## Abstract

Similarity is one of the most straightforward ways to relate objects and guide the human perception of the world. It has an important role in many areas, such as Information Retrieval, Natural Language Processing, Semantic Web and Recommender Systems. To help applications in these areas achieve satisfying results when finding similar concepts, it is important to simulate human perception of similarity and assess which similarity measure is the most adequate.

We propose Sigmoid similarity, a feature-based semantic similarity measure on instances in a specific ontology, as an improvement of Dice measure. We performed two separate evaluations with real evaluators. The first evaluation includes 137 subjects and 25 pairs of concepts in the recipes domain and the second one includes 147 subjects and 30 pairs of concepts in the drinks domain. To the best of our knowledge these are some of the most extensive evaluations in the field.

We also explored the performance of some hierarchy-based approaches and showed that feature-based approaches outperform them on two specific ontologies we tested. In addition, we tried to incorporate hierarchy-based information into our measures and concluded it is not worth complicating the measures only based on features with additional information since they perform comparably.

**Keywords:** Similarity, properties, feature-based similarity, hierarchy, ontology, instances

---

## 1. Introduction

Similarity is one of the main guiding principles which humans use to categorise the objects surrounding them. While in psychology the focus is on how people organise and classify objects, in computer science similarity plays a fundamental role in information processing and finds its application in many areas from Artificial Intelligence to Cognitive Science, from Natural Language Processing to Recommender Systems. Semantic similarity can be employed in many areas, such as text mining, dialogue systems, Web page retrieval, image retrieval from the Web, machine translation, ontology mapping, word-sense disambiguation, and item recommendation, to name just a few. Due to the widespread usage and relevance of semantic similarity, its accurate calculation which closely mirrors human judgement brings improvements in the above and many other areas.

Usually, semantic similarity measures have been tested on WordNet [12]. WordNet is a taxonomic hierarchy of natural language terms developed at Princeton University. The concepts are organised in synsets, which group words with similar meaning. More general terms are found at the top of the underlying hierarchy, whereas more specific terms are found at the bottom. Two important datasets used to test similarity measures on WordNet are the ones proposed by Rubenstein and Goodenough [29] and Miller and Charles [20]. These datasets are manually composed and contain rated lists of domain-independent pairs of words.

However, with the diffusion of ontologies as knowledge representation structures in many areas, there is a need to find similar and related objects in specific domain ontologies used in various applications, rather than just testing the similarity of concepts in WordNet. In these cases, the features of domain objects play an important role in their description, along with the underlying hierarchy which organises the concepts into more general and more specific concepts. The experiments with feature-based and hierarchy-based semantic similarity measures on specific domain ontologies are rare and do not have conclusive results [24, 36]. Hence, we decided to carry out some experiments with Dice feature-based similarity measure on two specific domain ontologies. For our first experiment, we chose the domain of recipes and used the slightly

modified Wikitaable dataset<sup>1</sup> previously used in [7]. For our second experiment, we chose the domain of drinks, developed previously by our research team for different purposes. It should be noted that it is difficult to find a publicly available ontology with defined properties, which is an important requirement for testing our approach.

35 In addition, the domains which could be tested with non-expert users are very limited, since the users should be able to evaluate the similarity of all (or at least most of) the pairs proposed in the test. This is the reason we could not have used any of the medical ontologies available, since in medical domain only expert evaluators can be used for evaluation purposes.

40 There are many different similarity measures around. It is not very clear which measure is the most suitable in a given situation and comparative studies are rare [21, 30]. Above all, the evaluation of the measures with users is limited often to very few participants. On the contrary, our experiments involve 137 and 147 real evaluators respectively, which is a significant number of participants compared to other studies.

45 Thus, we aimed to gain more insight into the behaviour of Wu and Palmer’s [34] and Li’s [18] hierarchy-based measures, as well as Dice feature-based similarity measure for ontology instances calculated from property-value pairs for compared objects. This led us to propose *Sigmoid similarity measure* as a feature-based counterpart of Li’s measure. Sigmoid measure could be applied in other domains where common and  
50 distinctive features of domain concepts are available. Also, we tried to combine Dice and Sigmoid similarity measures with hierarchy based approaches.

Our aim was to avoid any dependency on the weighting parameters which mark the contribution of each feature (known also as relevance factors). These parameters can be tuned for each single domain, but we wanted to test the contribution of each feature  
55 with its equal share.

The main contributions of this work are the following:

1. a concrete proposal for a new feature-based similarity measure, which could take underlying hierarchy into account;
2. new datasets which can be used for the evaluation of feature-based similarity

---

<sup>1</sup><http://wikitaable.loria.fr/rdf/>

60 measures, as well as an extensive evaluation using real human subjects.

The paper is organised as follows. In Section 2 we provide the background on the basic concepts we use in our work. In Section 3, we provide some details about the semantic similarity measures we will be dealing with: feature-based semantic similarity measures and hierarchy-based semantic similarity measures. For the sake of completeness we also give some background on Information Content similarity measures, 65 although we will not be dealing with them in this paper. In Section 4 we see how Dice feature-based measure corresponds to Wu and Palmer’s [34] hierarchy-based measure and propose Sigmoid measure as a new feature-based similarity measure which corresponds to Li’s [18] hierarchy-based measure. We also give details of the variations 70 of each of these similarity measures which might include or not the hierarchy-based similarity. The results of our extensive evaluation are reported in Section 5 followed by a Section 6 which summarises some additional works which exploit feature-based semantic similarity measures. In Section 7 we draw some conclusions and point some directions for future work.

## 75 2. Background on semantic knowledge representation

This section provides a background on the main notions used in this work.

### 2.1. Conceptual hierarchies

A *conceptual hierarchy* provides a taxonomy (a tree or a lattice) of concepts organised using the partial order IS-A relation, which specialises more general classes into 80 more specific classes [3, 33]. The IS-A relation is asymmetric and transitive and defines a hierarchical structure of the ontology, enabling the inheritance of characteristics from parent classes to descendant classes. W.r.t. similarity calculation, it enables the employment of hierarchy-based approaches.

### 2.2. Ontologies

85 Ontologies enable explicit specification of domain elements and their properties, hierarchical organisation of domain elements, exact description of any existing relationships between them and employment of rigorous reasoning mechanisms. An ontol-

ogy can be seen as a “formal, explicit specification of a shared conceptualisation” [13]. They are expressed with standard formats and languages (e.g., OWL.<sup>2</sup>), which allow  
90 for extensibility and re-usability.

Two layers can be identified in an ontology: *the ontology definition layer* which contains the classes which describe the concepts in the domain, and the *instance layer* which contains all the distinct individuals in the domain.

*The* relations between resources are defined by means of properties. Two types of  
95 properties exist:

- (i) *object properties* linking individuals among themselves;
- (ii) *data type properties* linking individuals and data type values.<sup>3</sup>

In this work, we only considered object properties, since the treatment of data type properties (such as literal values) requires further semantic analysis.

100 Instances in the ontology (also called individuals) describe concrete individuals. They are defined with individual axioms which provide their class memberships (property `rdf:type`), individual identities and values for their properties. All the properties of instances are inherited from the classes *to which the instances belong*. A specific value is associated to each property and some properties can have more than one value.  
105 Properties of instances enable the employment of feature-based similarity measures *for* ontology instances.

