ABSTRACT

Use of Extra-School Time and Child Behaviours: Evidence from the UK*

In this paper, we study the effects of extra-school activities on children's non-cognitive development, using data from the Millennium Cohort Study (UK) and focusing on children aged 7-11 years old. We classify the time spent out of school into six homogenous groups of activities, using principal component analysis, and estimate the relationship thereof with five behavioural dimensions drawn from the Strength and Difficulties questionnaire, exploiting the panel structure of the data. Results show the beneficial effects on children's behaviour of sports, school-related activities, time with parents and household chores, while a small detrimental effect of video-screen time is detected. We test the robustness of our estimates against omitted variable bias, and the results are confirmed. We also observe that children from more advantaged backgrounds have easier access to more beneficial activities. Overall, our results suggest that different uses of time may reinforce inequalities across children from different backgrounds.

NON-TECHNICAL SUMMARY

The aim of this paper is to study how the use of extra-school time influences child behaviour in the European context and, consequently, whether differences in the use of time between children from different family backgrounds should be seriously taken into account as an additional source of inequality.

We classify the time spent out of school into six homogenous groups of activities and estimate the relationship thereof with five behavioural dimensions of the child. Results show the beneficial effects on children's behaviour of sports, school-related activities, time with parents and household chores, while a small detrimental effect of video-screen time is detected.

We observe that children from different family backgrounds do not face the same opportunities in their extra-school time. We find a negative relationship between the presence of siblings and sport (probably for logistic reasons) and an expected positive relationship between income and sport, which is one of the few to-pay activities among those considered.

From a policy point of view, these two findings call for the provision of free/low-cost sport activities to be held at school, after a regular time. Differences by socio-economic background also emerge in terms of school-related activities, which the children of richer and more educated parents being more likely to engage thereof. More time devoted to school-related activities and less time spent on TV-computer could also be achieved with the expansion of after-school programs, at school or other public places.

Other sources of differences in the use of extra-school time (parental education, gender of the child, ethnicity) seem to be more cultural and may be influenced through parenting courses, which are becoming more and more common, not only around the births of children, but also at later stages.

1. Introduction

Increasingly, scientists from different disciplines are dedicating their efforts to understanding how childhood conditions influence the development of an individual. Both the school and the family play a relevant role in this process, by making children able to fully enhance their potential abilities. In particular, interest has grown in the role of early care. “Good” stimuluses (when the child is under the age of 3) have been shown to be very effective for development (Ruhm, 2004; Heckman et al, 2010; Brilli et al, 2016; Del Boca et al, 2018). Over time and across regions, there has been considerable heterogeneity in the way very young children are looked after, especially given the differences in the labour market participation of women, the availability of crèches, social policies, and the geographic proximity of grandparents. After the age of 3, about 85% of children in Europe are enrolled in kindergarten or pre-school (OECD, 2014). Apart from differences in the quality of the (pre) kindergarten and schools attended, the effects of which having already been thoroughly investigated (Card and Krueger, 1992; Elango, 2016), children are exposed to other heterogeneous sources of development opportunities. In particular, between the end of the day at school and bedtime at home, there is time-lag which can be used for more or less structured activities. For example, playing sport in a team, rather than playing freely in the park. Children can take part in these activities with other children (friends, siblings, cousins), or with other adults (non-working parents, grandparents, instructors).

The aim of this paper is to study how the use of extra-school time influences child behaviour in the European context and, consequently, whether differences in the use of time between children from different family backgrounds should be seriously taken into account as an additional source of inequality.

Very little is known about how children from different family backgrounds spend this time and what consequences it can have on their development and wellbeing. Moreover, little is known about the determinants of children’s participation in structured extra-curricular activities, such as sport, foreign languages and music. A child’s participation depends on their parents’ preferences, time and income constraints, the child’s own inclinations and talents, and even on which activities the child’s peers take part in. Parents may hold different beliefs about the importance of such extra-curricular activities for their children; alternatively, even if convinced of their values, they may not be able to afford them, as most activities are costly, or to manage the logistics. For example, they may not have the time to shuttle their child from school to an activity, and they may not want (or be able to afford) someone else do it in their stead. In families with children of different ages, the situation is even more complicated. It is

thus easy to expect that children from different family backgrounds have access to different opportunities, which can impact their development.

Evidence from US shows that inequality in opportunities is increasing across children, making the “American dream” less and less realistic. In the US, income inequality and the child achievement gap between high and low-income families has increased dramatically in the last 40 years (Duncan et al, 2017). Children’s lives and learning opportunities are strongly determined by the family in the form of marital stability and a supportive parenting style, as well as economic and cultural resources. Participation in extra-curricular activities is becoming a further mark of the diverging destinies of children from different backgrounds (Putnam, 2015). Not only do parents spend more money on their children, but parents spend more on childcare and education. Among various categories, social-cultural spending (music, arts, sports, toys, and holidays) accounted for one third of the total spent on American children in 2007 (Kornrich and Furstenberg, 2013).

