## **ABSTRACT** (words count: 224)

**Purpose:** To assess whether partitioning the elastance of the respiratory system ( $E_{RS}$ ) between lung ( $E_L$ ) and chest wall ( $E_{CW}$ ) elastance in order to target values of end-inspiratory trans-pulmonary pressure ( $P_{PLATL}$ ) close to its upper physiological limit (25 cmH<sub>2</sub>O) may optimize oxygenation allowing conventional treatment in patients with influenza A (H1N1)-associated ARDS referred for extracorporeal membrane oxygenation (ECMO).

**Methods:** Prospective data collection of patients with influenza A (H1N1)-associated ARDS referred for ECMO (October 2009-January 2010). Esophageal pressure was used to (a) partition respiratory mechanics between lung and chest wall; (b) titrate positive end expiratory pressure (PEEP) to target the upper physiological limit of  $P_{PLATL}$  (25 cmH<sub>2</sub>O).

**Results:** Fourteen patients were referred for ECMO. In 7 patients  $P_{PLATL}$  was  $27.2 \pm 1.2$  cmH<sub>2</sub>O; all these patients underwent ECMO. In the other 7 patients,  $P_{PLATL}$  was  $16.6 \pm 2.9$  cmH<sub>2</sub>O. Raising PEEP (from  $17.9 \pm 1.2$  to  $22.3 \pm 1.4$  cmH<sub>2</sub>O,  $P=0.0001$ ) to approach the upper physiological limit of trans-pulmonary pressure ( $P_{PLATL}=25.3 \pm 1.7$  cmH<sub>2</sub>O) improved oxygenation index (from  $37.4 \pm 3.7$  to  $16.5 \pm 1.4$ ,  $P=0.0001$ ) allowing patients to be treated with conventional ventilation.

**Conclusions:** Abnormalities of chest wall mechanics may be present in some patients with influenza A (H1N1)-associated ARDS. These abnormalities may not be inferred from measurements of end-inspiratory plateau pressure of the respiratory system

( $P_{PLATRS}$ ). In these patients, titrating PEEP on  $P_{PLATRS}$  may overestimate the incidence of hypoxemia refractory to conventional ventilation leading to un-appropriate use of ECMO.

**Key Words:** ARDS, Influenza A (H1N1), trans-pulmonary pressure, extracorporeal membrane oxygenation

## INTRODUCTION

Several reports describe cases of *influenza* A (H1N1)-associated acute respiratory distress syndrome requiring extracorporeal membrane oxygenation (ECMO) for severe hypoxemia refractory to conventional treatment [1-6]. However, uncertainty regarding the appropriate indication for ECMO in these patients still remains [7-10]. Moreover, clinical evidences in support of ECMO as rescue treatment for these patients are controversial [11].

The increase in elastance of the respiratory system [12] observed in patients with ARDS is mainly attributed to the increase in elastance of the lung ( $E_L$ ) [12]. Under these circumstances the elastic properties of the chest wall ( $E_{CW}$ ) contributes to  $E_{RS}$  by approximately 20% [13]. However, alterations in  $E_{CW}$  have been described in patients with ARDS [13-15]. In these patients  $E_{CW}$  may contribute to  $E_{RS}$  up to 50% [16]. This implies that for a value of end-inspiratory plateau pressure of the respiratory system ( $P_{PLATRS}$ ) of 30 cmH<sub>2</sub>O, the end-inspiratory trans-pulmonary pressure ( $P_{PLATL}$ ) will amount to 24 cmH<sub>2</sub>O in patients with a “normal” chest wall and 15 cmH<sub>2</sub>O in patients with a “stiff” chest wall [16]. This may be clinically relevant since: (*a*) several studies suggest that mechanical ventilation should be titrated on  $P_{PLATL}$  rather than on  $P_{PLATRS}$ ; (*b*) it has been suggested that the upper physiological limit of trans-pulmonary pressure that optimizes alveolar recruitment is 25 cmH<sub>2</sub>O [14, 15, 17].

We report a case-series of patients with *influenza* A (H1N1)-associated ARDS that were referred for ECMO but in whom assessment of trans-pulmonary pressure led

to a change of the ventilatory strategy that reversed refractory hypoxemia and avoided ECMO.

## METHODS

We report patients with *influenza* A (H1N1)-associated ARDS referred to the Molinette Hospital (University of Turin) for ECMO in the period from September 2009 to January 2010 [18]. The institutional ethics committee approved data collection and report.

Patients were centralized if conventional ventilation [19], associated to nitric oxide, and/or prone positioning and/or high frequency oscillation resulted in:  $\text{HbO}_2 < 85\%$ ; oxygenation index  $> 25$ ;  $\text{PaO}_2/\text{FiO}_2 < 100$  with  $\text{PEEP} \geq 10$   $\text{cmH}_2\text{O}$ ; hypercapnia and respiratory acidosis with  $\text{pH} < 7.25$ ;  $\text{SvO}_2$  or  $\text{SvcO}_2 < 65\%$  despite  $\text{Ht} > 30$  and administration of vaso-active drugs [18]. Criteria for initiating ECMO were: oxygenation index  $> 30$ ;  $\text{PaO}_2/\text{FiO}_2 < 70$  with  $\text{PEEP} \geq 15$   $\text{cmH}_2\text{O}$ ;  $\text{pH} < 7.25$  for at least 2 hours [18]. Exclusion criteria for ECMO were: intracranial bleeding and other major contraindication to anticoagulation; previous severe disability; poor prognosis because of the underlying malignancy; mechanical ventilation for longer than 7 days [18].

