In brief

How do epithelia dynamically maintain their integrity in a constantly changing environment? Gagliardi et al. show that apoptotic cells trigger ERK/Akt waves in their neighboring cells inducing survival for 3–4 h. At the cell population scale, this mechanism dynamically protects the epithelium from mild to acute environmental insults.

Highlights

- Apoptotic epithelial cells trigger ERK/Akt activity waves in their neighboring cells

- EGFR and metalloprotease signaling is required for the ERK/Akt activity wave

- Such a signaling wave induces 3–4 h of survival in the neighboring cells

- ERK/Akt waves maintain epithelial integrity in response to environmental insults

SUMMARY

Cell death events continuously challenge epithelial barrier function yet are crucial to eliminate old or critically damaged cells. How such apoptotic events are spatio-temporally organized to maintain epithelial homeostasis remains unclear. We observe waves of extracellular-signal-regulated kinase (ERK) and AKT serine/threonine kinase (Akt) activity pulses that originate from apoptotic cells and propagate radially to healthy surrounding cells. This requires epidermal growth factor receptor (EGFR) and matrix metalloproteinase (MMP) signaling. At the single-cell level, ERK/Akt waves act as spatial survival signals that locally protect cells in the vicinity of the epithelial injury from apoptosis for a period of 3–4 h. At the cell population level, ERK/Akt waves maintain epithelial homeostasis (EH) in response to mild or intense environmental insults. Disruption of this spatial signaling system results in the inability of a model epithelial tissue to ensure barrier function in response to environmental insults.

INTRODUCTION

An epithelium is a self-organizing tissue that coordinates cell division and death to maintain its barrier function. This ability, called epithelial homeostasis (EH), is especially important because of the frequent apoptosis observed in epithelia (Darwich et al., 2014). EH depends on cell density sensing, epithelial extrusion, spindle orientation, apoptotic-neighbor communication, and cell-cell adhesion dynamics to maintain epithelial integrity (Macara et al., 2014). Coordination between epithelial extrusion and cell division is crucial to maintain an adequate cell density (Eisenhoffer et al., 2012; Gudipaty et al., 2017; Marinari et al., 2012). Coordination of apoptotic cells with healthy neighboring cells is essential to close the gaps caused by extrusion of dying cells (Gagliardi et al., 2018; Gu et al., 2011).

Apoptosis can control the fate of neighboring cells. Mitogenic factors produced by apoptotic cells induce proliferation in neighboring cells, enabling wound repair (Li et al., 2010). Apoptotic cells can however also induce further apoptosis in neighboring cells during developmental processes that require coordinated cell death (Pérez-Garijo et al., 2013). Apoptosis can trigger survival fates in surrounding healthy cells in the *Drosophila* wing imaginal disk (Bilak et al., 2014). These different processes imply coordination of signaling pathways that regulate proliferation, survival, or apoptosis fates. However, how these signaling pathways are regulated at the single-cell level and spatio-temporally integrated at the population level remains poorly understood.

Mitogen-activated protein kinase (MAPK)/extracellular-signal-regulated kinase (ERK) and phosphoinositide-3 kinase (PI3K)/Akt signaling networks are crucial for regulation of cell fate. Recent evidence has shown that ERK/Akt signaling dynamics fine-tune fate decisions at the single-cell level. In epithelial cells, discrete ERK activity pulses of fixed amplitude and duration are observed at the single-cell level (Albeck et al., 2013). The ERK pulse frequency depends on the epidermal growth factor (EGF) concentration, which further correlates with the efficiency of cell-cycle entry. These ERK pulses emerge from the three-tiered Raf/MEK/ERK network structure with negative feedback from ERK to Raf (Albeck et al., 2013; Ryu et al., 2015; Santos et al., 2007) that provide ultrasensitivity and adaptation properties to shape their pulsatile dynamics. In addition to ERK pulses, Akt pulses that are synchronous with the latter have been observed in epithelial cells (Sampattavanich et al., 2018). These Akt pulses are thought to maintain metabolic stability in epithelia (Hung et al., 2017). Beyond the relationship that links EGF dose and proliferation fate, little is known about how ERK/Akt regulates additional single-cell fate decisions, such as survival or apoptosis, and how the latter are integrated at the cell population level to ensure EH.

Here, we show that apoptosis triggers a wave of ERK/Akt activity pulses that radially propagates for about three healthy cell layers. This signaling wave requires EGFR and MMP activity and acts as a survival signal that locally protects cells from apoptosis for a period of 3–4 h. This single-cell behavior maintains

population-level EH and tissue integrity in response to mild or intense cellular insults.

RESULTS

Collective ERK/Akt activity waves propagate from apoptotic cells in quiescent unstimulated epithelium

To investigate single-cell ERK/Akt activity dynamics in epithelia, we stably transduced MCF10A cells with histone 2B (H2B), ERK-KTR (Regot et al., 2014) and 1–396 Forkhead box O3 (FoxO3a) tagged with miRFP703 (Shcherbakova et al., 2016), mTurquoise2 (Goedhart et al., 2012), and mNeonGreen (Shaner et al., 2013) (Figure S1A). ERK-KTR and FoxO3a biosensors respectively report single-cell ERK and Akt activity by displaying reversible nuclear-to-cytosolic translocation upon phosphorylation (Figures S1A and S1B). While FoxO3a can be sensitive to ERK-dependent inputs, this has been shown to be negligible in MCF10A cells (Sampattavanich et al., 2018). We developed an automated image analysis pipeline to segment/track nuclei and to extract cytosolic/nuclear (C/N) fluorescence intensities that quantify ERK/Akt activities (Figure S1C). As previously shown (Albeck et al., 2013; Sampattavanich et al., 2018), starved MCF10A cells showed synchronous ERK and Akt activity pulses whose frequency increased with EGF stimulation (Figure 1A). The amplitudes of both ERK/Akt pulses were similar with or without EGF (Figure S1D). Visual examination (Figure 1B), as well as spatial clustering of trajectories (Figure 1C), revealed that starved monolayers display collective ERK/Akt activity in the form of radial waves.

These ERK/Akt activity waves originated from single apoptotic cells and radially propagated in a healthy neighborhood through sequential triggering of an ERK/Akt activity pulse in each successive cell layer (Figures 1D–1F; Video S1). In the first layer, ERK/Akt activity increased synchronously with apoptotic nuclear shrinkage and peaked at 10–15 min after this event (Figures 1G and S1E). In the second and third cell layers, delayed ERK/Akt activity peaked at 15–20 and 20–30 min, respectively. An apoptotic cell could trigger ERK/Akt activity in 0 to 35 neighbors, with a median of 6 (Figure 1H). Less than 5% of apoptotic events failed to trigger ERK/Akt (Figure S1F). The proportion of pulsing neighbors decreased across the layers; about 90% in the 1st, 30% in the 2nd, and 10% in the 3rd (Figure 1I). Further, ERK pulse amplitude in pulsing cells remained constant in the 1st and 2nd layer but significantly reduced in the third layer (Figure 1J). MCF10A cells are classically cultured in presence of cholera toxin (Debnath et al., 2003). We found that the latter altered ERK/Akt waves by reducing the apoptotic rate, wave size, and global ERK activity (Figures S1G–S1I). We therefore performed our experiments in absence of cholera toxin to avoid this confounding effect.

These results show that apoptotic cells induce radially propagating ERK/Akt waves in neighboring healthy cells.

ERK waves also occur in MDCK and NRK-52E monolayers and MCF10A acini

As previously described (Aoki et al., 2013), we also observed similar ERK waves triggered by apoptosis in Madin-Darby Canine Kidney (MDCK) and NRK-52E renal epithelial cell monolayers expressing the EKAREV-NLS ERK sensor (Figure 2A; Video S2). Analysis of signaling trajectories ranked according to the distance from the apoptotic cell showed that ERK activity propagated radially/unidirectionally in both lines (Figure 2B). MDCK ERK waves were large, often mixed with neighboring waves, and traveled outside the field of view. NRK-52E ERK waves involved mainly 1–2 layers, leading to activation of ~20 cells (Figures 2C and 2D). To exclude the possibility that signaling waves were artifacts of the monolayer culture, we evaluated ERK dynamics in 3D MCF10A acini cultures (Debnath et al., 2003). We found that single apoptotic cells can trigger radially propagating ERK waves in neighboring cells (Figures 2E and 2F). These waves occur alongside other, more frequent non-apoptotic ERK waves that occur spontaneously and control mammary acinar morphogenesis (Ender et al., 2020). These results show that at least ERK waves occur in different epithelial cell types, species, and culture dimensionalities.