### 3. Semantic similarity measures

In this section we give some details of the three main categories of semantic similarity measures, namely *those that are* hierarchy-based, feature-based and information  
110 content-based. As a result of trying to improve and combine the above approaches, many hybrid similarity measures were born. In our experiments we only dealt with Wu and Palmer’s and Li’s hierarchy-based measures and with Dice feature-based measure

---

<sup>2</sup><http://www.w3.org/TR/owl-ref>

<sup>3</sup>In OWL, there is also the notion of annotation property (`owl:AnnotationProperty`) and ontology property (`owl:OntologyProperty`), used in OWL DL.

and their combinations. We include information-content-based measures for the sake of completeness only .

### 115 3.1. Hierarchy-based similarity measures

Hierarchy-based or distance-based similarity measures use the underlying conceptual hierarchy directly and calculate the distance between concepts by calculating the number of edges or the number of nodes which have to be traversed in order to reach one concept from another. The hierarchy-based measure was first introduced by Rada et al. in [25] as a simple shortest path connecting the compared concepts and was the basis for the development of many measures of semantic similarity. A discussion and comparison with information content-based approaches can be found in [5]. In this section we give more details about three hierarchy-based measures: Wu and Palmer’s measure [34], Li’s measure [18] and Leacock and Chodorow’s measure [17].

#### 125 3.1.1. Wu and Palmer’s similarity measure

Wu and Palmer’s similarity measure [34] is based on the depths in the hierarchy of the two words being compared and on the depth of their common subsumer, which characterises their commonalities. If we denote by  $c$  the first subsuming node for the two compared nodes  $a$  and  $b$ , their similarity is calculated as follows:

$$\text{sim}_{WP}(a, b) = \frac{2N_c}{N_a + N_b}. \quad (1)$$

$N_n$  is the number of nodes along the path from the node  $n$  to the root.

This measure can also be expressed as a function of distances between nodes as follows:

$$\text{sim}_{WP}(a, b) = \frac{2\text{DIST}(c, r)}{\text{DIST}(a, r) + \text{DIST}(b, r)}. \quad (2)$$

$\text{DIST}(n, r)$  is the distance of  $n$  from the root, again calculated as the shortest path length between the two nodes.

If we write  $\text{DIST}(a, r) = \text{DIST}(a, c) + \text{DIST}(c, r)$  and  $\text{DIST}(b, r) = \text{DIST}(b, c) + \text{DIST}(c, r)$  this equation becomes:

$$\text{sim}_{WP}(a, b) = \frac{2\text{DIST}(c, r)}{\text{DIST}(a, b) + 2\text{DIST}(c, r)}. \quad (3)$$

In [34] this measure was used in lexical selection problems in machine translation  
 130 where the performance of inexact matches based on verb meanings is evaluated.

### 3.1.2. Li's similarity measure

Li et al. [18] proposed an approach for calculating the similarity between sentences which uses semantic information and word order information in the sentence. Similarity of singular words is calculated using the shortest path length between words ( $\text{DIST}$ ) and the depth of their common subsumer ( $h$ ) as follows:

$$\text{SIM}_L(a, b) = e^{-\alpha \text{DIST}(a, b)} \frac{e^{\beta h} - e^{-\beta h}}{e^{\beta h} + e^{-\beta h}} = \frac{e^{2\beta h} - 1}{(e^{2\beta h} + 1)e^{\alpha \text{DIST}(a, b)}}. \quad (4)$$

where  $\alpha \in [0, 1]$ ,  $\beta \in (0, 1]$  are parameters which control the contribution of shortest path length and depth, respectively. As  $\beta \rightarrow \infty$ , the depth of a word in the semantic nets is not considered. Their optimal values depend on the knowledge base used and  
 135 for WordNet they are  $\alpha = 0.2$  and  $\beta = 0.45$ . For the proposed benchmark dataset, the optimal values are  $\alpha = 0.2$  and  $\beta = 0.6$  (obtained experimentally). If the words  $a$  and  $b$  belong to the same synset then  $\text{DIST}(a, b) = 0$ , if they do not belong to the same synset but the synsets for  $a$  and  $b$  contain one or more common words, then  $\text{DIST}(a, b) = 1$  and for the remaining cases the actual path length between  $a$  and  $b$  is calculated.  
 140 This measure was introduced for purely theoretical purposes, as an improvement of the existing similarity measures.

### 3.1.3. Leacock and Chodorow's similarity measure

For the sake of completeness we would also provide details of Leacock and Chodorow's similarity measure [17] which was originally used for word sense disambiguation in a local context classifier. The most similar nouns from the training set are substituted for the ambiguous ones in testing. In order to calculate the distances between words, the authors use the normalised path length in WordNet [12] between all the senses of the compared words and measure the path length in nodes:

$$\text{SIM}_{LC}(a, b) = -\log \left( \frac{Np}{2\text{MAX}} \right). \quad (5)$$

$Np$  is the number of nodes in the path  $p$  from  $a$  to  $b$ , whereas  $\text{MAX}$  is the maximum depth of the hierarchy. The distance between two words belonging to the same synset

145 is 1.

If we want to express this measure as a function of distances between nodes we obtain the following formula:

$$\text{sim}_{LC}(a, b) = -\log\left(\frac{\text{DIST}(a, b)}{2_{\text{MAX}}}\right). \quad (6)$$

$\text{DIST}(a, b)$  is the distance between  $a$  and  $b$  calculated as the shortest path length between these two nodes.

The disadvantage of this similarity measure is that many pairs of non-similar words are estimated as similar, due to the equal edge lengths in their hierarchy.

### 150 3.2. Information content-based similarity measures

The measures seen above work on single knowledge structures and they do not need external sources for similarity calculation. In this section we present the most important approach which uses an external corpus to compute the similarity. The foundational work on information content-based similarity is due to Resnik [26, 27]. His approach is based on the fact that the more abstract classes provide less information content, whereas more concrete and detailed classes lower down in the hierarchy are more informative. The closest class that subsumes two compared classes, called a *most informative subsumer* is the class which provides the shared information for both, and measures their similarity. In order to calculate the information content of a concept in a IS-A taxonomy, Resnik turns to an external text corpus and calculates the probability of occurrence of the class in this corpus as its relative frequency (each word in the text corpus is counted as an occurrence of each class that contains it). The information content of a class in a taxonomy is given by the negative logarithm of the probability of occurrence of the class in a text corpus as follows:

$$\text{sim}_R(a, b) = \max_{c \in S(a, b)} [-\log p(C)] \quad (7)$$

where  $p(c)$  is the probability of encountering an instance of concept  $c$ , and  $S(a, b)$  is the set of all concepts that subsume  $a$  and  $b$ . According to Resnik this approach performs better than hierarchy-based approaches, based on human similarity judgements as a benchmark. He used this similarity measure to resolve the problems of ambiguity in  
155 natural language.

### 3.3. Feature-based similarity measures

The calculation of similarity based on properties goes back to Tversky's work on Features of Similarity [32] where similarity between two objects  $O_1$  and  $O_2$  is a function of their common and distinctive features:

$$\text{sim}_T(O_1, O_2) = \frac{\alpha(\psi(O_1) \cap \psi(O_2))}{\beta(\psi(O_1) \setminus \psi(O_2)) + \gamma(\psi(O_2) \setminus \psi(O_1)) + \alpha(\psi(O_1) \cap \psi(O_2))}. \quad (8)$$

160 In the formula above  $\psi(O)$  describes all the relevant features of the object  $O$ , and  $\alpha, \beta, \gamma \in \mathbb{R}$  are constants which allow for different treatment of the various components. For  $\alpha = 1$  common features of the two objects have maximal importance. For  $\beta = \gamma$  non-directional similarity measure is obtained. Depending on the values for  $\alpha, \beta, \gamma$ , we obtain the following variations of Tversky similarity:

- 165 • Jaccard or Tanimoto similarity for  $\alpha = \beta = \gamma = 1$ ;
- Dice or Sørensen similarity for  $\alpha = 1$  and  $\beta = \gamma = 0.5$ .