Qualitative research carried out in 10 primary schools in the North East and South East of England in 2015, administered to school staff, activity providers, parents, and pupils, suggests the mechanisms through which extra-school activities may influence children’s wellbeing, especially for disadvantaged children (Callanan et al, 2016). The study underlines that since during the school-day the emphasis is on academic attainment, out of school activities provide children who don’t highly achieve at school with the opportunity to feel that they are capable, thus increasing their self-esteem. For children from disadvantaged contexts, extra-school activities also offer the possibility to encounter new experiences and situations. According to parents, the major benefit is that their children experience the opportunity to socialize with new friends. Furthermore, when extra-school activities take place in schools or are organized by schools, teachers find students to be more prone to participating in class discussions, and students are more likely to say that, overall, what they do at school is interesting.

To date, there is no comprehensive European study on the implications of extra-school activities for child development. The only (non-European) studies which make use of data from children’s time use diaries and, thus, explore the full range of activities that are carried out, use American and Australian data. Hofferth and Sandberg (2001) use data from the 1997 Child Development Supplement to the Panel Study of Income Dynamics (around 2,000 children aged 0-12) and find that time devoted to learning activities such as reading is positively correlated with higher school achievement, as is structured time spent playing sports or social activities. Also, time spent eating meals with the family is associated with fewer behavioural problems.

Fiorini and Keane (2014) use time-diaries from the Longitudinal Study of Australian Children (around 1,300 children aged 4-9) to consider the impact of time use as a whole and, therefore, study the trade-off between the benefits of alternative activities. The result of their research is a ranking of activities (from the most to the least beneficial): time spent in educational activities, particularly with parents, is the most productive for cognitive skill development.

A larger number of studies consider single activities. Most of these studies focus on cognitive outcomes and school attainment. There is a consistency amongst the findings for the few studies that have examined the effects of reading: Anderson et al (1988) and Taylor et al (1990) find that the amount of time spent reading contributes significantly to gains in students' reading achievements (US data). More controversial are the results concerning the effect of computer use. Subrahmanyam et al (2000), in a review of the literature, report that using a computer is potentially linked to slightly better academic performance. However, access to computers decreases the amount of time children spend on other activities, putting children at risk of obesity. In addition, the use of computers to play games and the use of the Internet seem to be linked to fewer friendships. Gentzkow and Shapiro (2008), exploiting the heterogeneity in the timing of television's introduction into different local markets in the US, estimate the effect of preschool television exposure on test scores during adolescence. They find marginally significant positive effects on reading and general knowledge; effects that are largest for children from households in which English is not the primary language, for children whose mothers have less than a high school education, and for non-white children. Eccles et al. (2003) find that participation in service and religious activities predicts lower rates of drinking and drug use. Hille and Schupp (2015) examine how long-term music training during childhood and youth affects adolescents' development, using data from Germany. Their findings suggest that adolescents with music training have better cognitive skills and school grades and are more conscientious, open and ambitious. Among the earliest studies of the effects of sports, we cite the one by Spreitzer and Pugh (1973), which shows that athletic involvement has a positive effect on degree attainment expectations, after controlling for the socio-economic status of the family, parental academic encouragement, and student grade averages. More recently, Cuffe et al. (2014) studied the effect of high-school athletic participation on school absenteeism. They show that active competition and game days decrease absences, which are, however, partly offset by higher absenteeism on the days following games. There are also a few studies for Germany, where the availability of data from the German Socio-Economic Panel has allowed researchers to focus on the issue. Lechner (2009) analyses the effects of individual leisure sports participation and finds that sports activities have positive long-term effects on earnings, as well

as positive effects on health and subjective well-being. Pfeifer and Cornelißen (2010) find evidence that the effect of sport during childhood and adolescence on educational attainment is statistically significant and positive. Felfe et al (2016) analyse the effect of sports club participation and find positive effects on children's skill development.

We contribute to the topic by studying the effects of the use of extra-school time on child behaviours, using UK longitudinal data. We use available information on child assessments and on child time use up to the age of 11 from the Millennium Cohort Study. At the European level, the Millennium Cohort Study is one of the best sources of information currently available, tracking the lives of a sample of about 19,000 babies born in the UK in the year 2000/2001. The dataset has two great advantages: first, many of the questions and child indicators are repeated over time; second, it provides ample information about the child and the child's family from the time of the birth, information that may prove important to control for. We study the effects of different weekly activities in children's extra-school time on the behavioural dimension, employing statistical techniques that exploit the available longitudinal information that limits endogeneity issues. We also complement our analysis with a fixed effects approach and test the sensitivity of our results to possible biases due to potential unobserved variables.

To the best of our knowledge, this is the only study working on this topic with this data. The closest paper – using the same data – is the one by Hernandez-Alava and Popli (2017), which looks only at the effect of early parental time investments (reading to the child, helping him/her with homework, ...) on different aspects of cognitive and non-cognitive development.