ERK/Akt waves are initiated during the early morphological events of apoptosis

ERK/Akt waves were triggered by apoptosis that resulted from starvation but also when apoptosis was induced by doxorubicin or etoposide (Figures S2A–S2C). Apoptosis is associated with a prototypical sequence of morphological events that include nuclear shrinkage, plasma membrane blebbing, chromatin condensation, cell extrusion, nuclear fragmentation, and disaggregation into apoptotic bodies (Saraste and Pulkki, 2000). In epithelial cells, the two latter events are usually preceded by extrusion that removes the apoptotic body before fragmentation (Gagliardi et al., 2018; Rosenblatt et al., 2001). However, in MCF10A cells extrusion was only successful in 40% of apoptotic events, while in 60% of the events, formation of apoptotic bodies was occurring within the monolayer. The onset of the ERK/Akt waves coincided with nuclear shrinkage, the first event of the apoptosis sequence, which was then used as a reference to temporally align the collective events (Figures 3A and 3G). The other morphological hallmarks of apoptosis, including epithelial extrusion, occurred after the emergence of the signaling wave, ruling them out as potential initiators of the wave (Figures 3B–3G).

To causally link apoptosis with signaling wave initiation, we used OptoBAX, an optogenetic actuator that selectively induces apoptosis with single-cell resolution (Godwin et al., 2019). Low efficiency transfection was used to achieve stochastic expression of plasmids encoding Cry2-BAX and a mitochondrion-anchored Cib fusion in the monolayer (Figure 3H). Upon exposure to blue light, Cry2-BAX translocates to the mitochondrion and

induces mitochondrial outer membrane permeabilization (MOMP) (Figure 3I), causing apoptosis in less than an hour. We observed that OptoBAX-induced apoptosis triggered an ERK wave identical to the one caused by starvation-induced apoptosis (Figure 3J).

To further delineate the mechanisms that trigger the signaling wave, we treated cells with zVAD-FMK, a pan-caspase inhibitor. zVAD-FMK did not prevent ERK/Akt waves in starvation-induced

or OptoBAX-triggered apoptosis (Figures 3K, 3L, and S2D–S2H). Further, upon zVAD-FMK treatment, apoptotic cells triggering signaling waves still displayed caspase-independent nuclear shrinkage and chromatin condensation (Figures S2I and S2J) but did not exhibit caspase-dependent extrusion or apoptotic body formation (Figure S2K). This shows that ERK/Akt waves can be triggered by MOMP and correlate with the initial morphological events of apoptosis, independently of caspase activation.

ERK/Akt waves are triggered through EGFR and MMP signaling

To explore the signaling networks responsible for the apoptosis-triggered ERK/Akt waves, we treated starved monolayers with different inhibitors. MEK inhibition abrogated ERK waves without having any effect on Akt waves. Conversely, Akt inhibition abrogated Akt waves without any effect on ERK waves (Figures 4A and S3A–S3C). This suggests a common upstream activator of ERK/Akt. Paracrine EGFR signaling initiated by MMP-mediated cleavage of pro-EGF ligands occurs in different epithelial

systems (Aoki et al., 2017; Young et al., 2015). Inhibition of EGFR catalytic activity by gefitinib, ligand binding by cetuximab, or MMPs by batimastat completely abrogated apoptosis-triggered ERK/Akt waves (Figures 4A and S3D–S3F). OptoBax-triggered apoptosis yielded identical results (Figures 4B and S3G). Treatment with doramapimod and SP600125, inhibitors of p38MAPK and JNK activity, respectively, showed that ERK/Akt waves are independent from these two pathways (Figures 4A, S3I, and S3J). Treatment of cells with gefitinib, batimastat or the IGF-1R inhibitor BMS754807 and simultaneous stimulation with EGF or insulin-like GF (IGF-I), shows the specificity of EGFR inhibition on ERK/Akt activity (Figure S4A).

To understand whether ERK/Akt waves propagated due to free diffusion of secreted EGFR ligands, we evaluated signaling responses under flow using a microfluidic device (Ryu et al., 2015). Based on the typical diffusion coefficient of small secreted EGFR ligands (Nauman et al., 2007), we evaluated that a 25-μm/s flow was sufficient to counteract EGFR ligand's diffusion (Figure S4B). Using fluorescent beads, we calibrated the microfluidic device to apply the desired flow (Figures S4C–S4E; Video S3). ERK/Akt waves and their signaling trajectories did not differ in the presence or absence of flow (Figures 4C, S4F, and S4G). Furthermore, the flow did not affect the size or the symmetry of waves (Figures 4D and 4E), ruling out free diffusion of any EGFR ligand as a mechanism to shape waves.

Previous reports have identified ADAM metallopeptidase domain 17 (ADAM17) as the MMP involved in generation of ERK signaling waves induced by oncogenes in healthy neighbors or during wound repair *in vitro* (Aikin et al., 2020; Aoki et al., 2017). To explore its involvement in apoptotic ERK waves, we used ADAM17 knockout cells (ADAM17 KO) (Aikin et al., 2020). ADAM17 KO did not abrogate apoptosis-triggered ERK waves, but caused asynchronous, delayed, and smaller waves (Figures S4H–S4J). To understand whether apoptotic or neighboring cells require ADAM17 to transmit the signal, we performed co-culture experiments (Figures 4F and 4G). Wild-type (WT) apoptotic cells within ADAM17 KO neighbors yielded normal ERK waves. In contrast, ADAM17 KO apoptotic cells within WT neighbors triggered aberrant ERK waves as described above (Figures 4F–4H), without changing the wave size (Figure S4K). These local phenomena led to striking effects on the population-level frequency of ERK pulses. A pure ADAM17 KO cell population displayed a reduced ERK pulse frequency when compared with a WT cell population (Figure 4I). When co-cultured, ADAM17 KO cells showed an increased pulse frequency. Conversely, WT cells showed a decreased pulse frequency (Figures S4L and S4M). These results indicate MMP-mediated cleavage of pro-EGF ligands, partially through

ADAM17, regulates ERK/Akt waves in an EGFR-dependent fashion (Figure 4J).

ERK/Akt waves are not necessary for cell extrusion

Next, we explored the function of the apoptosis-triggered ERK/Akt waves. We hypothesized that ERK/Akt waves might regulate cytoskeletal processes during epithelial extrusion (Gagliardi et al., 2018; Rosenblatt et al., 2001). This is in line with the ERK waves regulating myosin contractility during wound repair (Aoki et al., 2017). To test this hypothesis, we detected cumulated apoptotic debris extruded in the supernatant (Figure S5A). We used starvation to trigger apoptosis and epithelial extrusion. Inhibition of extrusion caused by zVAD-FMK led to low amounts of apoptotic debris in the supernatant (Figures S5B and S5C). In contrast, inhibition of ERK/Akt waves using MEK, Akt, EGFR, and MMPs inhibitors did not block this process (Figure S5D). Direct observation of individual extrusion events in MCF10A cells (Figure S5E) and measurements of extrusion time in MDCK cells yielded similar results (Figure S5F). We also evaluated the assembly of the extrusion basal actomyosin ring using cells co-expressing LifeAct-mCherry and ERK-KTR-mTurquoise2 (Figure S5G). The closure of the basal actomyosin ring occurred during the first hour after nuclear shrinkage and completely depended on caspase activity. Trametinib-, gefitinib-, cetuximab-, or batimastat-mediated ERK or AZD5362-mediated Akt inhibition did not yield any noticeable effect on ring closure (Figure S5G). Altogether, these results imply that EGFR-dependent ERK/Akt waves are not necessary for cytoskeletal processes during epithelial extrusion.