Hence, in Jaccard and Dice case, the above formula becomes:

$$\text{sim}_J(O_1, O_2) = \frac{(\psi(O_1) \cap \psi(O_2))}{(\psi(O_1) \setminus \psi(O_2)) + (\psi(O_2) \setminus \psi(O_1)) + (\psi(O_1) \cap \psi(O_2))}. \quad (9)$$

$$\text{sim}_D(O_1, O_2) = \frac{2(\psi(O_1) \cap \psi(O_2))}{(\psi(O_1) \setminus \psi(O_2)) + (\psi(O_2) \setminus \psi(O_1)) + 2(\psi(O_1) \cap \psi(O_2))}. \quad (10)$$

In our setting, we will use the following notation:

- *common features of  $O_1$  and  $O_2$* :  $\text{cf}(O_1, O_2) = \psi(O_1) \cap \psi(O_2)$ ,
- 170 • *distinctive features of  $O_1$* :  $\text{df}(O_1) = \psi(O_1) \setminus \psi(O_2)$  and
- *distinctive features of  $O_2$* :  $\text{df}(O_2) = \psi(O_2) \setminus \psi(O_1)$ .

In order to calculate the above similarities for domain objects  $O_1$  and  $O_2$ , we need to calculate for each property  $p$  they have in common, how much it contributes to common features of  $O_1$  and  $O_2$ , distinctive features of  $O_1$  and distinctive features of  
175  $O_2$ , respectively. We denote these values by  $\text{cf}_p$ ,  $\text{df}_p^1$  and  $\text{df}_p^2$ .

Hence, we have to compare the property-value pairs between instances for each property they have in common. We will include in common features the cases when

the two objects have the same value for the given property  $p$ . We will include in distinctive features of each object the cases when the two objects have different values for the given property  $p$ .

We consider equal the properties defined with owl:EquivalentProperty. Repeating the above process for each property  $O_1$  and  $O_2$  have in common, we obtain all common and distinctive features of  $O_1$  and  $O_2$ :

$$CF(O_1, O_2) = \sum_{i=1}^n CF_{p_i}(O_1, O_2)$$

$$DF(O_1) = \sum_{i=1}^n DF_{p_i}^1(O_1) \quad DF(O_2) = \sum_{i=1}^n DF_{p_i}^2(O_2)$$

where  $n$  is the number of common properties defined for  $O_1$  and  $O_2$ . Then the above similarity measures become:

Jaccard similarity:

$$SIM_J(O_1, O_2) = \frac{CF(O_1, O_2)}{DF(O_1) + DF(O_2) + CF(O_1, O_2)} \quad (11)$$

Dice similarity:

$$SIM_D(O_1, O_2) = \frac{2CF(O_1, O_2)}{DF(O_1) + DF(O_2) + 2CF(O_1, O_2)} \quad (12)$$

### 3.3.1. Mathematical properties

Here we provide some basic mathematical properties of Dice similarity measure which we will address in the rest of the paper.

#### 1. Boundaries

$$\forall O_1, O_2, 0 \leq SIM_D(O_1, O_2) \leq 1.$$

#### 2. Maximal similarity

$$\text{If } O_1 \equiv O_2, \text{ then } SIM_D(O_1, O_2) = 1.$$

#### 3. Commutativity

$$\forall O_1, O_2, SIM_D(O_1, O_2) = SIM_D(O_2, O_1).$$

#### 4. Monotonicity

$$\text{If } CF(O_1, O_2) \leq CF(O_1, O_3) \text{ and } DF(O_1) = DF(O_2), \text{ then } SIM_D(O_1, O_2) \leq SIM_D(O_1, O_3).$$

$$\text{If } CF(O_1, O_2) \leq CF(O_1, O_3) \text{ and } DF(O_2) = DF(O_3), \text{ then } SIM_D(O_1, O_2) \leq SIM_D(O_2, O_3).$$

195 3.4. *Advantages and disadvantages of various similarity measures*

Since they only depend on the underlying hierarchy of the domain ontology, the hierarchy-based similarity measures are fairly simple and require a low computational cost. The known problem with hierarchy-based similarity measures is that all the edges in the hierarchy are considered to be of the same length, so many similarity values are not correct. The accuracy of these measures have been surpassed by more complex approaches which exploit additional semantic information.

The problem with Resnik’s similarity measure is the excessive information content value of many polysemous words (i.e. word senses not taken into account) and multi-worded synsets. Also, the information content values are not calculated for individual words but for synsets, hence the synsets containing commonly occurring ambiguous words would have excessive information content values. To deal with the problem of excessive information content value of many polysemous words, Resnik proposes *weighted word similarity* which takes into account all senses of the words being compared.

210 The main problem with information content-based similarity measures is their dependence on external corpora for the calculation of term frequencies. This requires disambiguation and annotation of terms in the corpus, very often done manually, hence affecting the applicability of this approach to large corpora. Also, with the change of corpora or the ontology, the term frequencies have to be recalculated. One step towards mitigating this problem was the introduction of intrinsic computation of information content [31] as we will see in Section 6. The methods based on intrinsic information content outperform corpora-relying approaches.

In this work, we particularly focus on feature-based and hierarchy-based similarity measures since they do not require external knowledge sources for their application, rather they rely solely on the domain ontology. Feature-based similarity measures evaluate both common and distinctive features of compared objects, hence exploiting more semantic information than hierarchy-based approaches. But this information is not always available and thus the applicability and accuracy of these measures is hindered. Feature-based similarity measures can also be applied in cross-ontology settings.

#### 4. Converting hierarchy-based similarity measures into feature-based similarity measures

In this section we would look more closely into the relationship between hierarchy-based similarity measures and feature-based similarity measures. Let us start from Wu and Palmer's similarity measure [34].

As we have seen, the formula for Wu and Palmer's measure can be written as

$$\text{sim}_{WP}(O_1, O_2) = \frac{2\text{DIST}(O_3, R)}{\text{DIST}(O_1, O_2) + 2\text{DIST}(O_3, R)}. \quad (13)$$

where  $O_1$  and  $O_2$  are the compared instances,  $O_3$  is their common subsumer and  $R$  is the root of the hierarchy. If we consider the distance between instances  $O_1$  and  $O_2$  as their distinctive feature and the distance from instance  $O_3$  to the root as the common feature of  $O_1$  and  $O_2$  we would obtain the formula:

$$\text{sim}_D(O_1, O_2) = \frac{2\text{CF}(O_1, O_2)}{\text{DF}(O_1) + \text{DF}(O_2) + 2\text{CF}(O_1, O_2)} \quad (14)$$

As we can see, this is exactly the Dice formula. Thus, the Dice similarity measure corresponds to Wu and Palmer's similarity measure.