The paper is organized as follows: in Section 2 we describe the Millennium Cohort Study, the selection of the sample, and the variables used throughout the analyses; in Section 3 we present the methods employed for the empirical analysis; Section 4 and 5 comprise the results and the robustness checks. Conclusions follow (Section 6).

2. Data, sample selection, and main variables of interest

The Millennium Cohort Study is a longitudinal survey conducted by the Centre for Longitudinal Studies, which tracks the lives of a sample of about 19,000 babies born in the UK in the year 2000/2001. The survey is conducted in different waves, with the first wave concentrating on the circumstances of pregnancy and birth, the first few months of life, and the socio-economic background of the family into which the child is born. Families and children were re-interviewed when the cohort-child reached about 3, 5, 7, and 11 years of age.

The initial wave 1 sample is composed by 18,818 children in 18,552 families; interviews took place when the children were roughly 9 months old. Not all families participated for the

entire duration of the survey: around 10% of the sample is lost between the second and third wave, along with another 10% percent between the third and the fourth wave. Slightly less of the sample was lost between the fourth and fifth wave. Because of the information we need for the analyses, we consider only children in families participating in the survey up to wave 4 or 5, when child outcomes can be observed. In addition, we decide to exclude twins due to the possibility of different timings in their development with respect to single-birth children (Mowrer, 1954; Mittler, 1971). The sample is further restricted to children with non-missing information on the dependent variables. Our final samples consisted of 10,597 children in wave 4 (children aged 7 years old) and 9,462 in wave 5 (children aged 11 years old). Table A1, in the Appendix, shows how the final samples we analyse differ from the initial sample in wave 1 because of attrition. It turns out that the final samples include more educated and work-attached parents than the general population interviewed in wave 1.

The Millennium Cohort Study has repeated measurements of a child's cognitive and non-cognitive outcomes and contains rich information about parental socio-economic background, employment status, child care arrangements, and specific parental inputs at various points in time. Of particular interest to the present research are the variables reporting extra-curricular activities and indicators of the child's development and wellbeing when s/he is 5, 7 and 11 years old. We focus on non-cognitive outcomes, specifically on child behaviour indicators derived from the Strength and Difficulties questionnaire.

The Strength and Difficulties questionnaire is composed of 25 items that ask parents about the behavioural attributes of their child. Devised by UK child psychiatrist Robert Goodman (Goodman et al, 1997), this questionnaire is used to screen for emotional and behavioural problems in children and adolescents aged 3-16. The 25 items measure 5 child behavioural dimensions (emotional symptoms, conduct problems, hyperactivity/inattention, peer relationships problems, and prosocial behaviour); each dimension is derived from 5 items. The *emotional symptoms* subscale contains items referring to fears, worries, misery, nerves, and somatic symptoms; the *conduct problems* subscale enquires about tantrums, obedience, fighting, lying, and stealing; and the *hyperactivity/inattention* subscale covers restlessness, fidgeting, concentration, distractibility, and impulsivity. The *peer relationships* subscale items include questions about popularity, victimization, isolation, friendship, and ability to relate to children as compared to adults. The *prosocial* subscale covers consideration of others, ability to share, kindness to younger children, helpfulness when other children are distressed, and willingness to volunteer to comfort. An example is going to show how a quantitative indicator for each child behavioural dimension is usually derived. Take the item "Shares readily with

other children”, referring to the extent the mother believes her child tends to share things with other children. Possible answers are given on a three-point scale with the following labels: “not true”, “somewhat true”, and “certainly true”. The answers are then converted into numerical values of 0, 1 or 2. Therefore, groups of five answers are summed up in a total score, ranging from 0 to 10. Lower scores are “good” for the first four behavioural dimensions, while a higher score is “good” for prosocial behaviour. The distributions of the outcomes when children are aged 7 and 11 are reported in Figure 1. In the Figure we notice that, for each of the outcomes, roughly 30 to 40% of children do not show any problem (an exception being hyperactivity; regarding which, (almost) the entire sample demonstrates some problems). Not only, despite these scores seem continuous variables, they do not really express quantities. Therefore, we decided to further recode these variables into dummies, which take a value of 1 if the child has a score larger than 0 for the first four behavioural dimensions and lower than 10 for the prosocial behaviour. In a more straightforward way, the dummies indicate the presence of “problematic” behaviour in each of the five dimensions, and we have thus labelled “anti-social behaviour” as the last dimension. Table 1 summarises the dependent variables for children aged 7 and 11 years old.