Apoptosis-triggered ERK/Akt waves provide local survival signals

We then explored whether signaling waves regulate fate decisions. ERK pulses regulate EGF-dependent cell-cycle entry (Albeck et al., 2013). However, starved MCF10A cells seldom proliferate (Ethier and Moorthy, 1991). Given that ERK/Akt signaling also regulates survival (Franke et al., 2003; Lu and Xu, 2006), we hypothesized that the signaling waves provide local survival signals. To test this, we evaluated how signaling dynamics regulates survival and apoptosis fates at the single-cell level. We restricted the analysis to ERK signaling, produced a high-quality dataset of trajectories with 1 min resolution, and annotated >1,000 apoptotic events. First, we compared ERK trajectories in a 6 h window before apoptosis with those of non-apoptotic cells during the same window. For that purpose, we trained a convolutional neural network (CNN) to classify apoptotic and non-apoptotic cells based on ERK activity (Figures 5A and 5B). A tSNE projection of the data-driven features learned to separate

Developmental Cell
Article

CellPress

the classes showed clustering of apoptotic and non-apoptotic ERK trajectories (Figure 5A). Prototype trajectories, for which the model confidence was the highest, showed that the ERK pulse frequency is the most discriminative factor used by the CNN to separate apoptotic from non-apoptotic fates (Figure 5B). Based on this observation, we compared ERK pulse frequency with the cell fate and with the CNN classification output. ~65% of cells that did not exhibit any ERK pulses were apoptotic. In contrast, only ~30% of cells with 2–5 pulses and 0% with >5 pulses underwent apoptosis (Figure 5C). Evaluation of ERK trajectories in MDCK and NRK-52E cells also revealed a reduced pulse frequency in apoptotic cells compared with non-apoptotic cells (Figure S6A). These results suggest that the apoptosis/survival fates in starved monolayers depend on the ERK pulse frequency.

Second, we quantified differences in participation of apoptotic and non-apoptotic cells in collective signaling events. We developed a computational approach that automatically identifies collective ERK waves (Figures 5D and S6B). We found that 24% (SD = 6) of ERK pulses were part of such events and that 67% (SD = 8) of collective waves were triggered by apoptosis within a 20 min time window. Then, we temporally aligned ERK trajectories of apoptotic cells with respect to apoptotic events, overlaid occurrences of collective events, and compared the incidence of the latter with those of non-apoptotic cells (Figure 5E). Collective ERK signaling events occurred in only ~32% of apoptotic trajectories, compared with ~53% non-apoptotic cells (Figures 5E and 5F). Moreover, ERK pulsing during a 3 h window before apoptosis was less frequent than in the time before (Figures 5E and S6C). These results indicate that cells that experience collective ERK events are less likely to die than cells that do not.

Third, we explored whether an ERK pulse within an apoptosis-triggered signaling wave locally promotes survival. Thus, we evaluated the signaling history of "secondary" apoptotic cells located within the 1st layer of neighbors of a primary apoptotic event (Figures 5G–5I; Video S4). We found that up to 4 h after the primary apoptosis, secondary apoptosis is significantly less likely to occur in cells that experienced an ERK pulse induced by the primary event (Figure 5J). We obtained the same result with the 2nd layer of neighbors (Figure S6D). Evaluating the cumulative distribution of the probability of a secondary apoptotic event revealed a lower apoptosis probability for neighbors that received a pulse from the primary apoptotic event compared with those that did not (Figure S6E). This strongly suggests that apoptosis induces waves of ERK and Akt activity that locally induce survival for approximately 4 h. We term this process apoptosis-induced survival (AiS).
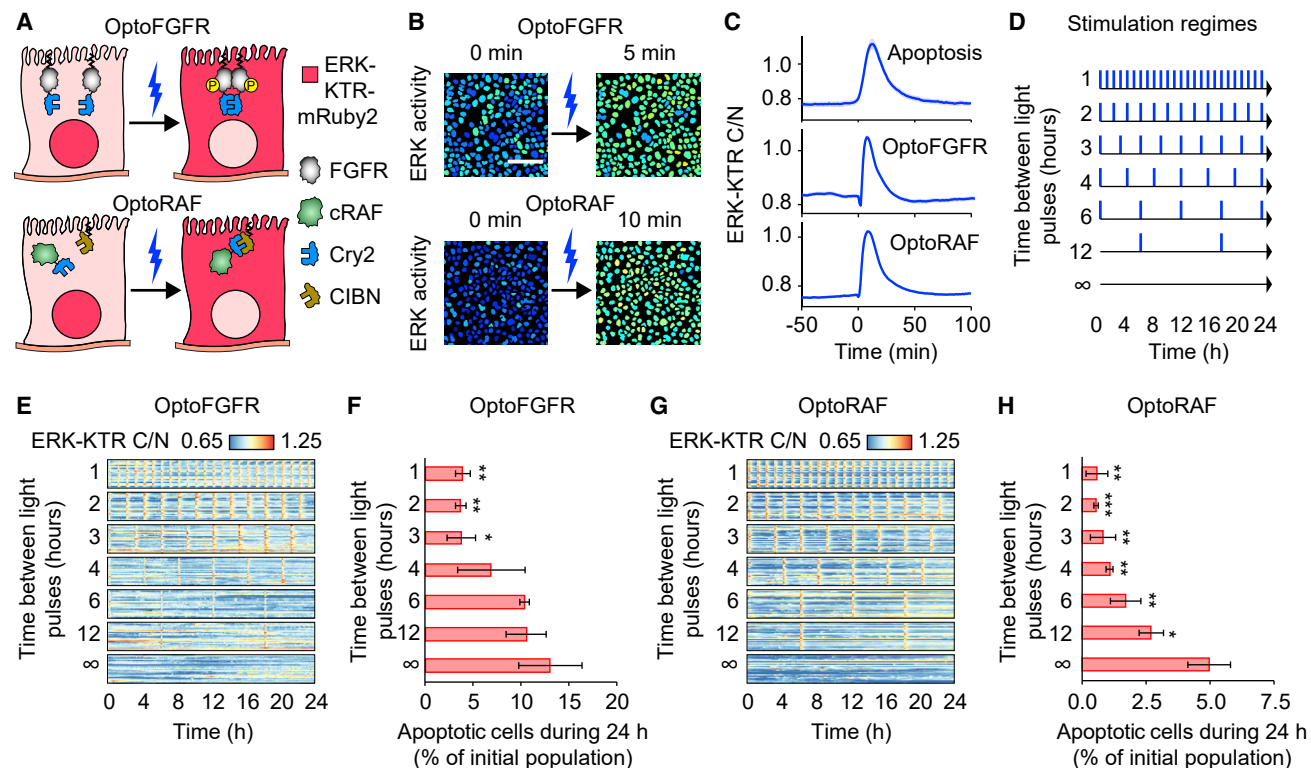

ERK pulse frequency determines survival fate

To establish whether specific signaling dynamics regulates the survival fate, we used 2 optogenetic systems to evoke different signaling pulse frequencies. We simultaneously measured ERK activity using spectrally compatible ERK-KTR-mRuby2 (Figure 6A). The first system is a photo-excitable fibroblast growth factor (FGF)-1-based receptor (OptoFGFR) that activates both ERK and Akt signaling (Kim et al., 2014) and thus mimics the EGFR-dependent signaling observed in our cell system. The second is a photo-excitable RAF construct (OptoRAF) that

selectively controls ERK activity (Aoki et al., 2017). For both systems, a 100 ms of 3 W/cm^2 pulse of blue light could induce a robust ERK pulse of similar amplitude (Figures 6B and 6C; Video S5). We induced ERK pulses with light stimulation applied every 1, 2, 3, 4, 6, and 12 h with both optogenetic systems during a 24-h period after starvation (Figures 6D, 6E, and 6G). We measured a robust reduction of the apoptotic rate when ERK pulses were triggered at least every 3 h with OptoFGFR (Figure 6F; Video S6). At the cell population level, this almost completely suppressed the peak of apoptosis triggered by starvation (Figure S6F). ERK or Akt inhibition abrogated the protection granted by the stimulation of OptoFGFR at high frequency (Figure S6G). We observed similar effects with OptoRAF in which high stimulation frequencies (1, 2, 3, and 4 h pulse periodicity) provided robust protection, which then gradually diminished at lower frequencies (Figure 6H). Contrary to OptoFGFR, the effect of OptoRAF pulses on survival was independent from Akt activity (Figure S6H) and completely dependent on the MAPK pathway (Figures S6I and S6J). Using batimastat, which unspecifically increases the apoptosis rate regardless of light pulses, we also excluded a possible ERK-ADAM17-EGFR axis through which OptoRAF could exert its pro-survival effect (Figure S6K). Using both optogenetic systems, ERK pulses induced every 3–4 h were sufficient for survival. OptoFGFR mediated its effect through both ERK and Akt, while OptoRAF only through ERK. However, the expression of the OptoRAF system increases basal survival (compare Figures 5F and 5H), introducing a small bias in our system.

