals qualification.[13,31,36] The mean duration of EOL conversations varied from 47 minutes (range 20-75 minutes),[19] to a range from <5 to >15 minutes,[34,35] up to >1 hour[36] (Table 1).

Definition of End-of-Life Conversations

The definition of EOL conversations differed (Table 1): eight studies defined it as a "discussion" about life-sustaining treatments or care goals,[21,27,35] advanced directives,[14,34] the risks and benefits of invasive treatments such as feeding tubes[36] or other treatments,[31] the prognosis, the possibility to withdraw treatments, palliative care options, or care for psychological, spiritual, and existential problems.[4] Three studies defined EOL conversations as "speaking" about life-sustaining treatments and symptom management[20] or future care;[30,33] one defined it as "talks" about how the NH resident was doing[13] or as "receiving information" about the NH resident's health problems or what to expect.[37] Three studies used a combined definition: EOL conversations required "receiving information and speaking about NH resident's condition and medical treatment"[2] or "receiving/providing information, discussing and understanding what to expect and medical treatment options".[19,32] Only one study[19] explicitly adopted "structured" conversations that systematically addressed the NH resident's health condition, clinical course and prognosis, the family's care goals and how to achieve them while explaining the risks and benefits of potential treatments. However, the majority of the studies did not report the characteristics nor the structure of EOL conversations. In one study, family attendance at care plan meetings was an indicator of EOL conversation.[21]

Definition of Life-Sustaining Treatments

The definition of life-sustaining treatments changed across the studies (Table 2). Some authors explored one medical intervention, such as resuscitation[14] or tube feeding,[36] while others[13] only hospitalizations and surgery. Four studies defined life-sustaining treatments as resuscitation, hospitalization, artificial feeding, hydration, intubation, antibiotic use, only comfort care, terminal sedation, or euthanasia.[19,21,27,30] One study did not define life-sustaining treatments.[4]

Please, insert here table 2.

End-of-Life Conversations and Life-Sustaining Treatments

Seven studies reported the prevalence of decisions to limit or withdraw life-sustaining treatments and were included in the quantitative synthesis (Table 2);[4,13,14,19,21,27,36] the risk of bias is presented for each study in Table A2, Appendix 1 and by a funnel plot of ORs by the size of the study sample (Figure A1). No publication bias was detected (Eagger test p=0.4483).

As shown in Figure 2, healthcare professionals-family EOL conversations were positively associated with the family's decision to limit or withdraw life-sustaining treatments (OR=2.23, 95% CI 1.58-3.14). Although there was relatively low heterogeneity (I^2=40.9%), a quality sensitivity analysis and a meta-regression were performed. The overall effect remained stable after removing low- and medium-quality studies (OR=2.51, 95% CI 1.96-3.22 I^2=0%, Figure A2). Family member's kinship, sex, age, and multi-healthcare professional EOL conversations, were not associated with such decision. Instead, education explained all the observed heterogeneity, with family members with higher education being less influenced by EOL conversations (Figure A3).

End-of-Life Conversations and Quality of Dying

Six studies[2,4,21,31,33,36] reported the prevalence of in-hospital death (6%[33]-22[31]). Discussing EOL issues was associated with fewer in-hospital deaths[4,31] and increased odds of receiving strong opioid analgesics in the last 24 hours of life.[4] Unplanned hospital admission and length of hospital stay in the last month of life also decreased, although not significantly.[4] However, healthcare professionals-family EOL conversations on prognosis and health complications were unrelated to NH resident's comfort during the dying process.[37] Similarly, nurse-family EOL conversations were negatively associated with residents' physical distress and dying symptoms,[33] nor were they a predictor for hospice use.[31]

End-of-Life Conversations and Family Satisfaction with End-of-Life Care

Five studies (764 family members) investigated the association between healthcare professionals-family EOL conversations and family satisfaction with EOL care.[2,19,20,32,35] Families that received scarce or confusing information were up to 6-fold more dissatisfied with EOL care than those who felt adequately informed,[2] while satisfaction with nurse communication was associated with higher satisfaction with EOL care.[32] EOL care satisfaction increased with the duration[35] and the frequency[20] of EOL conversations.

Discussion

This systematic review suggests that healthcare professionals-family EOL conversations may promote a palliative care approach in NH residents, with less aggressive treatments regardless the social, geographical and cultural contexts. Families involvement in EOL conversations increased 2-fold more the likelyhood to limit or withdraw life-sustaining treatments, with an average of 56% of residents receiving limited or no life-sustaining treatments (16.4%[14]-94.3%[19]).

In the cancer literature, discussing EOL issues has been shown to increase patients' and families' acceptance of the illness as terminal, their preference for comfort treatments aimed at relieving pain and discomfort, and receiving more as needed drugs without increasing pain or anxiety.[38,39] However, it should not be taken for granted that these conversations occur, particularly in Latin countries where non-disclosure appears as a way to maintain hope and continuity of social life.[40] In Latin countries, less than 65% of cancer patients are aware of their diagnosis and usually information about prognosis is even poorer than about diagnosis.[41]