The main independent variables in our analysis are the activities undertaken by children in their extra-school time. The data provides information about a large number of activities: playing a musical instrument, going to the library, attending religious services and classes, doing sport activities, doing household chores, watching TV, playing electronic games, etcetera. In wave 4 (at age 7), we also have information on other activities carried out with the parents: parents reading to the child, playing music with the child, and drawing with the child. Unfortunately, the data does not provide the number of minutes/hours spent in each activity, but only an indication of the frequency (e.g., more than once per week / once per week / once per month). We recode the activities in dummy variables, where 1 indicates that the activity is carried out at least once per week. The only exceptions are represented by homework and video-screen activities, where 1 indicates at least one hour per day. All activities are listed and described in Table 2. We report activities at age 7 and 11, ages at which we study their effects on behaviours, but also at age 5, since we will use past activities as further controls (see Section 3). Table 2 provides an overview of both the activities recorded over time (e.g., sport activities) and the more age-specific ones (e.g., parents reading to the child). Among the activities recorded over time, we observe an increase in time devoted to sport (without parents) and computer use.

With so many variables of interest, the interpretation of results can prove to be difficult, especially as some of the reported variables are likely to capture types of activities that are relatively similar to each other. Thus, we implement a principal component analysis (PCA), aimed at developing better insight into the number of common latent dimensions that the different activities may share. Given the binary nature of the variables, we use polychoric correlations to construct the covariance matrix from which the eigenvalues and eigenvectors are calculated. To choose the number of components retained, we apply the Kaiser criterion, selecting a number of components equal to the number of eigenvalues greater than 1. Finally, to facilitate the interpretation of the extracted components, we rely on orthogonal rotation using the varimax approach.

Tables A2, A3, and A4 in the Appendix report the principal component analysis. In wave 3, we obtain four components, while in wave 4 and 5 we obtain six components. In Figure 2, we summarise the grouping of activities in the different components, which we name: 1) activities with parents; 2) sports; 3) library and religious activities; 4) video-screen time 5) household chores; 6) school-related activities. There are no factors expressing school-related and household chores activities for children when they are 5 years old.

3. Empirical methods

To study the effects of different uses of time on children's behaviours, we use two regression models. Our aim is to identify the impact of extra-school activities, our main independent variables (as defined above), on children's behaviour and non-cognitive development (our main outcomes). However, there may be variables that influence both the use of time and child outcomes and therefore bias our estimates, such as personal characteristics, parents' and family characteristics, and socioeconomic circumstances. Let us take, for example, an indicator of the child's behaviour, the *emotional symptoms* outcome of the child: it measures to what extent the child seems often worried, easily scared, nervous or clingy in new situations. As we want to measure the effect of different uses of time on children's emotional dimensions, we include (as regressors) the factors expressing the frequency with which children carry out certain activities. However, parental wellbeing may influence the child's emotional development, and the same is true for the other outcomes. In order to reduce this possibility, we include a rich set of control variables and exploit the longitudinal nature of the data.

We include different subsets of control variables, whose descriptive statistics are reported in Tables 3 to 5. We consider a number of variables that describes the environment/context that children face when not at school and not involved in the extra-school activities, which we call

environmental variables (Table 3). They are measured at the same wave as the main outcomes (at age 7 and 11) and are related to the school dimension (attendance of pre/after school) or to the household dimension (presence in the household of mother, father, siblings, grandparents; parental hours of work). A second set of variables takes into consideration previous *parental investments* (before age 7), and are fixed over time (Table 4): whether the child was breastfed, how long the mother stayed at home after birth, type of childcare when the child was 30 months, father's involvement with the child when the child was 9 months, and parental education. We finally include more *socio-demographic* control variables concerning the *child*, the *parents* and the *household* (Table 5). Control variables about the child are all measured in the first wave: gender, nationality, birth weight, age, number of siblings at birth, hospitalizations and accidents, three indicators of child development in the first year of life,¹ which capture child endowments at an early age and are known to be predictive of later development (Hernández-Alava and Popli, 2017). We include the following variables concerning the parents: quality of the child-mother relationship,² locus of control of the mother,³ mother's personality type,⁴ and parents' mental wellbeing.⁵ Concerning the household, we include the presence of new-borns and household equivalent income (both measured at the current wave), household location (England, Scotland, Wales, Northern Ireland), and whether the child has been on holidays outside the UK in the past year.

Finally, in addition to child's development at 9 months, in order to take into account the correlation between the different abilities of the child as he/she grows older, we include one variable measuring the child's cognitive ability at the previous wave, which is derived through a factor analysis of the cognitive items available in the survey (see Table A6 in the Appendix). At age 7, we consider past measures of abilities in giving names to objects, in coordinating figures in the spatial dimension, and in problem solving (measured at age 5). For age 11, we have past measures of abilities in reading, in math, and in coordinating figures in the spatial dimension (measured at age 7).

¹ The three indicators of child development in the first year of life refer to the communication, motor, and motion dimensions. They are derived – through factor analysis – from information in wave 1 (see Table A5 in the Appendix).

² Two variables are included (measured in wave 2) that regard child-mother's closeness and conflicts (see the MCS Guide to the Psychological, Developmental and Health Inventories (IOE, 2012, page 38).

³ Measured in wave 1. It is a dummy variable on mother's locus of control that corresponds to her statement "I usually have a free choice and control over my life".

⁴ The two variables are measured in wave 4 and regards mother's being extrovert and neurotic (see IOE, 2012, page 45).