AiS maintains epithelial integrity in response to environmental insults of different intensities

AiS might contribute to population-level EH and epithelial integrity in response to environmental insults. To explore that, we evaluated the rate of apoptosis in response to starvation and compared it with population-averaged ERK/Akt activity (Figure 7A). Monolayer starvation resulted in a transient peak of apoptosis that started 2–3 h after starvation and lasted for another 4–5 h until a steady state, low apoptosis rate ensued. Strikingly, population-averaged ERK/Akt activities immediately decreased with starvation and transiently reactivated with kinetics that were slightly delayed with respect to the apoptotic rate. This suggests that the whole monolayer can adapt to starvation-induced stress by dynamically regulating survival to maintain EH and epithelial integrity.

We built a mathematical model to capture the dynamic relationship between apoptosis and survival. The model consists of 2 interacting components: apoptotic cells, and the protection from cell death mediated by ERK/Akt activity (Figure 7B). The increase in protection level depends on the rate of apoptosis, which in turn is negatively regulated by the amount of protection in the system. We varied the rate constants of apoptosis and protection activation and calculated the fold change in the half-life of the initial cell pool with respect to the half-life of a pure exponential decay, i.e., a model without the protection component (Figure 7C). We investigated 3 scenarios (Figures 7C and 7D). In scenario 1, we set a low rate of apoptosis and a high rate of protection activation to mimic our starvation experiment (Figure 7D). The model agreed with the starvation experiment (Figure 7A) in that an episode of increased apoptosis is followed

Figure 6. Frequency of ERK pulses determines the survival fate

(A) Cartoon of the two optogenetic tools used to induce synthetic pulsed ERK signaling regimes. OptoFGFR is a CRY2-based, blue-light-dimerizable, plasma-membrane-linked FGFR1 intracellular domain. OptoRAF consists of cRAF fused to CRY2 and a plasma-membrane-targeted truncated (amino acids 1-170) version of cryptochrome-interacting basic-helix-loop-helix1 (CIBN).

(B) Representative micrographs of ERK-KTR C/N ratio in OptoFGFR- and optoRAF-expressing cells before and after a blue-light pulse. Scale bar, 100 μm.

(C) Average ERK activity trajectories from apoptotic neighbors, or from cells expressing OptoFGFR or OptoRAF in response to blue light. Mean and 95% confidence interval are shown.

(D) Different blue-light stimulation regimes ranging from 1 pulse/h to no pulsing.

(E) ERK signaling trajectories in OptoFGFR-expressing cells responding to the stimulation regimes in (D).

(F) Apoptotic rate of OptoFGFR-expressing cells during 24 h after starvation in response to the stimulation regimes in (D).

(G and H) Same as (E and F) but using OptoRAF-expressing cells. Error bars represent the standard deviation of 3 replicates. t test with respect to unstimulated cells (*p < 0.05; **p < 0.01; ***p < 0.001).

by a delayed induction of protection. In scenario 2, we increased the rate of apoptosis (e.g., as possibly induced by a cytotoxic drug), which yielded higher apoptosis and protection levels after the initial transient (Figure 7D, upper panel). Although the cell number decreases faster in scenario 2 than in scenario 1, the high protection level prevents cells from dying with the rate of a pure exponential decay (Figure 7D, lower panel). In scenario 3, we maintained the high apoptosis rate, but we lowered the protection rate (e.g., by inhibiting ERK/Akt activity). Here, the apoptosis rate exhibits a much slower transient due to a weaker protection (Figure 7D upper panel), leading the cell count to closely follow a pure exponential decay (Figure 7D, lower panel).

To experimentally validate the results obtained from the model (scenarios 2/3), we treated our cells with doxorubicin, which induces apoptosis by oxidative stress in MCF10A cells (Gajewski et al., 2007). A dose response screen identified 2.5 and 5 μM doxorubicin as concentrations that induce potent cell death (Figure S7A). This induced a steep apoptosis increase from 5 to 7 h after incubation, followed by steady apoptosis levels that corresponded to approximately 3%–4% of the cell population per

hour for more than 10 h (Figure S7B). The steep apoptosis increase was followed by a slightly delayed increase of ERK/Akt population average activity that then remained high (Figures 7E, S7C, and S7D). Lower doxorubicin doses that promoted low apoptosis only led to low ERK/Akt activity (Figures S7C and S7D). These results are in line with the predictions of scenario 2 of our model (Figure 7D). To exclude that ERK/Akt activation was due to accumulation of EGFR ligands in the supernatant, we kept the cells under constant perfusion (Figure S4C). With doxorubicin, we observed an increase in the apoptotic rate reaching about 4% at 13 h post addition (Figure S7E). This also resulted in higher ERK/Akt activities compared with the untreated control (Figures S7F–S7H). This excludes accumulation of ligands as the cause of the global increase in ERK/Akt activity.