##### 4.1. Sigmoid similarity

In this section we will try to find the hierarchy-based similarity measure which corresponds to Li's similarity measure [18]. Since the similarity measure increases with the increasing number of common features, common features can be taken as an argument of the sigmoid function. Furthermore, the similarity values should decrease with the increasing number of distinctive features, hence the distinctive features should be an argument of the negative sigmoid function translated by 1. Thus we obtained the following function:

$$\begin{aligned} \text{sim}_S(O_1, O_2) &= \frac{e^{\text{CF}(O_1, O_2)} - 1}{e^{\text{CF}(O_1, O_2)} + 1} \left( 1 - \frac{e^{\text{DF}(O_1) + \text{DF}(O_2)} - 1}{e^{\text{DF}(O_1) + \text{DF}(O_2)} + 1} \right) \\ &= \frac{2(e^{\text{CF}(O_1, O_2)} - 1)}{(e^{\text{CF}(O_1, O_2)} + 1)(e^{\text{DF}(O_1) + \text{DF}(O_2)} + 1)} \end{aligned} \quad (15)$$

This result is similar to just taking the distinctive features as an argument to inverse exponential function since these two functions have similar graphs and behaviours for

arguments greater than 0. But the exponential in the denominator increases very fast, so the similarity values were getting extremely small very quickly. Hence we decided to leave just the distinctive features in the denominator. Adding 1 prevents the case of the division with zero when there are no distinctive features among the compared objects. Also, we need to divide by 2 so that the final result is in the interval  $[0, 1]$ . Hence, the final **Sigmoid similarity** has the following formula:

$$\text{sim}_S(O_1, O_2) = \frac{e^{\text{cf}(O_1, O_2)} - 1}{(e^{\text{cf}(O_1, O_2)} + 1)(\text{df}(O_1) + \text{df}(O_2) + 1)} \quad (16)$$

#### 4.1.1. Mathematical properties

Here we report some basic mathematical properties of Sigmoid similarity measure.

##### 235 1. Boundaries

$$\forall O_1, O_2, 0 \leq \text{sim}_S(O_1, O_2) \leq 1.$$

##### 2. Maximal similarity

If  $O_1 \equiv O_2$ , then  $\text{sim}_S(O_1, O_2) = 1$ , since  $\text{df}(O_1) = 0$  and  $\text{df}(O_2) = 0$  and the function  $S(x) = \frac{e^x - 1}{e^x + 1}$  tends to 1 when  $x$  tends to infinity.

##### 240 3. Commutativity

$$\forall O_1, O_2, \text{sim}_S(O_1, O_2) = \text{sim}_S(O_2, O_1).$$

##### 4. Monotonicity

If  $\text{cf}(O_1, O_2) \leq \text{cf}(O_1, O_3)$  and  $\text{df}(O_1) = \text{df}(O_2)$ , then  $\text{sim}_S(O_1, O_2) \leq \text{sim}_S(O_1, O_3)$ .

If  $\text{cf}(O_1, O_2) \leq \text{cf}(O_1, O_3)$  and  $\text{df}(O_2) = \text{df}(O_3)$ , then  $\text{sim}_S(O_1, O_2) \leq \text{sim}_S(O_2, O_3)$ .

245 Hence, the values of Sigmoid similarity measure belong to  $[0, 1]$  and the maximal value is obtained when the compared objects do not have any distinctive features. Commutativity and monotonicity are straightforward.

Next, we will see how we tried to include the hierarchical information into these measures.

250 The basic question we wanted to answer with these experiments was how much the actual hierarchical information contributes to the similarity of two objects and if this information can be simulated by properties. Basically, the hierarchical information could be either integrated into the measures by considering the `rdf:type` property (basic measures) or it could be integrated into the measures by excluding the `rdf:type` prop-

erty and including the hierarchical information in some different way. We also tried to see how including both would affect the performance. We decided to distinguish the following two variations for Dice and Sigmoid measures:

V1: the measures *without considering* the property `rdf:type` but including the hierarchical information in the feature-based similarity formula. In this case, since the greater distance between two objects means that they are less similar, we decided that the distance between objects counts as their distinctive feature. In the following formulae  $\text{DIST}(O_1, O_2)$  is the number of edges along the path connecting  $O_1$  and  $O_2$  and  $\text{MAX}$  is the maximum depth of the class hierarchy.

$$\text{SIM}_{Dnth}(O_1, O_2) = \frac{2\text{CF}(O_1, O_2)}{\text{DF}(O_1) + \text{DF}(O_2) + 2\text{CF}(O_1, O_2) + \frac{\text{DIST}(O_1, O_2)}{2\text{MAX}}} \quad (17)$$

$$\text{SIM}_{Snth}(O_1, O_2) = \frac{2(e^{\text{CF}(O_1, O_2)} - 1)}{(e^{\text{CF}(O_1, O_2)} + 1)(\text{DF}(O_1) + \text{DF}(O_2) + 1 + \frac{\text{DIST}(O_1, O_2)}{2\text{MAX}})} \quad (18)$$

V2: the original measures *considering* the property `rdf:type` *and* including the hierarchical information in the feature-based similarity formula. This approach counts the hierarchical information twice in a way but in two subtle ways. Including the property `rdf:type` takes into account all the objects which are of the same recipe type, whereas including the hierarchical information accounts for the distance between the compared objects. These measures ( $\text{SIM}_{Dh}$  and  $\text{SIM}_{Sh}$ ) showed slightly better performance results with respect to the original measures, as we will see in Section 5. But, in our opinion, the improvement in performance does not justify the increased complexity and execution times of the proposed variants.

Let us illustrate our ideas with some simple examples. In the recipe domain, all the recipes could be instances of the class `Recipe` or there could exist an underlying hierarchy of recipe types and each recipe could be an instance of its corresponding recipe type. In our case, instead of having all the recipes be instances of `DishType`, we made the recipes instances of various dish types, such as `BreadDish`, `CakeDish`, `PastaDish` etc. This choice has the following consequences:

- instead of having the same values for the property `rdf:type` for all the dishes, we can distinguish them according to various values for the property `rdf:type`;

- in case we want to take the hierarchical information into account, we can calculate the distance between various dishes, rather than assume that they all have the same similarity, since they all have the same parent. Since we deal with the instances in the ontology, we decided to consider them “descendants” of their classes, otherwise the instances of one class would all be equal.

280

## 5. Evaluation

The most commonly used datasets to test similarity measures are the ones proposed by Rubenstein and Goodenough in [29] and Miller and Charles in [20]. Rubenstein and Goodenough’s experiment dates back to 1965. They asked 51 native English speakers to assess the similarity of 65 English noun pairs on a scale from 0 (semantically un-  
285 related) to 4 (highly related). Miller and Charles’ experiment in 1991 considered a subset of 30 noun pairs and their similarity was reassessed by 38 undergraduate students. The correlation w.r.t Rubenstein and Goodenough results was 0.97. Resnik [27] repeated the same experiment in 1995 with 10 subjects. The correlation w.r.t. Miller  
290 and Charles results was 0.96. Finally, Pirró [23] repeated the experiments in 2009 with 101 participants, both English and non-English native speakers. His average correlation w.r.t. Rubenstein and Goodenough was 0.97, and 0.95 w.r.t. Miller and Charles. We can see that similarity judgements by various groups of people over a long period of time remain stable.

295 All the experiments cited above [29, 20, 27, 23] were dealing with common English nouns and the correlation with these results was mostly used to test similarity measures on WordNet [12]. But our focus is different. We wanted to experiment with the similarity measures on specific domain ontologies, which represents more complex entities. We needed data representation where features of domain objects are explicitly  
300 provided, which is not the case with WordNet.