⁵ Measured with the Kessler K6 Scale in each wave (see IOE, 2012, pages 41-43).

We exploit the longitudinal nature of the data twofold: in a first specification, by including in the regressions lagged uses of time and lagged behavioural dimensions; in a second specification, by employing child fixed-effects regressions.

For each child behavioural dimension, we first estimate the following linear equation, once for outcomes at age 7, once for outcomes at age 11:

$$Y_{i,t} = \alpha_t + X'_{i,t}\beta_t + X'_{i,t-m}\gamma_t + \delta_t Y_{i,t-m} + Z'_{i,t}\theta_t + \varepsilon_{i,t} \quad (1)$$

where Y represents one of the five child behavioural dimensions, the vector X indicates the factors expressing different uses of time, the vector Z the control variables of the child i at the age t or before age t . The subscript m is equal to 2 when we estimate the effects age 7, including time-use factors and outcomes measured at age 5; it is equal to 4 when we estimate the effects age 11, including time-use factors and outcomes measured at age 7. β , γ , δ , are the effects we are interested in measuring. With this model (value-added cumulative model), we include information regarding the past use of the child's time (allowing for a "lagged" effect) and information on the child's behavioural starting level, which can control for most of the differences across children. This model is equivalent to compare the emotional symptoms of two children at age 11 who used to have the same emotional symptoms at age 7, but may have used their time in a different ways between age 7 and 11.

Then, using data from both waves, we estimate the following equation

$$Y_{i,t} = \alpha_t + X'_{i,t}\beta_t + Z'_{i,t}\theta_t + v_i + e_{i,t} \quad (2)$$

With this second model, including child fixed-effects v_i , we can observe whether a change in the frequency of activities carried out between age 7 and 11 explains part of the difference in the child's behavioural dimension over time, cleaning out the effect of the child's preferences and talents, but also of other family unobserved characteristics fixed over time.

The value-added cumulative model and the child fixed-effects model rely on different assumptions of the relationship between the child's time use and outcomes. In the first case, the model allows for a temporal adjustment, and the present effect of an activity can be different to the effect of the same activity in the past. For example, when studying the emotional sphere of the child at age 11, we could find that spending a lot of time engaged in video-screen activities at age 7 is bad, while at age 11 there is no additional detrimental effect of the current quantity of time dedicated to video-screen activities. With the child fixed-effects model, we assume the

effect of video-screen time is constant over time. At first sight, the value-added cumulative model seems more informative. However, the child fixed-effects model deals better with the unobservable characteristics of the child and the family. Given the assumptions, we will only consider the results provided by the fixed-effects estimator when the two value-added cumulative models indicate there to be a similar effect of a certain activity at ages 7 and 11.

4. The effects of the use of extra-school time

The effects of the extra-school activities – summarised through factors – on the five behavioural dimensions are presented in Tables 6-10. For each outcome, the Tables report the results of the value-added cumulative model at age 7 (second column), at age 11 (third column), and the results of the fixed-effects model (last column). Given that the dependent variables assume value 1 if there is a behavioural problem, a negative sign of the independent variable indicates that the activity reduces the probability of having behavioural problems, thus has a “beneficial” effect, and *viceversa*.

Overall, we find there to be a beneficial effect of sports, school-related activities, time with parents, and household chores, all of which tend to reduce behavioural problems, while we detect a detrimental effect of video-screen time. No effects are found for participating in parish activities and going to the library. The child dimension, which can be more easily influenced by the use of extra-school time, is the prosocial behaviour, the ability to share with others and to be helpful. On the contrary, the weakest effects are found for problems related to the hyperactivity and inattention of the child. Lagged activities have less effects than contemporaneous ones. All behavioural dimensions are strongly correlated over time and, interestingly, we observe that better cognitive abilities correspond to better behavioural dimensions. The only exception is represented by the prosocial behaviour, which definitely appears to be the most malleable, irrespective of the cognitive development of the child. It is also interesting to note that, for some activities, a significant effect emerges only at age 11 and that, in most cases, when a beneficial effect is detected at age 7, it is also present at age 11; it is rare that a relationship between time use and behaviour detected at age 7 subsequently disappears.

We now comment on the strongest results, in terms of both econometric robustness and time consistency (i.e. when we find significant effects on behaviours at both ages 7 and 11), as confirmed by taking into account the unobservable characteristics of the child/family fixed over time. For these results, we also provide the size of effects on the probability of behaving in a

certain way when doing more/less frequently certain activities, which is otherwise difficult to interpret, given that we are using factor variables.