To explore if this sustained population-level ERK/Akt activity was due to AiS, we inhibited EGFR, MMPs, ERK, or Akt and evaluated apoptosis rates. While individual inhibitors had only modest effect on apoptosis, their combination with doxorubicin caused a dramatic increase in the apoptotic rate (Figures 7F, S7I, and S7J), as predicted in scenario 3 of our model (Figure 6D). To
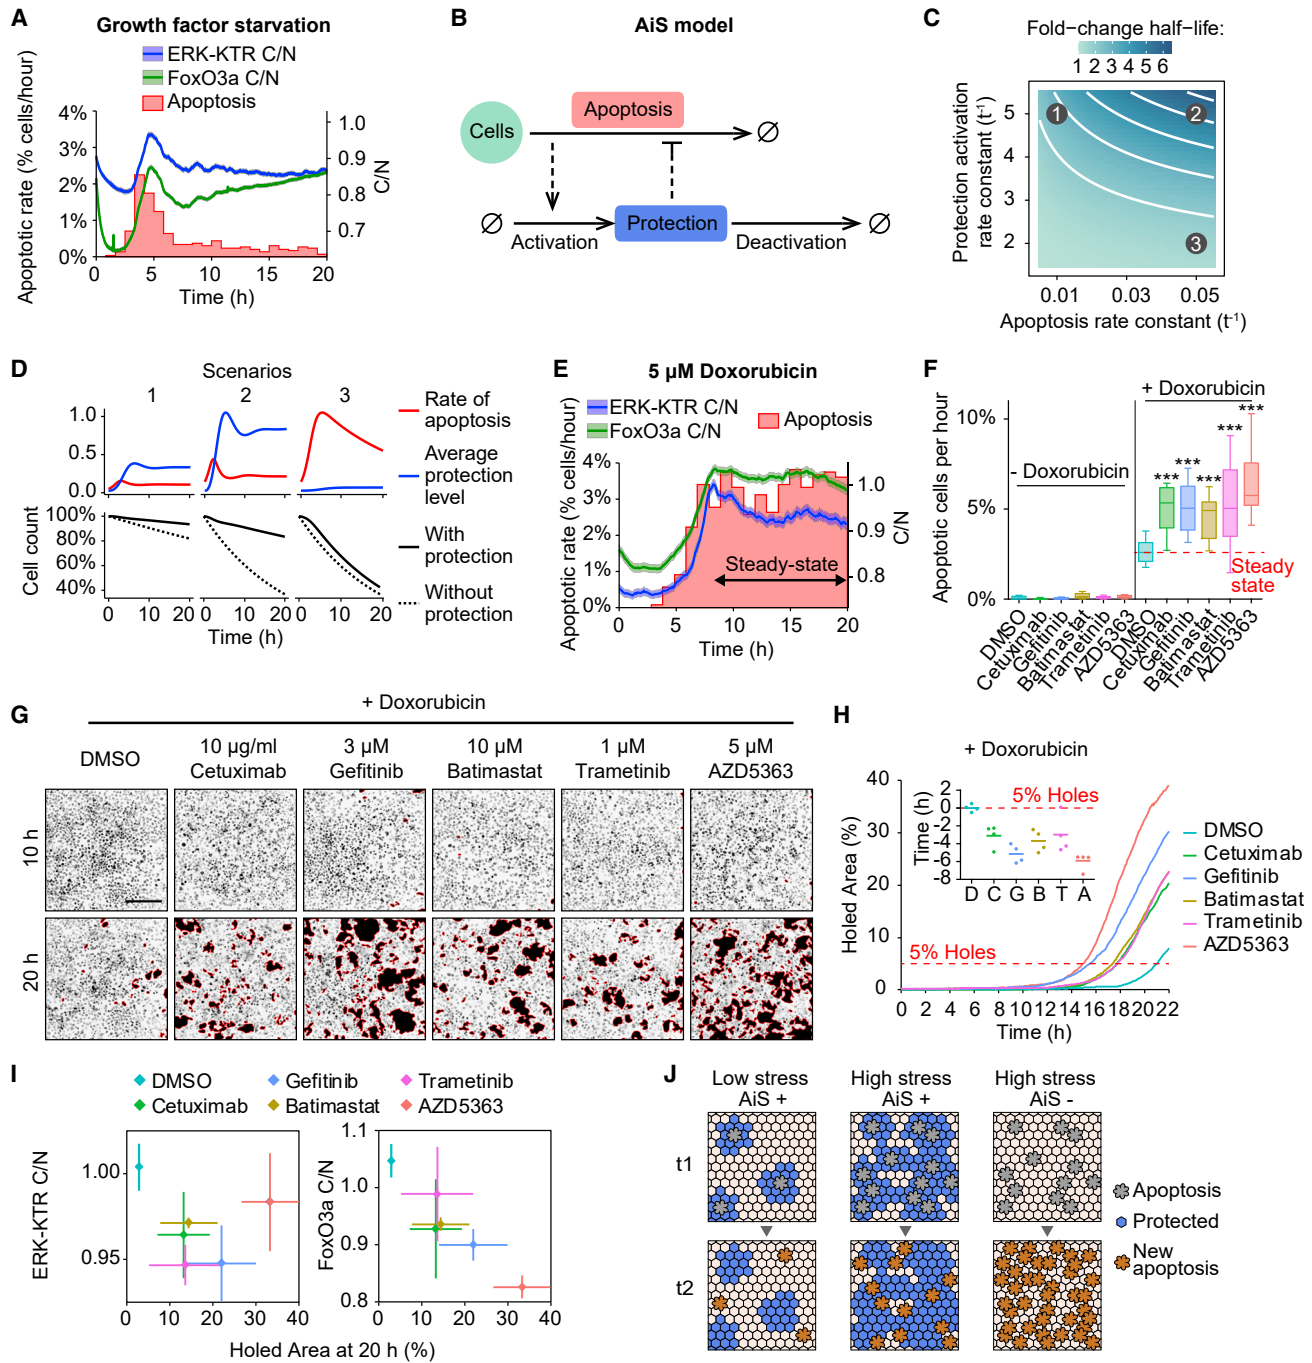

Figure 7. AiS maintains epithelial tissue integrity

(A) Rate of apoptotic cells per h after starvation, superimposed with average ERK/Akt activity trajectories of all cells in the analyzed FOVs. Shaded areas represent 95% CI.

(B) Two-component model of AiS. The rate of apoptosis induces the protection, which then inhibits apoptosis in the neighbors. The onset of protection is multi-stage, which introduces a delay in the apoptosis inhibition.

(C) Exploration of the model parameter space. Half-decay time of the initial pool of cells calculated as a fold change with respect to the half-decay time of an exponential decay without induction of protection. Isolines represent 2–6 fold-change half-life. Points indicate 3 scenarios explored in the next panel.

(D) Predicted rate of apoptosis, protection level and the cell count for 3 scenarios corresponding to: (1) starved untreated epithelium, (2) acute pro-apoptotic treatment, (3) acute pro-apoptotic treatment and AiS inhibition. The cell count is compared with an exponential decay without protection.

(E) Rate of apoptotic cells per hour after treatment with 5-µM doxorubicin, superimposed with average ERK and Akt activity trajectories. Shaded areas represent 95% CI.

(F) Distribution of the rate of apoptotic cells per hour 8–20 h after doxorubicin addition and in presence of different treatments.

characterize how changes in apoptosis rate impact epithelial integrity, we measured hole formation in the monolayer. We found that doxorubicin-drug combinations quickly led to loss of epithelial integrity ∼15 h after drug treatment, while doxorubicin alone only led to few holes (Figures 7G and 7H; Video S7). Further, we observed an inverse correlation between population-averaged ERK/Akt activity levels and the holed area 20 h after doxorubicin treatment (Figure 6I). These results strongly suggest that AiS contributes to epithelial integrity by reacting to environmental insults of different intensities (Figure 6J).

DISCUSSION

Epithelial tissues require dynamic coordination of apoptosis, survival, and proliferation to maintain a critical cell density and barrier function (Macara et al., 2014). We report on AiS, a signaling mechanism that preserves EH in response to environmental stresses (Figure 6J). At the single-cell scale, AiS involves apoptosis-triggered ERK/Akt waves that protect nearby cells from apoptosis for 3–4 h. At the population scale, AiS allows the cell collective to adjust survival fate levels to react to environmental insults of different intensities. This mechanism is conserved across different epithelial cell lines and might also contribute to mammary acinar morphogenesis.

Mechanism of ERK/Akt wave propagation

We find that the ERK/Akt wave propagation depends on canonical EGFR signaling (Figure 4J). This does not involve free diffusion of an EGFR ligand from apoptotic cells (Figures 4C–4E) but rather MMP-mediated cleavage of membrane-bound precursor EGFR ligands such as amphiregulin (Dong et al., 1999). This might generate a trigger wave, in which each cell layer sequentially activates the next one through EGFR/MMP signaling. We show that ADAM17 might be required for shedding of the EGFR ligand from the apoptotic cell (Figure 4J). However, ADAM17 loss does not completely abrogate ERK/Akt waves, suggesting the involvement of additional players. Similar EGFR/MMP-dependent ERK waves control myosin contractility to organize collective epithelial cell migration in MDCK cells (Aoki et al., 2017; Hino et al., 2020). This suggests that EGFR/MMP-dependent ERK/Akt waves are an evolutionarily conserved pathway that can spatially regulate collective cell migration and AiS-dependent EH.

Another factor that shapes the signaling wave is the non-linearity of the MAPK cascade (Birtwistle and Kolch, 2011). The Raf/MEK/ERK cascade exhibits ultrasensitivity and adaptation (Ryu et al., 2015; Santos et al., 2007; Sparta et al., 2015), producing short ERK pulses of full amplitude even at low EGFR input. The finding that the number of ERK pulsing cells decreases in the successive layers of the wave (Figure 1I) suggests that the EGFR/MAPK cascade operates at the threshold input required

for production of all-or-nothing ERK responses. This is consistent with the minute amounts of EGFR ligand that might be released by MMPs. Thus, the observed 3-layer reach of the signaling wave might partly stem from the architecture of the MAPK network. A similar network logic might produce Akt pulses.