Our experiment was conducted with the goal of evaluating the feature-based similarity of instances and its comparison with hierarchy-based approaches. In our first experiment we evaluated our approach in the domain of recipes using the slightly mod-

ified Wikitaable dataset<sup>4</sup> used in [7]. In our second experiment we evaluated our  
305 approach in the drinks domain using an ontology developed previously by our research  
team. We assumed that both datasets represent information known by a wide range of  
people, without the need to be an expert *in order* to assess the similarity of the pro-  
posed domain items. The datasets used in our experiments are available here:  
<http://www.di.unito.it/lombardi/SimilarityTest/>

### 310 5.1. Hypotheses

We wanted to verify that:

- H1: feature-based similarity measures perform better than hierarchy-based approaches;
- H2: Sigmoid measure obtained by converting Li’s hierarchy-based measure into feature-  
based measure shows better performance than Dice feature-based measure;
- 315 H3: hierarchical information is encoded better with features than with underlying  
hierarchy;
- H4: combining the hierarchy and feature-based approach beyond linear combination  
further improves the feature-based similarity measures.

### 5.2. Subjects

320 A total of 137 people (60 female and 77 male, average age 30) took part in the first  
test and 147 (65 female and 82 male, average age 32) took part in the second test.

The subjects were selected among authors’ colleagues and among the second and  
third year undergraduate students at the Faculty of Philosophy at the University of  
Torino, Italy. The participants were recruited according to an availability sampling  
325 strategy.<sup>5</sup> All the participants were native Italian speakers. Following other similar  
studies in the literature [29, 20] we only focused on native speakers, rather than on  
their age. A different population sample could have led to different results, but the

---

<sup>4</sup><http://wikitaable.loria.fr/rdf/>

<sup>5</sup>Although a more suitable way to obtain a representative sample is random sampling, this strategy is  
time consuming and not financially justifiable. Hence, much research is based on samples obtained through  
non-random selection, such as the availability sampling, i.e. a sampling of convenience, based on subjects  
available to the researcher, often used when the population source is not completely defined.

choice of the domains was based on our decision to maximise the understanding of the domain items by all the sample users. Hence, in our opinion, a different population sample would not have affected the results significantly.

### 5.3. Materials

We designed two experiments to test our hypotheses.

In the first experiment, we designed a web questionnaire with 25 pairs of recipes, chosen from Wikitaable dataset, covering a range of recipes *which we expected to be judged as very similar* to not similar at all. The original recipes from the dataset were translated to Italian. The original dataset contains 1666 recipes. The properties defined for the recipes are the following: `rdf:type`, `can.be.eaten.as`, `has.ingredient`, `suitable.for.diet`, `not.suitable.for.diet` and `has.origin`. This dataset provided us with a good setting to test our approach. We only made the following slight modifications: in the original ontology all the recipes were instances of `Recipe` class, whereas we needed to use the hierarchical structure of the ontology to test hierarchy-based similarity measures, as well as incorporate the hierarchical information into our measures, hence we made the recipes instances of various `Dish_Type` classes. In the original ontology `rdf:type` is a property, whereas in our case, we *used it once* as a property and once as an underlying hierarchical information. 1 shows the basic Wikitaable taxonomy of recipes, but only including the top categories and the ones from which we used the instances to test our approach. The properties are omitted for clarity.

The main dish type classes are: `RollDish`, `CrepeDish`, `SoupAndStuffDish`, `BakedGoodDish`, `BeverageDish`, `PancakeDish`, `MousseDish`, `SweetDish`, `SaladDish`, `SaltedDish`, `SauceDish`, `WaffleDish`, `PreservedDish`, `SpecialDietDish`. The recipes we used in our evaluation did not belong to all recipe groups, since the complexity of the test would have been too high and we would have obtained random answers from the users.

In the second experiment, we again used a web questionnaire, this time containing 30 pairs of drinks chosen from the ontology describing drinks. The original ontology has 148 classes, with the main drink classes being: `Water`, `AlcoholicBeverage`, `DrinkInACup`, `PlantOriginDrink` and `SoftDrink`. The properties defined for the

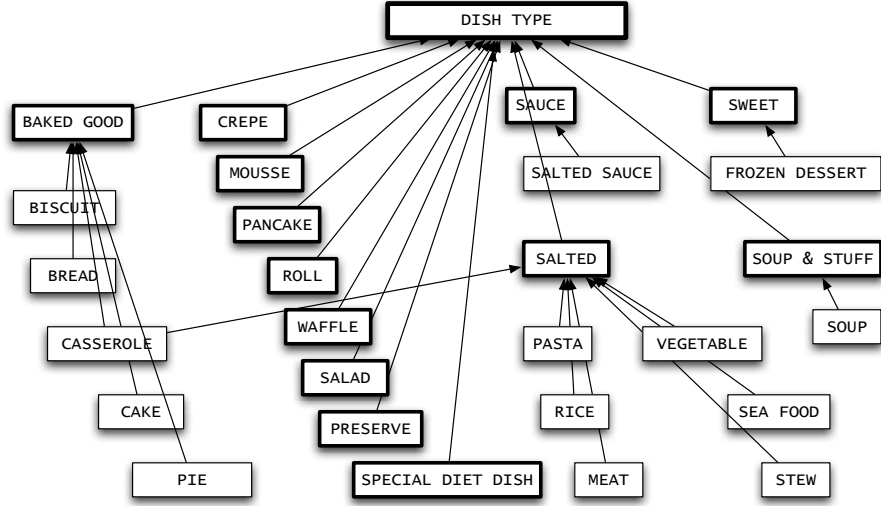

Figure 1: Recipe taxonomy

drinks are the following: `has_alcoholic_content`, `has_caloric_content`, `has_ingredient`, `is_sparkling`, `is_suitable_for` and `rdf:type`. Figure 2 shows the basic taxonomy of drinks, again only including the main categories and omitting the properties.

In each experiment the participants were asked to assess the similarity of these 25 pairs (respectively 30 pairs) by anonymously assigning them a similarity value on the scale from 1 to 10 (1 meaning not similar at all, 10 meaning very similar). The ordering of pairs was random. The users' similarity values were then turned into the values from the  $[0, 1]$  interval to make them match the similarity values produced by various algorithms.

In each experiment, the participant group P was divided into two groups: P1 was used as a reference group and P2 was used as a control group to measure the correlation of judgements among human subjects, as in [26]. We experimented with different partitions of P1 and P2 and obtained similar results.

In this paper we considered the following feature-based similarity measures:

1. Dice similarity  $sim_D$ ;

Figure 2: Drinks taxonomy

## 2. Sigmoid similarity $\text{sim}_S$ ;

375 For the comparison, we considered the following hierarchy-based similarity measures:

1. Wu and Palmer's similarity  $\text{sim}_{WP}$ ;
2. Li's similarity  $\text{sim}_L$ .
3. Leacock and Chodorow's similarity  $\text{sim}_{LC}$ ;

380 For each of the feature-based measures, we considered the following variants:

- V1. the measure *without* the `rdf:type` property but combined with underlying hierarchy (measures  $\text{sim}_{Dnth}$  and  $\text{sim}_{Snth}$ );
- V2. the measure *with* the `rdf:type` property combined with underlying hierarchy (measures  $\text{sim}_{Dh}$  and  $\text{sim}_{Sh}$ ).

## 385 5.4. Measures

We used the Spearman rank correlation coefficient  $\rho$  to measure the accuracy of similarity judgement.