We find sport to have a beneficial cumulative-time effect on children's problems in terms of relationships with peers (Table 9). If we compare two similar children where the first one does sports, active games and goes to the playground at least once per week, and the second one carries out these activities less often, we observe that the probability of having problems with peers is six percentage points lower for the first child than for the second (the probability increases from 45% (first child) to 51% (second child)). Time spent with parents in reading, playing and doing games has a beneficial cumulative-time effect on the prosocial behaviour of the child (Table 10). The probability of acting in an anti-social way decreases from 60% to 46% for children who have regular opportunities to spend time with their parents. Children who carry out household chores more often have fewer conduct problems (Table 7) and better prosocial behaviour (Table 10). The probability of problems in conduct decrease from 67% to 62%, while the probability of anti-social behaviour drops from 47% to 36% for children who help more in the household. Finally, we find a beneficial effect of school-related activities on anti-social behaviour (Table 10). More time spent doing homework implies a decrease of four percentage points (the probability of acting in an anti-social way drops from 49% to 45%).

Video-screen time has the expected detrimental effect (both long-lasting and cumulative) on the emotional dimension of the child (i.e. whether the child looks worried and unhappy) (Table 6). The effect is however quite small: the probability increase of being worried and sad for children who spend more time on TV and PC is of two percentage points (rising from 61% to 63%).

Most of the beneficial effects we find on child's behaviours are in line with previous findings on the cognitive dimensions of children. In addition to the positive influence of sports and of activities with parents on many educational outcomes detected by previous studies,⁶ in this paper we find positive effects on non-cognitive outcomes, especially on relationships with peers and prosocial behaviour. Completely new evidence is instead provided for the beneficial effects of time spent in household chores and in school-related activities. Time spent using TV and PC has the expected detrimental effect on the emotional sphere of the child. When looking at cognitive outcomes, previous literature found that time on TV has either no effects, or even positive effects, on the language proficiency of immigrant children (Gentzkow and Shapiro, 2008). On the other hand, the psychological literature has shown that watching TV below age

⁶ Among the others, Fiorini and Keane (2014), Spreitzer and Pugh (1973), Cuffe et al. (2014), Lechner (2009), Pfeifer and Cornelißen (2010), Felfe et al. (2016).

2 has negative effects the child cognitive and especially non-cognitive development, while after age 5 the relationship changes, largely depending on the content, with interactive programs possibly having a positive impact (Medina, 2010). Unfortunately, we do not have this information.

The results are coherent with psychological research on child behavioural development, which underlines the beneficial effects of active and dynamic uses of time versus the detrimental effects of passive activities. Among the different uses of time considered in this paper, the only one with detrimental effects is time spent on TV/PC, which is also the only “passive” activity considered. While dynamic uses of time imply effort and perseverance and, consequently, bring feelings of satisfaction to the child, this is not the case for inactive uses of time (Veenhove, 1984; Emmons, 2003). The dimension mostly negatively influenced by video-screen time (Emotional symptoms) is in fact the most intimate, the one which most concerns the personal dimension of the child. Another interesting finding is the substantial influence of several activities on the prosocial behaviour of the child, which we can consider as a sort of feeling of empathy towards other people. This is an attitude that is expected to grow with the individual, a behavioural dimension that measures the passage from “childhood” (when behaviours are motivated by the need for attachment) to “adulthood” (when behaviours are motivated by the feeling of looking after someone else) (Solomon and George, 1996; Nuttall et al., 2015). Probably, this ability could be learnt by spending time with parents and other caring adults, and by observing them. In fact, we find positive effects on children’s empathy of time spent with parents, time spent in doing homework (that could be shared with parents), receiving extra-classes (with a tutor), and in helping with household chores (that can be shared with other family members). We also find a beneficial effect of sports on prosocial behaviour, an effect which could be due to another mechanism, the need for collaboration (Lichtenberg et al., 2012). In order to “succeed”, in fact, the child needs to interact in a proficient way with his/her companions.

We investigate the possible heterogeneous effects of the use of extra-school time. Specifically, we look at the different impacts of extra-school time by the socio-economic status of the family (education / income), the structure of the family (presence of both parents in the household / presence of siblings), and the ethnic background of the child (British/other). We test these hypotheses since we can expect that more structured activities (like sport) could be more beneficial for children from disadvantaged families. We also suppose that different family structures may characterise activities with parents and household chores differently, with consequential heterogeneous effects. Finally, for non-British children a better comprehension

of the language (through TV) can also improve relationships with peers and adults. However, we do not find strong evidence for any heterogeneous effect.⁷

4.1 Robustness to omitted variables bias

When studying the relationship between uses of time and the child's behaviours, we are able to control for a rich set of variables, past child behaviour values, and unobserved child and family characteristics, as fixed over time. This should help in interpreting our results in a casual way. However, there is still the possibility that other time-varying factors influence both the use of the time and behaviour, biasing our estimates. For example, parents may observe their child as having difficult relationships with peers, and then choose to enrol him/her in a sport activity.

We deal with this issue by applying a method designed to assess the stability of coefficients in the presence of unobservable selection (Oster, 2017) to our value-added cumulative model. This method, building on previous work by Altonji et al. (2005), evaluates the robustness of results against omitted variables bias, assuming that the relationship between the treatment and the unobservables can be recovered from the relationship between the treatment and the observables, and allows the coefficient of interest to be bound in the presence of such omitted variables bias.