Fate decision regulation by ERK/Akt pulse frequency

EGF-stimulated and apoptosis-triggered ERK/Akt pulses are virtually indistinguishable when compared outside of their spatial context (Figures 1A and S1D). We show that low versus higher ERK pulse frequencies correlate with apoptosis and survival respectively (Figures 5A–5C). EGF stimulation can further increase pulse frequency, leading to cell-cycle entry (Albeck et al., 2013). This suggests that low, medium, and high ERK/Akt pulse frequencies, respectively, correlate with apoptosis, survival, and proliferation fates. In native tissues, combinatorial control of ERK/Akt pulses triggered by apoptosis or other sources might fine-tune EH by contributing to both survival/proliferation fates.

How does a cell interpret the ERK/Akt signaling frequency into these specific fates? Several known ERK or Akt substrates have been implicated in regulating survival, such as the Akt substrate BCL2 associated agonist of cell death (BAD) (Datta et al., 1997) or the ERK substrate Bcl-2-like protein 11 (BIM) (Harada et al., 2004). Another fate decision mechanism might involve ERK/Akt-dependent control of transcriptional programs (Avraham and Yarden, 2011). In the case of ERK, this involves immediate early genes (IEGs) that produce unstable transcripts with lifetimes of 30–40 min, that in turn regulate the transcription of delayed early genes (DEGs) with a lifetime of 1–3 h. Thus, one digital ERK/Akt pulse might switch on gene expression that fluctuates on the AiS timescale, allowing the cell collective to reset its survival fate and to remain responsive to future stimuli. High signaling frequencies might then allow to control the proliferation fate by regulation of IEGs such as Fra-1 that can linearly integrate ERK activity over time (Gillies et al., 2017). Another function of Akt pulses might be the single-cell regulation of metabolic activities required for enforcing specific fate decisions (Hung et al., 2017). Finally, we speculate that the ERK pulses might regulate myosin contractility on the timescale of minutes (Aoki et al., 2017; Hino et al., 2020) and fate decisions such as survival on the timescale of hours. Thus, the MAPK pathway might function in an integrative fashion by regulating processes at different timescales to coordinate cytoskeletal and survival/proliferation responses during morphogenetic processes.

Population-level AiS responses

Our experiments and computational simulations show that upon the induction of apoptosis, e.g., through starvation or cytotoxic drugs, the feedback embedded in AiS allows the epithelium to

dynamically adapt to different apoptotic rates. This might help to mitigate acute spikes of apoptotic rates that potentially compromise epithelial integrity, and to reach a new steady-state rate of apoptosis compatible with the regenerative capability of the epithelial tissue. Our mechanistic explanation of AiS is consistent with numerous reports in which targeting EGFR-ERK/Akt sensitizes cancer cells to chemotherapeutic agents (Barbuti et al., 2019; Holt et al., 2012; Smolensky et al., 2017). This provides a rationale to test further targeted/cytotoxic combination therapies to obtain better therapeutic responses in cancer.

Physiological relevance of AiS signaling

Further studies are needed to understand the role of AiS *in vivo*. ERK activity waves have been observed *in vivo* in mouse epithelia (Hiratsuka et al., 2015). Here, the ERK activity waves correlate with G2/M cell-cycle progression, but it is conceivable that additional inputs, not present in our starved monolayer, control this specific fate decision. Valon and colleagues (Valon et al., 2021) reported apoptosis-triggered, EGFR-dependent ERK pulses during development of the *Drosophila* pupal notum. This might provide robustness against external perturbations during development. These similarities suggest that AiS is a highly conserved mechanism regulating epithelial integrity throughout the animal kingdom.

Limitations of the study

Here, we have focused on how apoptosis-induced ERK/Akt waves regulate survival. However, we cannot formally exclude that other signaling pathways also feed into the regulation of survival.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

RESOURCE AVAILABILITY

Lead contact
Further information and requests for resources and reagents should be directed to the Lead Contact, Olivier Pertz (olivier.pertz@izb.unibe.ch).

Material availability
Plasmids generated in this study are available upon request.

Data and Code Availability
The original data and R notebooks with code required to reproduce the plots have been deposited to Mendeley Data (https://doi.org/10.17632/kd3n5k784m).

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Cell lines
Wild-type human mammary epithelial cells MCF10A cells were a gift of J.S. Brugge, Harvard Medical School, Boston, MA. ADAM17 KO MCF10A cells expressing H2B-iRFP (no selection), ERK1-mRuby2 (Blast), ERK-KTR-mCerulean3 (Hygro) and their WT counterpart were a gift of T. Aikin and S. Regot, Johns Hopkins School of Medicine, Baltimore, MD (Aikin et al., 2020). MCF10A cells were cultured in growth medium composed by DMEM:F12 supplemented with 5% horse serum, 20 ng/ml recombinant human EGF (Peprotech), 10 μg/ml insulin (Sigma-Aldrich/Merck), 0.5 mg/ml hydrocortisone (Sigma-Aldrich/Merck), 200 U/ml penicillin and 200 μg/ml streptomycin. All the experiments were carried out in starvation medium composed by DMEM:F12 supplemented with 0.3% BSA (Sigma-Aldrich/Merck), 0.5 mg/ml hydrocortisone (Sigma-Aldrich/Merck), 200 U/ml penicillin and 200 μg/ml streptomycin. Growth factor and serum starvation experiments were executed by removing the growth medium, 2 washes in PBS and replacement with starvation medium. MDCK and NRK-52E expressing EKAREV-NLS were a gift from K. Aoki (Aoki et al., 2013, 2017). MDCK and NRK-52E cells were cultured in DMEM supplemented with 10% FBS, 200 U/ml penicillin and 200 μg/ml streptomycin.

METHOD DETAILS

Compounds and proteins
AZD5363 (Selleck Chemicals), Batimastat (MedChem Express), BMS-754807 (MedChem Express), Doramapimod (MedChem Express), Doxorubicin (MedChem Express), Etoposide (MedChem Express), Gefitinib (Sigma-Aldrich/Merck), SCH772984 (MedChem Express), SP600125 (MedChem Express), Trametinib (Selleck Chemicals) and zVAD-FMK (UBPBio) were dissolved in DMSO and preserved at -20°C in small aliquots to avoid thaw-freeze cycles. Cetuximab was purchased from MedChem Express. EGF (Peprotech) and IGF-I (Peprotech) were dissolved in aqueous solution and preserved at -20°C.

Plasmids
The stable nuclear marker H2B-miRFP703 was a gift from Vladislav Verkhusha (Addgene plasmid # 80001) (Shcherbakova et al., 2016), and subcloned in the PiggyBac plasmid pPBbSr2-MCS. ERK-KTR-mTurquoiose2 and ERK-KTR-mRuby2 sequences were synthesized (GENWIZ) by fusing the ERK Kinase Translocation Reporter (ERK-KTR) CDS (Regot et al., 2014) with mTurquoiose2 (Goedhart et al., 2012) and mRuby2 (Lam et al., 2012) CDSs, respectively. FoxO3a-mNeonGreen sequence was synthesized (GENWIZ) by fusing the 1-1188 portion of the homo sapiens forkhead box O3 a (FoxO3a) CDS with mNeonGreen CDS, a green fluorescent protein derived by Branchiostoma lanceolatum (Shaner et al., 2013). ERK-KTR-mTurquoiose2, ERK-KTR-mRuby2, FoxO3a-mNeongreen and LifeAct-mCherry were cloned in the PiggyBac plasmids pMP-PB, pSB-HPB (gift of David Hacker, Lausanne,

Developmental Cell
Article

CellPress

(Balasubramanian et al., 2016)) or pPB3.0.Blast, an improved PiggyBac plasmid generated in our lab. For stable DNA integration we transfected the PiggyBac plasmids together with the helper plasmid expressing the transposase (Yusa et al., 2011). Transfection of MCF10A cells was carried out with FuGene (Promega) according to the manufacturer protocol. Stable clones with the different biosensors/optogenetic tools were generated by antibiotic selection and image-based screening.