The Spearman rank correlation coefficient measures statistical dependence between two ranked variables. It actually describes the relationship between two variables us-

MEASURE	execution time (in seconds)	MEASURE	execution time (in seconds)
Wu and Palmer	0.225	Wu and Palmer	0.047
Li et al.	0.267	Li et al.	0.064
Leacock and Chodorow	0.413	Leacock and Chodorow	0.061
Dice	0.028	Dice	0.018
Sigmoid	0.007	Sigmoid	0.003

Table 1: Execution time for the Recipes ontology

Table 2: Execution time for the Drinks ontology

ing a monotonic function. It is equal to the Pearson correlation between the ranked variables. For a sample of size  $n$ , the two sets of values  $X = \{x_1, \dots, x_n\}$  and  $Y = \{y_1, \dots, y_n\}$  are converted to ranks  $\{r(x_1), \dots, r(x_n)\}$  and  $\{r(y_1), \dots, r(y_n)\}$  and then the Pearson coefficient is calculated as follows:

$$\rho = \frac{\sum_{i=1}^n (r(x_i) - \overline{r(x)})(r(y_i) - \overline{r(y)})}{\sqrt{\sum_{i=1}^n (r(x_i) - \overline{r(x)})^2 (r(y_i) - \overline{r(y)})^2}}$$

where  $\overline{r(x)}$  and  $\overline{r(y)}$  are the sample means of the two sets of ranked values. The value of Spearman coefficient ranges from +1 (indicating a strong similar rank) to -1 (indicating a strong dissimilar rank). Value 0 means there is no correlation.

### 5.5. Implementation and performance

The test software to compare the different measures has been developed in Java, using the Apache Jena library to extract data from the ontology. The test has been performed on a MacBook Pro with a 2.66 GHz Intel Core i7 processor and 8 GB 1067 MHz DDR3 RAM. Tables 1 and 2 show the execution times for the different measures obtained in the Recipes and the Drinks experiments, respectively. In both cases, feature-based approaches significantly outperform hierarchy-based ones. A possible explanation for this could be that hierarchy-based approaches need to traverse the hierarchy to calculate the distance between two nodes, while feature-based ones simply need to extract properties and their values for the two nodes.

## 5.6. Results and discussion

For the first experiment (Recipes) Table 3 reports the Spearman rank correlation between the reference group P1 and control group P2, as well as the Spearman rank correlation between the participant group P and the hierarchy-based approaches. Tables 4, 5, 6 report the Spearman rank correlation between each of the above measures and the participant group P for the base case and for the 2 variations introduced in Section 4. The best performing measure in each group is reported in bold.

For the second experiment (Drinks) Table 7 reports the Spearman rank correlation between the reference group P1 and control group P2, as well as the Spearman rank correlation between the participant group P and the hierarchy-based approaches. Tables 8, 9, 10 report the Spearman rank correlation between each of the above measures and the participant group P for the base case and for the 2 variations introduced in Section 4.

### 5.6.1. Participants group and the hierarchy-based approaches

The correlation for both experiments with the human subjects, i.e. the comparison of the two groups of participants (row P1-P2), is 0.945 (respectively 0.977) and similar

MEASURE	$\rho$
P1 - P2	<b>0.977</b>
Wu and Palmer	0.891
Li et al.	0.781
Leacock and Chodorow	0.680

Table 7: Drinks - P1 - P2 and edge-based

MEASURE	$\rho$
Dice no t. + h.	0.888
Sigmoid no t. + h.	<b>0.900</b>

Table 9: Drinks - base case without `rdf:type` with hierarchy

MEASURE	$\rho$
Dice	0.876
Sigmoid	<b>0.900</b>

MEASURE	$\rho$
Dice + h.	0.861
Sigmoid + h.	<b>0.900</b>

Table 10: Drinks - base case with hierarchy

to the one reported in [26]. From this good correlation we can conclude that the participants' responses were coherent among themselves in both experiments and that we can trust the human ratings.

Furthermore, w.r.t. the correlation of participants group with hierarchy-based approaches we can see that in the first experiment (Recipes) with hierarchy-based approaches we obtained similar results for all three measures (the best one being Wu and Palmer's measure) and they all have a relatively weak positive correlation with the human judgement. In the second experiment (Drinks) the performance is better (the best one again being Wu and Palmer's measure).

This can be explained with the fact that the underlying hierarchy in the ontology of drinks is **better designed to mirror** human categorisation than the ontology of recipes (which was indeed flat at the beginning and **to which** we performed only minimal changes to obtain the main categories of recipes). But it also shows how dependant the measure is on the ontology design.

### 5.6.2. Base case for feature-based similarities and the comparison with hierarchy-based approaches

Tables 4 and 8 show the results for the base case for Dice similarity measure  $\text{sim}_D$  and Sigmoid similarity measure  $\text{sim}_S$  (proposed in Section 4) in both experiments, where the property `rdf:type` was included in the calculations and no further hierarchical information was taken into account. From these two tables we can see that in each experiment Sigmoid measure  $\text{sim}_S$  performs consistently better than Dice measure. This confirms our hypothesis H2.

Furthermore, in the first experiment (Recipes) both feature-based measures in Table 4 perform better than the hierarchy-based measures from Table 3. In the second experiment (Drinks) both feature-based measures in Table 8 perform better than Leacock and Chodorow’s measure and Li et al.’s measure and  $\text{sim}_S$  performs better even than Wu and Palmer’s measure.

This shows that we can obtain better similarity results by considering properties for instances in an ontology, rather than hierarchy underlying the ontology. This confirms our hypothesis H1 that the feature-based similarity shows better performance than hierarchy-based approaches. Often, other proposed methods in the literature do not surpass Li’s measure, even when they surpass other hierarchy-based methods. On both of our datasets, the best performing hierarchy-based similarity measure is Wu and Palmer’s measure. But all feature-based measures in the first experiment and some of the measures in the second experiment surpass Wu and Palmer’s measure and all surpass the other two hierarchy-based measures. This means that properties play a more important role than the underlying hierarchy when describing ontological instances and their mutual similarity.

### 5.6.3. Substituting `rdf:type` with hierarchical information

Tables 5 and 9 show the results for the 2 similarity measures in both experiments, where the property `rdf:type` was excluded from the calculations and where we tried to simulate this information with hierarchical information. We tried to incorporate the hierarchy-based similarity by including the normalised distance between concepts (calculated as  $\frac{\text{DIST}}{2_{\max}}$ ) in the feature-based formulae as a part of distinctive features.

In the first experiment (Recipes), better results are obtained by the simple base measure, hence by using `rdf:type` instead of hierarchical information (Table 4), whereas in the second experiment (Drinks) results are comparable when using the base case (Table 8) or when using hierarchical information without `rdf:type` (Table 9).

465 This confirms our hypothesis H3 that hierarchical information is encoded better with features than with underlying hierarchy.

#### 5.6.4. Including both, `rdf:type` and hierarchical information

Finally, we wanted to combine hierarchical information with features to see if the similarity values could be improved. A simple linear combination of feature-based  
470 similarity and hierarchy-based similarity would not yield better results, since hierarchy-based similarity would just decrease the correlation. Hence, we included the hierarchy information as in the above. The results are reported in Table 6 and Table 10.

In the first experiment (Recipes) we obtained small improvements for the basic measures, whereas in the second experiment (Drinks) the Sigmoid measure  $\text{sim}_{Sh}$  shows  
475 equal performance and no improvement appears for Dice measure  $\text{sim}_D$ .

Hence, w.r.t. the hypothesis H4 we can conclude that combining the hierarchy and feature-based approach beyond linear combination provides good correlation with human judgement but sometimes better results are obtained without incorporating the underlying hierarchy. This means that combining the hierarchy and feature-based ap-  
480 proaches does not justify the increased complexity and execution time of the obtained measures.