In order to work with this procedure, we need to choose a level of R_{\max} , which corresponds to the R -squared from a hypothetical regression of the outcome on the treatment and both observed and unobserved controls. If the outcome could be fully explained by the treatment and full controls set, then R_{\max} would be 1; however, in many empirical settings, it seems likely that the outcome cannot be fully explained, even if the full control set is included (e.g. due to measurement error). Therefore, ones need to choose a bound of R_{\max} , and Oster (2017) proposes to focus on bounds that are a function of the observed R -squared of the regression with a full set of *observable* controls. We choose a $R_{\max} = 1.3$ R -squared, as suggested by Oster (2017).⁸

Then, we calculate the bounds of the estimated coefficients, for different values of the relative degree of the selection on observed and unobserved variables (δ). We focus on $\delta = 0$, corresponding to the original estimates, and $\delta = 1$ as the upper bound, which correspond to the assumption of equal selection between observed and unobserved variables, as suggested by Oster (2017).

⁷ Results available from the authors upon request.

⁸ This value has been calculated so that at least 90% of randomised results would survive and at least 45% of non-randomised results would survive.

The bounds are reported in Column (7) of Table A7 in the Appendix.⁹ We observe that the 0 is never included in the calculated bounds, except for video-screen time on conduct and peer problem outcomes in wave 5. This implies that most of our estimates are robust regarding the presence of omitted variable bias, as the estimates are never equal to 0.

To confirm our results, we also report the value of δ such that β would be 0 given the assumed R_{\max} , and we see that this is greater than 1 in all cases (again except for the two cases mentioned above). A δ greater than 1 would imply that unobservables are more important than all the observables in explaining selection into treatment. Such values of the bounds and of δ suggest that the effects of the activities on the outcomes that we find are robust, even in the presence of other possible omitted variables that we cannot observe in our data.¹⁰

5. Extra-school time opportunities across children

We find evidence of the beneficial effects on child behaviours of time spent with parents, doing sports, household chores and school-related activities, while the detrimental effects of video-screen time are also recognised. We do not find strong heterogeneous effects of these uses of time, but we can expect that children from different contexts may have a different likelihood of spending time in these activities: if this is the case, even under homogeneous effects, inequalities in behavioural development would arise across different groups.

In particular, it is policy relevant to consider whether children with fewer economic and cultural resources have the same opportunities in their extra-school time as children with more resources. Once we take into account economic resources, the family composition may also play a role: a large number of siblings or the absence of one of the two parents in the household could influence the logistics of some activities. Finally, whether determined by preference or culture, the gender of the child may affect the use of their time.

To account for the effects of child and family characteristics on children's uses of time (grouped under the same factors as before), we perform a set of regressions in which extra-school activities are estimated as a function of the relevant variables. Table 11 reports the results. From an inequality point of view, we observe that children from a more advantaged background, in terms of parental education and income, are more exposed to enriched uses of their time (sports, school activities) and are less exposed to detrimental ones (TV and computer). On the other hand, richer and labour-market attached parents spend less time with

⁹ Estimations are done in Stata with *psacael*.

¹⁰ A negative delta means that if the observables are positively correlated with the treatment, the unobservables have to be negatively correlated with the treatment to get a $\beta = 0$.

their children. The family structure influences two uses of time in an opposite but compensatory way: an only child spends more time with their parents, whilst a child with siblings spends more time helping in household chores. Having siblings also decreases the probability of doing sport, probably for logistic reasons (since income is controlled for). The presence of the father (or of a stepfather) does not influence the use of extra-school time, while the presence of grandparents leads children to more “quiet” activities (TV, computer, religious services, and library). British children spend more time with their parents and in sport activities, while children from ethnic minorities spend more time doing homework, helping in the household, and attending the library and religious services. From a gender point of view, the results are as expected: girls are more likely to spend time on school-related activities and in household chores and are less likely to engage in sport and TV/computer use.

6. Conclusions

In this paper, we study the relationship between the use of extra-school time and child behaviours, using UK longitudinal data. We find that different extra-school activities influence the behavioural development of the child. Time with parents, time spent in household chores, school-related activities and sports have beneficial effects, whereas time spent watching TV and using a computer have a detrimental effect. The more easily influenced dimension is the prosocial behaviour of the child. We also show that our results are robust with regard to possible omitted variable bias.

Most of the beneficial effects we find on child’s behaviours confirm previous findings on the cognitive dimensions of the child. In addition to the positive influence of sports and of time with parents on many educational outcomes, in this paper, we detect positive effects thereof on relationships with others. Completely new evidence is provided for the beneficial effects of time spent engaged in household chores and school-related activities.