The MOMP optogenetic actuator Cry2(1–531).L348F.mCh.BAX.S184E and Tom20.CIB.GFP, originally designated as the OptoBAX 2.0 system, and here termed as OptoBAX, was generated by Robert M Hughes (Godwin et al., 2019). Lyn-cytoFGFR1-PHR-mCit, expressing myristoylated FGFR1 cytoplasmic region fused with PHR domain of cryptochrome2 and mCitrine, here defined as OptoFGFR, was a gift from Won Do Heo (Addgene plasmid # 59776) (Kim et al., 2014). Lyn-cytoFGFR1-PHR-mCit was subcloned in a lentiviral backbone for stable cell line generation. pPB3.0-PuroCRY2-cRAF-mCitrine-P2A-CIBN-KrasCT, here defined as OptoRAF, was generated as an improvement of the previously reported light-induced ERK activation system, gift from Kazuhiro Aoki (Aoki et al., 2017). Cloning was done in two steps. First, the CRY2-cRaf sequence was cut from the pCX4puro-CRY2-cRAF plasmid using EcoRI and NotI. mCitrine was PCR amplified from the OptoFGFR plasmid adding NotI and XhoI sites and digested. Both sequences were ligated in the pPB3.0-Puro opened with EcoRI and XhoI. The GSGP2A-CIBN-KRasCT sequence (synthesized by GENWIZ) was digested with BsrGI and AflII and ligated in the opened pPB3.0-Puro-CRY2-cRAF-mCitrine.

Live imaging
MCF10A cells were seeded on 5 μg/ml Fibronectin (PanReac AppliChem) on 24 well 1.5 glass bottom plates (Cellvis) at 1×10^5 cells/well density two days before the experiment. Imaging experiments were performed on an epifluorescence Eclipse Ti inverted fluorescence microscope (Nikon) controlled by NIS-Elements (Nikon) with a Plan Apo air 20× (NA 0.8) or a Plan Apo air 40× (NA 0.9) objectives. Laser-based autofocus was used throughout the experiments. Image acquisition was performed with an Andor Zyla 4.2 plus camera at a 16-bit depth. The following excitation and emission filters (Chroma) were used: far red: 640nm, ET705/72m; red: 555nm, ET652/60m; NeonGreen: 508nm, ET605/52; GFP: 470nm, ET525/36m; mTurquoise2: 440nm, HQ480/40.

MCF10A acini
3D live imaging experiments with MCF10A acini and the accompanying image analysis were performed as described in (Ender et al., 2020). Single MCF10A cells were embedded in growth factor-reduced Matrigel (Corning) and kept in DMEM/F12 supplemented with 2% horse serum, 20 ng/ml recombinant human EGF, 0.5 mg/ml hydrocortisone, 10 μg/ml insulin, 200 U/ml penicillin and 200 μg/ml streptomycin, which induced the development of acini. After 3 days in culture, EGF, insulin and horse serum were removed from the medium. 25 mM Hepes was to the medium added before imaging.

Images were acquired on an epifluorescence Eclipse Ti2 inverted fluorescence microscope (Nikon) equipped with a CSU-W1 spinning disk confocal system (Yokogawa) and a Plan Apo VC 60X water immersion objective (NA = 1.2). Image acquisition was done at 16 bit depth with a Prime 95B camera (Teledyne Photometrics). A temperature control system and gas mixer (both Life Imaging Services) were used throughout imaging, as well as laser-based autofocus.

3D segmentation of nuclei and extraction of cytosolic/nuclear ERK KTR fluorescence intensity levels were performed using an updated version of the open source LEVER software (Winter et al., 2016). The apoptotic event was manually identified and annotated.

Optogenetic experiments
Cells expressing OptoBAX, OptoFGFR or OptoRAF were kept in the dark for at least 24h before the experiments and all preparatory microscope setup was carried out with red or green light (wavelength > 550 nm). In the case of OptoBAX, cells expressing H2B-miRFP703 and ERK-KTR-mTurquoise2 were transfected with OptoBAX plasmids the day before the experiment to obtain sparse transfected cells (< 1% of the total cell population) in the MCF10A epithelium. Cells expressing the OptoBAX system were identified through the expression of Cry2(1–531).L348F.mCh.BAX.S184E fusion protein that contains mCherry. Fields of view containing confluent monolayers and at max 1-2 OptoBAX cells were selected for the experiment. Cells were illuminated with whole field blue light at 440nm every two minutes for the entire duration of the experiment to both induce translocation of BAX to mitochondria and to image ERK-KTR-mTurquoise2. Additionally cells were illuminated at 508nm to visualize Tom20.CIB.GFP, 555nm for mCherry (BAX fusion protein) and 640nm H2B-miRFP703. In the cases of OptoFGFR or OptoRAF, cells expressing H2B-miRFP703 and ERK-KTR-mRuby2 were infected with the lentiviral vector expressing Lyn-cytoFGFR1-PHR-mCit or transfected with pPB3.0.PURO.CRY2.cRAF.mCitrine.P2A.CIBN.KrasCT plasmid to generate stably expressing clones. Cells were imaged at 555nm for mRuby2 and 640nm H2B-miRFP703, and stimulated with 488 nm blue light for 100 ms at 3 W/cm^2, when required by the experiment protocol. Stimulation experiments were controlled by NIS jobs.

Image analysis
For nuclear segmentation, we used a random forest classifier based on different pixel features available in Ilastik software (Berg et al., 2019). For the training phase, we manually annotated nuclear (in 20-50 cells) and background pixels in 16-bit time-lapse TIF images of the nuclear channel (H2B-miRFP703). The probability map of nuclei was then exported as 32-bit TIF images to perform threshold-based segmentation using CellProfiler 3.0 (McQuin et al., 2018). Expansion of nuclear objects by a predefined number of pixels was used to identify the area corresponding to the cytoplasm on a cell-by-cell basis, as described previously (Pargett et al., 2017). Cytosol/nuclear ratio was calculated by dividing the average cytosolic pixel intensity by the average nuclear pixel intensity. For visualization and quality control, we created images of segmented nuclei color coded according to ERK-KTR C/N. Single-cell tracking was performed on nuclear centroids in MATLAB using μ-track 2.2.1 (Jaqaman et al., 2008). For FRET experiments with

CellPress

Developmental Cell
Article

MDCK and NRK-52E expressing EKAREV-NLS we used a partially modified pipeline. We used the donor channel for pixel classification of nuclei in Ilastik. We then used CellProfiler 3.0 to correct uneven illumination, to segment nuclei from the Ilastik nuclear prediction, and to calculate the FRET ratio, where the FRET image is divided pixel-by-pixel by the Donor image. Single-cell tracking was performed on nuclear centroids in MATLAB using μ-track 2.2.1.

Apoptotic events were annotated manually based on nuclear shrinkage to set time to 0. This approach showed higher accuracy compared to any available computational or marker-based methods.

Holes in the epithelial layer were identified using Ilastik's machine learning algorithm starting from the manual annotation of holes in a combined ERK-KTR-mTurquoiose2 FoxO3a-mNeonGreen channel. After segmentation of the hole probability, their total area in each frame and field of view was calculated with Fiji.

Extrusion assay

MCF10A cells were seeded in 6 well plates (TPP Techno Plastic Products AG) at 4×10^5 cells and grown for 3-4 days till reaching the homeostatic confluent state. The evening before, the wells were washed twice with DMEM:F12, 0.3% BSA, 0.5 mg/ml hydrocortisone, 200 U/ml penicillin and 200 μg/ml streptomycin. After 16h, suspended material, including cell debris, was collected, concentrated and stained for 10 min with Hoechst and CellMask orange (Thermo Fisher). The stained debris were put in between two coverslips and acquired with a widefield fluorescence microscope with a 20× objective. Particles were segmented with CellProfiler 3.0 and data analyzed with R.