EOL conversations generally involved family. According to Flemish physicians, only 22% of NH residents were involved in such conversations, although more than 60% were capable or partly capable of medical decision making at admission.[30] This poor involvement, in addition to the low prevalence of advanced directives (0-32%), which were reported in only six of 16 studies (USA,[13,27,35] Flanders,[30,33] and Canada[2]), suggests a tendency to avoid or delay EOL conversations until the

resident's health has deteriorated.[42,43] In fact, previous literature showed that 75% of direct care staff would talk to families about death, dying, and treatment options only when the NH resident became terminal.[44] Shifting the focus to comfort care would facilitate timely interventions aimed at promoting quality of living and dying[45] but requires healthcare professionals to confront the issue of how residents want to die and to care for their spiritual needs.[46] Spiritual care is a milestone of palliative care, but only one study assessed it in EOL.[4] Meeting the spiritual needs, in addition to symptom control, limiting or withdrawing aggressive care, and avoiding hospital admissions, are considered quality indicators for EOL care, particularly in severely cognitively impaired patients[1] (the majority of our sample). In patients with advanced dementia, treatments such as terminal hospitalization and tube feeding are considered aggressive[1,47] and perceived as poor EOL care by families .[36]

Confronting EOL issues may be emotionally challenging for healthcare professionals.[48] However, timely, sensible communication with staff is necessary to ensure quality care[47,49] and does not worsen predeath grief in families:[34] a clear explanation of treatment choices by the physician was associated with a dignified death according to families,[50] and up to 91% of DNR decisions were made by family members.[14] The presence of the family at care plan meetings favors a shared decision; however, family members were present in only one of five such meetings,[21] in spite of their wish to be involved in discussions on NH resident's treatment[51] and health condition.[44] No discussion occurred in over one-third of the cases,[4] and only half of the decisions to withdraw/withold life-sustaining treatments were discussed.[4,52] Similarly, only 41% of competent NH residents were involved in discussions about starting life-sustaining treatments.[12]

EOL conversations were often brief (<5 minutes)[16,35] and infrequent (>60% of physician-family EOL conversations occurred less than once a month).[13] However, some conversation was offered to the families of all terminal residents and their effect was measured mostly in observational studies, that differently from trials, reflect the actual routine care. Our findings show an emerging positive change, but much work is still to be done to make this palliative approach routine care. Moreover, this positive trend was mainly limited to North America (n=11)[2,13,19-21,27,31,32,34-36] and Northern

Europe (n=3);[30,33,37] while examples from other countries are few.[4,14] Differences in the definition of palliative care[53] and NH[54] exist across countries. Culture may influence healthcare professionals' involvement in and the structure of EOL conversations, however, our findings suggest that any family involvement in EOL conversations has a positive effect regardless the lack of cohesive definitions and differences across countries.

EOL conversations need improvement. Families often reported dissatisfaction with the provision of information about what to expect during the dying process,[2,4,18,55] the clarity of the information,[2] and the opportunity to share the preferences and wishes of the dying person.[2] Qualitative studies reported that families wanted more information about the condition of their loved ones and were upset by the lack of contact.[43] Families may feel overwhelmed by their EOL decision-making role if they feel ill-equipped to make such decisions,[56] exposing them to undue burden.[57] This raises the issue of balance between family autonomy and medical paternalism.[58] This balance is largely influenced by the societal context, as suggested by a qualitative study involving NH American and Dutch physicians: the former informed families about appropriate care and let them make choices supporting autonomy, while the latter took the final decision although keeping families involved in the decision-making process (paternalistic approach).[9] Patients and families need guidance about life-and-death decisions.[58] Experts recommend the involvement of patients and their families in "expectation conversation" to make them aware that critical decisions (e.g., hospitalization, artificial feeding) may be required in the coming weeks.[57,59] Families tend to choose comfort care when they acknowledge that the NH resident's health is not expected to improve. For example, surrogates of dementia patients without a full understanding of the situation scored their relative's quality of life as worse when active treatment was not provided.[13]

EOL conversations might not be associated with a better quality of dying.[33,37] Only residents whose surrogates understood the poor prognosis were less likely to receive aggressive therapeutic or diagnostic interventions.[17,60] Highly-educated family members were less influenced by EOL conversations, likely because skilled enough to refer to other information sources (i.e., the Internet).

However, quality of dying is difficult to measure, and distressing symptoms such as dyspnea may be uncontrollable. This may explain the apparent lack of association between EOL conversations and dying symptoms.[33,37] This issue should be better explored in future studies.

Our systematic review suggests that EOL conversations shape families' satisfaction with EOL care, and satisfaction increased with the duration[35] and frequency of discussion,[20] suggesting that in-depth, scheduled EOL conversations promote family members' gradual involvement and awareness with a positive effect on their satisfaction with EOL care.[61]

Limitations

The results of this review should be considered in light of several limitations. First, although we used a systematic search strategy, eligible studies may have been missed. Second, one valuable study[30] was not included in the meta-analysis, because the authors did not provide additional information. Third, characteristics of EOL conversations were largely unreported, thus we could not explore whether the different definitions (e.g., speaking, discussion, talk) implied differences in the structure of conversation. Finally, unmeasured confounders like medical or NH culture or religious attitudes may have accounted for the association between EOL conversations and the decision to limit or withdraw life-sustaining treatments. However, our findings remained consistent despite differences in context, interventions, or nursing home culture, suggesting that EOL conversations may play a positive role in promoting a palliative approach.

Conclusions/Relevance

This systematic review provides the first comprehensive evaluation of the role of EOL conversations on EOL care outcomes, and particularly on the decision to limit or withdraw life-sustaining treatments. EOL conversations influence adoption of a palliative approach, thus reducing aggressive interventions, possibly by making NH residents and families better understand their lack of benefit. Our findings suggest that EOL conversations should not be confined to the final days of life but

offered from an early stage with NH administrators offering healthcare professionals regular training on EOL conversations. This is the first step to more meaningful participation and shared decision making, which improves EOL care outcomes including families' satisfaction. Future research should explore whether and how differences in the structure of conversations affect EOL care outcomes.