We observe that children from different family backgrounds do not face the same opportunities in their extra-school time. We find a negative relationship between the presence of siblings and sport (probably for logistic reasons) and an expected positive relationship between income and sport, which is one of the few to-pay activities among those included. From a policy point of view, these two findings call for the provision of free/low-cost sport activities to be held at school, after a regular time. Differences by socio-economic background also emerge in terms of school-related activities, which the children of richer and more educated parents being more likely to engage thereof. More time devoted to school-related activities and less time spent on TV-computer could also be achieved with the expansion of after-school

programs, at school or other public places. Other sources of differences in the use of extra-school time (parental education, gender of the child, ethnicity) seem to be more cultural and may be influenced through parenting courses, which are becoming more and more common, not only around the births of children, but also at later stages.

There are three main limitations to this study. First, we do not know how much time the child spends in the activities. Not only would this be another important source of heterogeneity across children, but it could also reveal the non-linear effects of these activities. Second, in order to better interpret the results we obtain for children's non-cognitive development, it would be useful to know more details of the activities carried out. For example, to understand the level of passiveness of activities under the video-screen category, we should know whether children are watching a movie/cartoon, a cartoon with interactions, playing video-games, watching other people playing those video-games, singing or dancing whilst watching musical videos, or searching for commercial videos (e.g., the unboxing of toys). Finally, we don't have full description of the use of extra-school time; thus, we are missing important children's activities, such as "pure" playtime (playing by themselves or with siblings/cousins), time at dinner and social events, sleeping routines, and the management of moments of boredom and of waiting-time. Future research should investigate such factors to completely unveil the relationship between the child's time use and the child's non-cognitive development.

Figures

Figure 1: Child behavioural indicators

Notes: the five colours represent the five behavioural indicators (Emotional symptoms, Conduct problems, Hyperactivity / inattention, Peer relationship problems, Prosocial behaviour). Each indicator goes from 0 to 10, depending on the answers the caregivers give to the five questions for each child behavioural dimension. 0 means “absence of problems” and 10 “presence of all problems” for the first four indicators, while 10 means “absence of problems” and 0 “presence of all problems” for the Prosocial behaviour.

Table A7: Robustness against omitted variables bias

Wave (1)	Outcome (2)	Factor (3)	Beta (4)	Se (5)	r2 (6)	Bounds (7)	Delta (8)
4	Peer problem	Sports	-0.067	(0.015)	0.204	[-0.067,-0.004]	1.05
4	Emotional	Video-screen	0.031	(0.012)	0.183	[0.021,0.031]	2.77
4	Emotional	Household chores	-0.031	(0.014)	0.183	[-0.031,-0.019]	2.25
4	Conduct	Household chores	-0.042	(0.013)	0.247	[-0.042,-0.003]	1.07
4	Hyperactivity	Household chores	-0.030	(0.008)	0.166	[-0.030,-0.007]	1.26
4	Anti-social	Parents	-0.057	(0.014)	0.174	[-0.057,-0.043]	2.67
4	Anti-social	Sport	-0.038	(0.015)	0.174	[-0.045,-0.038]	-13.51
4	Anti-social	Video-screen	0.023	(0.012)	0.174	[0.010,0.023]	1.66
4	Anti-social	Household chores	-0.085	(0.014)	0.174	[-0.085,-0.053]	2.28
4	Anti-social	School	-0.039	(0.013)	0.174	[-0.039,-0.032]	4.15
5	Peer problem	Sport	-0.108	(0.014)	0.192	[-0.108,-0.077]	2.91
5	Peer problem	Library	0.032	(0.017)	0.192	[0.017,0.032]	1.89
5	Peer problem	Video-screen	0.027	(0.012)	0.192	[-0.004,0.027]	0.87
5	Emotional	Sport	-0.058	(0.013)	0.168	[-0.058,-0.033]	2.13
5	Emotional	Video-screen	0.021	(0.012)	0.168	[0.008,0.021]	1.55
5	Conduct	Parents	-0.039	(0.013)	0.240	[-0.039,-0.028]	2.99
5	Conduct	Video-screen	0.033	(0.012)	0.240	[-0.005,0.033]	0.88
5	Conduct	Household chores	-0.031	(0.014)	0.240	[-0.045,-0.031]	-2.61
5	Conduct	School	-0.044	(0.013)	0.240	[-0.044,-0.017]	1.56
5	Hyperactivity	Parents	-0.033	(0.010)	0.176	[-0.033,-0.029]	4.86
5	Hyperactivity	Video-screen	0.031	(0.009)	0.176	[0.001,0.031]	1.03
5	Anti-social	Parents	-0.075	(0.014)	0.166	[-0.075,-0.062]	3.95
5	Anti-social	Sport	-0.042	(0.015)	0.166	[-0.042,-0.039]	6.88
5	Anti-social	Video-screen	0.026	(0.013)	0.166	[0.000,0.026]	1.01
5	Anti-social	Household chores	-0.094	(0.015)	0.166	[-0.094,-0.086]	8.03
5	Anti-social	School	-0.076	(0.014)	0.166	[-0.076,-0.070]	6.21

Notes: robustness analyses are reported only for significant coefficients from the valued-added cumulative models (Tables 6-10).