At arrival, all patients were ventilated according to the ARDS Network protocol [19]. Mechanics of the respiratory system was partitioned between lung and chest wall. Throughout the period of data recording all patients were oro-tracheally intubated and in semi-recumbent position (head of bed from  $30^\circ$  to  $45^\circ$  inclination), sedated and paralyzed, as prescribed by the attending physicians.

Flow and  $P_{\text{PLATRS}}$  were measured. The pressure required to distend the chest wall was estimated using the measurement of esophageal pressure ( $P_{\text{ES}}$ ) [20].  $E_{\text{RS}}$ ,  $E_{\text{CW}}$ , and

$E_L$  were calculated as previously described [20].  $P_{PLAT_{CW}}$  and end-inspiratory plateau pressure of the lung ( $P_{PLAT_L}$ ) were estimated using the following equations [16]:

$$P_{PLAT_{CW}} = E_{CW} / E_{RS} * P_{PLAT_{RS}}$$

$$P_{PLAT_L} = P_{PLAT_{RS}} - P_{PLAT_{CW}}$$

Shape of the airway opening pressure vs. time during constant flow (*stress index*) was recorded as previously described [21-24].

If values of  $P_{PLAT_L}$  during conventional ventilation were  $<25$  cmH<sub>2</sub>O, PEEP was further increased until  $P_{PLAT_L}$  was equal to 25 cmH<sub>2</sub>O [14, 15, 17]. ECMO criteria were hence evaluated 20-30 min after of ventilation with new PEEP setting. If values of  $P_{PLAT_L}$  during conventional ventilation were  $\geq 25$  cmH<sub>2</sub>O, ECMO criteria were evaluated with ventilator settings as set on entry.

Data are presented as mean $\pm$ standard deviation. Comparisons were performed using paired and unpaired T-test, as appropriate. Differences were considered significant if  $P < 0.05$ .

## RESULTS

In the period October 2009-January 2010, 36 patients with novel A (H1N1) infection were admitted to the ICUs of the Piedmont region. Among them, 20 patients had ARDS and 14 were transferred to the regional coordinating center with ECMO facility because developing the pre-established criteria.

Values of oxygenation index and of  $\text{PaO}_2/\text{FiO}_2$  ratio indicated immediate use of ECMO in all patients [18]. Partitioning of respiratory mechanics showed that in 7 patients  $\text{P}_{\text{PLAT}_L}$  was higher than 25 cmH<sub>2</sub>O ( $27.2 \pm 1.2$  cmH<sub>2</sub>O) while in the other 7 patients was lower than 25 cmH<sub>2</sub>O ( $16.6 \pm 2.9$  cmH<sub>2</sub>O) (**Table 1**). Values of  $\text{P}_{\text{PLAT}_{RS}}$  were similar in the groups ( $31.0 \pm 1.0$  vs.  $31.5 \pm 0.5$  cmH<sub>2</sub>O, respectively). While in the former extracorporeal support was immediately initiated (**ECMO**), in the latter increasing PEEP until  $\text{P}_{\text{PLAT}_L}$  reached the upper physiological limit of trans-pulmonary pressure ( $25.3 \pm 1.7$  cmH<sub>2</sub>O) resulted in an increase of oxygenation index and of  $\text{PaO}_2/\text{FiO}_2$  to an extent that criteria for extracorporeal support were no longer met and patients were treated with conventional ventilation associated to low-flow CO<sub>2</sub> removal [25] in 4 patients (**NO ECMO**) (**Figure 1**).

**Table 2** shows physiological parameters in the **ECMO** and in the **NO ECMO** group. Although values of  $E_{RS}$  did not differ,  $E_L$  was higher ( $32.3 \pm 5.3$  vs.  $20.2 \pm 4.7$  cmH<sub>2</sub>O/L;  $P=0.001$ ) and  $E_{CW}$  was lower ( $6.1 \pm 0.7$  vs.  $17.2 \pm 1.7$ ;  $P=0.0001$ ) in **ECMO** than in **NO ECMO** group. In the latter, increasing PEEP from  $17.9 \pm 1.2$  to  $22.3 \pm 1.4$  cmH<sub>2</sub>O ( $P=0.0001$ ) to target an increase in  $\text{P}_{\text{PLAT}_L}$  from  $16.6 \pm 2.9$  to  $25.3 \pm 1.7$  cmH<sub>2</sub>O/L