#### 5.6.5. Concluding considerations

We can see that in both domains, the consistently best performing measure is the Sigmoid similarity  $\text{sim}_S$ . In the domain of Recipes  $\text{sim}_S$  brings the improvement of  
485 4.9% w.r.t.  $\text{sim}_D$  for the base case, whereas in the domain of Drinks we obtained the improvement of 2.74%.

In both cases very small additional improvement is obtained by considering the underlying hierarchy together with `rdf:type`. Hence, there is little benefit in adding this additional information to the basic similarity measures.

490 Also, in both cases, there is an improvement w.r.t. the best hierarchy-based measure (Wu and Palmer): 13.5% in the case of Recipes and 1.01% in the case of Drinks. This again shows how dependant the hierarchy-based similarity measures are on the design of the underlying conceptual hierarchy.

We can see that even with relatively small number of properties defined for the  
495 concepts in the ontology, the feature-based similarity outperforms hierarchy-based approaches. Of course, the number of defined properties plays an important role in semantic similarity calculation.

The dataset used also plays an important role in the similarity calculations. To the best of our knowledge, the datasets used in this work include significantly higher  
500 number of participants than many works in the field. Usually, the similarity measures are tested on WordNet [12], but we are providing the community with yet another rich dataset to experiment with.

We summarise here our main findings as the responses to our hypotheses.

H1: Dice feature-based similarity measure performs better than hierarchy-based ap-  
505 proaches.

H2: Sigmoid similarity measure  $\text{sim}_S$  improves the performance of Dice similarity measure  $\text{sim}_D$  by 4.9% in the domain of recipes and of 2.74% in the domain of drinks.

H3: We cannot conclude if the hierarchical information is encoded better with fea-  
510 tures than with underlying hierarchy.

H4: Combining the hierarchy and feature-based approach beyond linear combination further improves Dice similarity and Sigmoid similarity measures but to a very small degree, hence it is questionable if these modifications are worth the higher complexity and execution time.

## 515 5.7. Comparison with the performance on WordNet

Since most of the similarity measures in the literature have been tested on WordNet, we include here the comparison of our results with the corresponding results provided in Sánchez et al. [30]. We include only the results for Miller and Charles' dataset [20], since the ones for Rubenstein and Goodenough's dataset [29] are not always avail-

MEASURE	WordNet	Wikitaable	Drinks
Leacock and Chodorow	0.74	0.603	0.754
Wu and Palmer	0.74	0.630	0.882
Li et al.	0.82	0.627	0.857
Tversky/Dice	0.73	0.746	0.872
Dice + hierarchy (no type)	N/A	0.688	0.903
Dice + hierarchy (with type)	N/A	0.748	0.874
Sigmoid	N/A	0.758	0.832
Sigmoid + hierarchy (no type)	N/A	0.714	0.856
Sigmoid + hierarchy (with type)	N/A	0.761	0.819

Table 11: Comparison with WordNet regarding correlation

520 able (see Table 11). To this aim, we calculated the Pearson correlation coefficient for our measures, so that we can compare them with the rest of the measures which used correlation.

We can see that the hierarchy-based measures (Leacock and Chodorow, Wu and Palmer and Li et al.) perform better on WordNet than on Wikitaable dataset but the  
525 performance is better on the Drinks dataset. This is due to the hierarchical structure of Wikitaable and Drinks datasets. The hierarchy in Wikitaable is rather shallow, hence the information obtained from the underlying conceptual hierarchy is not so rich. On the other hand, the Drinks ontology has a deeper underlying hierarchy and provides more precise information. We can see that Tversky’s/Dice similarity measure performs  
530 slightly better on Wikitaable dataset and decisively better on Drinks dataset, since there are more properties defined for the concepts. We include also the results for Dice + hierarchy (with and without type), Sigmoid and Sigmoid + hierarchy (with and without type).

## 6. Related work

535 In this section we give a brief summary of related work dealing with feature-based similarity in different domains and with different purpose . These approaches calculate

feature-based similarity in different ways, starting from Tversky similarity measure but taking into account different aspects w.r.t. us (antecedent classes, descendant classes etc., whereas we compare property-value pairs). We include these works here to have  
540 a more complete picture of feature-based similarity measures. We did not test these measures since the scope of our work was to evaluate the performance of Tversky (more precisely Dice) similarity measure and Sigmoid similarity measure (as an improvement of Dice similarity) calculating them from property-value pairs for compared objects. Also, some of these measures are not applicable in our context. For example, we  
545 cannot calculate the number of descendant classes since we deal with instances in the ontology.

An interesting approach to feature-based similarity calculation is given by Pirrò [23] and Pirrò and Euzenat [24]. Both works translate the feature-based model into information content (IC) model, with a slightly different formulation of Tversky's formula  
550 where Tversky's function describing the saliency of the features is substituted by the information content of the concepts. In [23] *Intrinsic Information Content* iIC, introduced in [31], is used taking into account the number of subconcepts of a concept and a total number of concepts in a domain. In [24] *Extended Information Content* EIC is used instead of iIC where iIC is combined with EIC as a average iIC for all the  
555 concepts connected to a certain concept with different relations. Both approaches use the underlying ontology structure directly, where all the defined semantic relations are used, rather than relying on an external corpus. Their new similarity measure called *FaITH* is based on this novel framework. Also, this new IC calculation can be used to rewrite the existing similarity measures in order to calculate relatedness, in addition to  
560 similarity.

Sánchez et al. [30] also introduce a new feature-based approach for calculating ontology-based semantic similarity based on taxonomical features. They evaluate the semantic distance between concepts by considering as features the set of concepts that subsume each of them. Practically, the degree of disjunction between their feature sets  
565 (non-common subsumers) model the distance between concepts, whereas the degree of overlap (common subsumers) models their similarity. The problem with this approach is that if the input ontology is not deep enough or built with enough taxonomical de-

tails or it does not consider multiple inheritance, the knowledge needed for similarity calculation might be scarce. The authors also provide a detailed survey of most of the ontology-based approaches and compare their performance on WordNet 2.0. From this analysis they draw important conclusions about the advantages and limitations of these approaches and give directions on their possible usage. A slightly different version of this measure was used by Batet, Sánchez and Valls [2] on SNOMED CT ontology to evaluate the similarity of medical terms.

Rodríguez and Egenhofer [28] and Petrakis et al. [21] propose similar measures for calculating semantic similarity based on matching of their synonym sets, semantic neighbourhoods (semantic relations among classes) and features which are classified into parts, functions and attributes. This enables separate treatment of these particular class descriptions and introduction of specific weights which would reflect their importance in different contexts. In [28] these similarities are calculated using Tversky's formula, where parameters in the denominator are calculated taking into account the depth of the hierarchies of different ontologies. Synonym sets and semantic neighbourhoods are useful when detecting equivalent or most similar classes across ontologies. Features are useful when detecting similar but not equivalent classes. Petrakis et al. [21] eliminate the need for the parameters in the denominator in Tversky's formula, hence they do not rely on the depth of the corresponding ontologies. This leads to matching based only on common words for synset similarity calculation. Also, set similarities are calculated per relationship type. Finally, their similarity does not have weights for different similarity components. The novelty of their work is the application of this and various other similarity measures to MeSH ontology (Medical Subject Headings). Both methods can be used for cross-ontology similarity calculation.