Microfluidic device fabrication and preparation

Microfluidic devices were prepared as described previously (Ryu et al., 2015). Polydimethylsiloxane (PDMS) polymer (Dow Corning) was mixed with the catalyzer in 10:1 ratio in a plastic beaker. A first layer of 4–5 g was poured on the master and then degassed in a desiccator before solidifying at 80°C for 1 h. Eight-well reservoir strips (Evergreen) were divided in 2 and then glued on the first layer using PDMS and solidifying at 80°C for 30 min. Finally, the second layer of 15–20 g of PDMS is used to finalize the device. The PDMS replica was cut and punched at the appropriate inlets and outlets. Plasma treatment was used to bond the PDMS replica to the 50 × 70 mm coverslip (Matsunami, Japan) to allow for proper sealing that resists the high-pressure applied during the experiments. To enhance the bonding strength, the device was heated for 15 min in an 80°C dry oven. After bonding, the device was immediately filled by adding 200 μl of 10 μg/ml fibronectin solution in PBS to each outlet reservoir and put at 37°C. To increase coating efficiency in the device, 10 μl of the fibronectin solution was aspirated 3× from the cell seeding port after 1 h each before seeding cells.

MCF10A cell suspensions were prepared at a concentration of 1×10^7 cells/ml. 30 μl of this cell suspension was added to the outlet reservoir and aspirated with a pipette from the cell reservoir inlet port. 250 μl complete medium was added to each outlet reservoir and 150 μl of starving medium to each inlet reservoir. Devices were kept overnight in the incubator. Before experiments, the medium in the inlet and outlet reservoir was removed and 240 μl of appropriate medium was added to the inlet reservoir. Before imaging, devices were connected to an Elevsys OB-1 flow controller and the desired air pressure (0 or 500 mPsi was applied).

Data analysis

To analyze and visualize single-cell ERK/Akt activity time series, we used Time Course Inspector (Dobrzyński et al., 2020) and we wrote a set of custom R/Python codes. All R notebooks with code required to reproduce the plots and the underlying data are available as supplementary information (link to online repository: https://doi.org/10.17632/kd3n5k784m).

Convolutional Neural Network (CNN)

The convolutional neural network (CNN) was trained as a binary classifier that discriminates between apoptotic and non-apoptotic cells based on their ERK activity time series. These come from four experiments where ERK activity in MCF10A cells was measured every minute. We manually annotated apoptotic cells by visual inspection of the movies and obtained 448 time series with a duration of 8h before the nuclear contraction. To create a balanced dataset and to avoid classification bias towards either of the classes, we selected 448 random time series of equal duration with cells that did not undergo apoptosis. We performed a data augmentation step by taking random 6h-long segments at every training epoch of the CNN analysis.

We chose a plain CNN architecture as described previously (Zhou et al., 2016). It consists of several convolution layers followed by global average pooling (GAP) and a fully connected layer right before the output layer. The advantages of this architecture are a low number of parameters and a strong overfit counterweight with the GAP layer. The architecture comprises 6 successive 1D convolutional layers, all composed of 20 filters except for the last layer with 7 filters. In these layers, the convolution kernel sizes are (5, 5, 5, 5, 3, 3), respectively, with a stride of 1 and a padding that ensures a constant size of the input representation throughout the network. Each convolutional layer is followed by batch normalization and ReLU activation.

The whole dataset (training and validation sets) was passed once through the network and the representation of time series after the GAP layer was projected in 2D with tSNE (Figure 5A). Time series that maximized the model confidence for a given class were reported as prototypes. Time series for which entropy of the classification output was maximal (*i.e.* the model returns nearly 50% confidence for both classes) were reported as low-confidence prototypes.

Article

 CellPress

Peak detection

The number of ERK activity peaks was calculated with an algorithm that detects local maxima in time series. A local maxima is defined as a point that exceeds the value of its neighbors by a threshold that we manually set for each dataset. The thresholds were: 1.5e-1 for MCF10A cells; 5.0e-2 for the MCF10A/ADAM17KO co-culture experiments; 5.0e-3 for MDCK cells; 5.0e-3 for NRK cells.

Identification of collective events

To estimate spatial correlations in ERK activity, for every field of view and a time-lapse frame we calculated the local indicators of spatial association (Anselin, 1995) using the `lisa` function from the `ncf` package available for R. The function assumes the value of ERK-KTR C/N fluorescence intensity and X/Y positions of the nucleus' centroid. It then outputs the Moran's I autocorrelation coefficient for cells within a radius, which we set to 100px, and the permutation two-sided p-value for each observation based on 1000 resamples. After thresholding cells for the correlation > 0.5 and the p-value < 0.05 we applied the dbscan algorithm from the R package `dbscan` to identify clusters of collective ERK activity. We assumed that a collective event consisted of a minimum 3 cells with the maximum distance between cells of 100px. This procedure yielded individual collective events in each frame of the time lapse movie. We chose only those collective events where ERK-KTR C/N was above a threshold. To estimate the threshold, we performed k-means clustering with 2 centers on individual ERK-KTR C/N values from all collective events. The threshold was the midpoint between the two cluster centers. Movies of nuclei color-coded according to ERK-KTR C/N with collective events indicated with convex polygons were prepared with `ffmpeg` software from individual png files produced by `ggplot2` in R scripts.

Analysis of cells' history

We matched the X/Y/T coordinates of manually annotated apoptotic events to single-cell time series using the `distance_join` function from the `fuzzyjoin` package for R. Using the maximum euclidean distance of 10px we automatically matched ~95% of apoptotic events. For further analysis, we chose only time series longer than 6h. To plot the ordered heatmaps in Figure 4E, we overlaid the instances of collective events onto C/N ERK-KTR time series of single cells that underwent apoptosis. As a negative control, for each apoptotic event, we chose a random cell from the same time frame that did not undergo apoptosis during the entire experiment. We only compared sections of time series that matched the lifetime of apoptotic cells. To calculate the average percentage of non-apoptotic cells affected by collective events during a time window before apoptosis of the corresponding apoptotic cell (Figure 5F), we repeated the selection of random non-apoptotic cells 1000 times.

Mathematical model

The set of ODE equations was solved numerically using the function `ode` from the `deSolve` package in R:

$$C'(t) = -\frac{k_{apo}}{P_4(t)+1}C(t), \quad C(0)=1$$

$$P_1(t) = k_a(-C'(t)) - k_d P_1(t), \quad P_1(0)=0$$

$$P_2(t) = k_a P_1(t) - k_d P_2(t), \quad P_2(0)=0$$

$$P_3(t) = k_a P_2(t) - k_d P_3(t), \quad P_3(0)=0$$

$$P_4(t) = k_a P_3(t) - k_d P_4(t), \quad P_4(0)=10$$

Where: $C(t)$ - the total number of cells, $P_{1-4}(t)$ - protection steps, k_{apo} - the rate of apoptosis, k_a - the rate of protection activation, k_d - the rate of protection deactivation. For all simulations k_d was set to 1. Other parameters for scenarios in Figures 4B and 4C: (1) $k_{apo}=0.01$, $k_a=5$, (2) $k_{apo}=0.05$, $k_a=5$, (3) $k_{apo}=0.05$, $k_a=2$. The ratio $P_3(t)/C(t)$ was used as a measure of the average protection level per cell.

The R notebook and an interactive R/Shiny app are available as supplementary material (link to online repository: https://doi.org/10.17632/kd3n5k784m). An interactive R/Shiny web-app to explore the parameters can be accessed online at https://macdobry.shinyapps.io/model-apo-prot/.

QUANTIFICATION AND STATISTICAL ANALYSIS

All graphs were assembled and statistics were performed using R or Excel. The details of each statistical test performed are given in the legend accompanying each figure. Box plots depict the median and the 25th and 75th percentiles; whiskers correspond to maximum and minimum values in Figures 1H, 1I, 1J, 2C, 2D, 7F, S2E, S2H, S3H, S4E, S5C, and S5D or to 1.5 interquartile range drawn up to the largest observed point with the external observed points plotted as outliers in Figures 4D, 4H, 4I, S1D, S4I, S4J, S4K, S5F, and S6C. Histograms represent the mean ± standard deviation. XY line plots represent the mean and the shaded area represents the 95% confidence interval, except for Figures 3A, 3C, S1E, S2I, and S2J where it represents the standard deviation and Figures S7A and S7I where it represents the standard error of the mean. Plots represent single-cell measurements or their distribution, except Figures 6F, 6H, and S6G–S6K that represent the distribution of biological replicates. The statistical tests used and the significance thresholds are given in each respective legend. N, when indicated, represents the number of apoptotic ERK/Akt waves analyzed.