An interesting approach is investigated by Coletti et al. [6], who propose to consider weights which can be interpreted as the significance (positive or negative) of groups of attributes. They take into account the significance values of different features and their mutual interactions or degree of contribution to similarity.

In recent years, novel paradigms have been proposed to compute semantic similarity based on different ontologies.

An important work on feature-based similarity regarding ontological concepts is

described by Zadeh and Reformat [36]. They start from Tversky’s assumption that  
600 similarity is determined by common and distinctive features of the compared objects  
and consider the relations between concepts as their features. They linearly combine  
two similarities. The first similarity is obtained from direct connections between two  
objects, as well as common features shared between both concepts (in this case the  
similarity between relations is calculated using Wu and Palmer’s measure [34]). The  
605 second similarity is based on distinctive features of each object. Their approach can  
be used to calculate similarity at the class level, as well as the similarity of instances.  
Furthermore, it is possible to take into account only specific relations which leads to  
context-aware similarity. The problem is that the proposed method is assessed only on  
4 pairs of concepts

610 Yang et al. [35] propose a new similarity measure combining both super concepts  
and their common specificity feature. The common specificity feature considers the  
depth of the Least Common Subsumer (LCS) of two concepts and the depth of the  
ontology to obtain a more accurate similarity between concepts. Multiple inheritance  
is taken into account by all superconcepts of the evaluated concepts. The proposed  
615 measure has been evaluated using two datasets of biomedical term pairs scored for  
similarity by human experts and exploiting the standard medical ontology SNOMED  
CT as the input ontology. They compare the correlation obtained by their measure with  
human scores against other measures.

A semantic similarity measure for OWL objects introduced by Hau, Lee and Dar-  
620 lington [14] is based on Lin’s information theoretic similarity measure [19]. They  
compare semantic description of two services and define their semantic similarity as  
a ratio between the shared and total information of the two objects. The semantic  
description of an object is defined using its description sets which contain all the state-  
ments (triples) describing the given object and their information content is based on  
625 their “inferencibility”, i.e. the number of new RDF statements that can be generated  
by applying a certain set of inference rules to the predicate. They use their measure to  
determine the similarity of semantic services annotated with OWL ontologies.

Lastra-Díaz et al. [16] advance a proposal for an efficient and scalable represen-  
tation model for taxonomies (called PosetHERep) together with a new semantic mea-

630 sures library based on this model and implemented in Java (called Half-Edge Semantic Measures Library or HESML). Most ontology-based semantic similarity measures are implemented, as well as Information Content (IC) models.

Similarity can find many applications in Recommender Systems. Di Noia et al. [10] developed a content-based movie recommender system based on Linked Open Data 635 (LOD) in which they adapt a vector space model (VSM) approach to compute similarities between RDF resources. Their assumption is that two movies are similar if they have features in common. The whole RDF graph is represented as a 3-dimensional matrix where each slice refers to one property in the ontology and for each property the similarity between two movies is calculated using their cosine similarity.

640 Piao and Breslin [22] start from the basic concept of Linked Data Semantic Distance (LSDS) for calculating the distance between resources and extend it in various directions to develop various semantic distance measures: by including the number of connected resources via a link, by employing different normalization strategies and by using a statistical approach for calculating the semantic distance between two re- 645 sources. The proposed measures were evaluated in the context of a LOD-based recommender system which provides the top-N recommendations.

Another area of application of similarity measures is information retrieval. For example, Uma Devi and Meera Gandhi [9] propose a novel semantic similarity measure based on a domain ontology, that brings out a more accurate relationship between the 650 two words for the retrieval of resources in a more meaningful and accurate way. They start from a Bag of Words and extend it by referring to an ontology in order to include the terms that are related to the original ones. Then they compute Cosine Similarity among the extended concepts and calculate the mean of the similarity values computed in all the iterations. The performance analysis in terms of Precision and Recall for 655 traditional search and semantic similarity search is high compared to the traditional search.

Similarity among concepts can be also automatically learned. *Similarity learning* is an area of supervised machine learning, closely related to regression and classification, where the goal is to learn from examples a similarity function that measures how 660 similar or related two objects are. Similarity learning is used in information retrieval

to rank items, in face identification and in recommender systems. Moreover, many machine learning approaches rely on some similarity metric. This includes unsupervised learning such as clustering, which groups together close or similar objects, or supervised approaches like K-nearest neighbour algorithm. Metric learning has been  
665 proposed as a preprocessing step for many of these approaches. Automatic learning of similarity among concepts in an ontology is used especially for ontology mapping (also known as ontology alignment, or ontology matching) [11], the process of determining correspondence between ontology concepts. This is necessary for integrating heterogeneous databases, developed independently with their own data vocabulary or different  
670 domain ontologies. There are several works which have exploited machine learning techniques towards ontology alignment. Ichisse [15] organised the ontology mapping problem into a standard machine learning framework, exploiting multiple concept similarity measures (i.e, synset-based, Wu and Palmer, description-based, Lin). In [8] David proposes a multi-strategy learning to obtain similar instances of hierarchies to  
675 extract similar concepts using Naïve Bayes (NB) technique. In [1], following a parameter optimisation process on SVM, DT and neural networks (NN) classifiers, an initial alignment was carried out. Then the user’s feedback was used to improve the overall performance. All these works considered concepts belonging to different ontologies while we concentrated on concepts in a same ontology.

## 680 7. Conclusions and future work

In this work we present *Sigmoid feature-based similarity measure* based on properties defined in an ontology. Sigmoid similarity measure is an improvement of Dice feature-based similarity measure and it corresponds to Li’s hierarchy-based similarity measure.

685 We evaluated Sigmoid and Dice measures on a slightly modified Wikitaable dataset in the domain of recipes and on a Drinks ontology designed by our researchers previously. Our first evaluation included 137 subjects and 25 pairs of concepts and our second evaluation included 147 subjects and 30 pairs of concepts. This is a significant number of real evaluators compared with other evaluations in the literature. In

690 the domain of Recipes Sigmoid similarity brings the improvement of 4.9% w.r.t. Dice  
similarity, whereas in the domain of Drinks we obtained the improvement of 2.74%.  
These values can be thought of as good results for similarity measures field.

We also evaluated 3 hierarchy-based measures (Wu and Palmer, Leacock and Chodorow  
and Li) on the same datasets. Our conclusion is that feature-based measures perform  
695 better than the hierarchy-based approaches.

We further proposed two variations of Dice and Sigmoid measures, to see how  
much the underlying hierarchical information contributes to accurate similarity mea-  
surement. We came to the conclusion that the underlying hierarchical information does  
provide some additional information when calculating similarity. However, the im-  
700 proved performance is very small, so it might not be worth adding the complexity to  
the similarity calculation.

In terms of future work, it would be interesting to see how the similarity measures  
would perform in the presence of more properties or on a different dataset. MeSH  
and SNOWMED are some possible candidate datasets, although in these cases expert  
705 opinion would be needed. Also, it would be interesting to add hierarchical structure  
among property values. For example, in the present approach we consider Fusilli  
and Spaghetti two different domain items (hence, two different property values). But  
Fusilli and Spaghetti are both descendants of Pasta so they could be considered  
as “almost” the same values for properties.

710 Moreover, in this work we only consider object type properties. Taking data type  
properties, such as literals, into account might be an interesting area for future investi-  
gation. In this case, it would be necessary to determine when two literal values can be  
considered equal.

In addition, similar experiments can be applied to linked open data [4] or any other  
715 data structure where the objects are described by means of their properties.