( $P=0.0001$ ) significantly decreased the oxygenation index from  $37\pm 4$  to  $16\pm 1$  ( $P=0.0001$ ). The significant ( $P=0.0001$ ) increase of  $P_{\text{PLATRS}}$  from  $31.5\pm 0.5$  to  $38.4\pm 1.0$   $\text{cmH}_2\text{O}$  observed with conventional ventilation and higher PEEP was associated to: (a) the increase in  $E_{\text{RS}}$  (from  $37.4\pm 4.2$  to  $43.8\pm 3.3$   $\text{cmH}_2\text{O/L}$ ;  $P=0.0001$ ) and  $E_{\text{L}}$  (from  $20.2\pm 4.7$  to  $28.6\pm 2.3$   $\text{cmH}_2\text{O/L}$ ;  $P=0.0001$ ); (b) the increase of *stress index* (from  $0.922\pm 0.033$  to  $1.052\pm 0.032$ ;  $P=0.0001$ ); (c) the reduction in  $\text{PaCO}_2$  (from  $54.6\pm 8.4$  to  $42.9\pm 8.0$ ;  $P=0.001$ ). Increasing PEEP significantly increased right atrial pressure (from  $17\pm 2$  to  $20\pm 3$   $\text{mmHg}$ ,  $P=0.001$ ) but did not affect mean systolic pressure, cardiac output and cardiac index.

**Table 3** shows the clinical and demographic characteristics of the patients. Except for age ( $35.4\pm 11.1$  vs.  $53.3\pm 11.7$  years;  $P=0.01$ ) and fluid balance prior to admission to the referral center ( $718\pm 270$  vs.  $1384\pm 332$   $\text{ml}$ ;  $P=0.01$ ), Murray' score [26] ( $3.82\pm 0.19$  vs.  $3.61\pm 0.43$ ) and other clinical variables did not differ between the ***ECMO*** and ***NO ECMO*** group.

## DISCUSSION

The present case-series shows that partitioning of respiratory mechanics between lung and chest wall revealed a subset of patients with *influenza A* (H1N1)-associated ARDS in whom hypoxemia was refractory to the conventional treatment not because of a profound alteration of the lung parenchyma but because a large amount of the pressure applied at the airways was not transmitted to the lung parenchyma but dissipated against a “stiff” chest wall. In these patients, targeting PEEP to reach the upper physiological limit of trans-pulmonary pressure (25 cmH<sub>2</sub>O) [14, 15, 17] instead of the “safe” limit of P<sub>PLATRS</sub> (30 cmH<sub>2</sub>O) [19], improved oxygenation to an extent that ECMO criteria were no longer met.

The reported incidence of patients with influenza A (H1N1)-associated ARDS transitioning from conventional ventilation to ECMO is extremely variable. Reports from Australia and New Zealand [1] and from France [2] indicate that patients on ECMO were 34% and 50% of the mechanically ventilated patients, respectively. In Hong Kong [3] and Canada [4] only 6% of the patients were shifted from conventional ventilation to ECMO. In the present study, 14 patients were referred to the regional center to initiate ECMO for refractory hypoxemia. Partitioning of respiratory mechanics between lung and chest wall allowed to identify 7 patients that responded to conventional treatment and avoided ECMO provided that PEEP was sufficiently high to be transmitted to the collapsed lungs and to overcome chest wall stiffness. By doing so, the incidence of ECMO in the Piedmont region went from the possible 39% (14 on a

total of 36 mechanically ventilated patients) to the observed 19% (7 of the 36 mechanically ventilated patients) (Table 1).

Both in the ECMO and in the NO ECMO group the oxygenation index was equally compromised (Table 2) suggesting equal impairment of lung function. However, the oxygenation index is calculated using mean *airway* pressure. Indeed, the mean *transpulmonary* pressure during conventional mechanical ventilation was lower in **NO ECMO** than in the **ECMO** group ( $13.4 \pm 1.6$  versus  $21.4 \pm 1.7$ ,  $P = 0.01$ ) and therefore the oxygenation index calculated using the mean *transpulmonary* pressure was significantly lower in the **NO ECMO** than in the **ECMO** group ( $19.8 \pm 1.6$  versus  $28.7 \pm 4.8$   $P=0.01$ ).

The “open lung” approach aims at maximizing alveolar recruitment and counteract tidal recruitment of unstable alveoli by setting PEEP as high as possible to match a  $P_{PLATRS}$  of 30 cmH<sub>2</sub>O [27-29]. A recent meta-analysis suggests that this approach may reduce mortality in patients with ARDS in comparison to the conventional approach [30]. Recently, Mercat and coworkers proposed an open lung protocol in which PEEP was individually set as high as possible to match an  $P_{PLATRS}$  target of 30 cmH<sub>2</sub>O [28]. The open lung strategy adopted in the present report is based on the same rationale but, in order to overcome the bias induced by chest wall stiffness, aimed at an end-inspiratory transpulmonary pressure of 25 cm cmH<sub>2</sub>O. Of note this value is regarded as the he upper physiological limit of trans-pulmonary pressure [14, 15, 17] and is the value recorded in patients with ARDS and normal  $E_{CW}$  ( $E_{CW}/E_{RS}$  ratio

of 0.2) at a  $P_{\text{PLATRS}}$  of 30 cmH<sub>2</sub>O. This approach differs from the one proposed by Talmor and coworkers that titrated PEEP in order to obtain values of *end-expiratory* transpulmonary pressure ranging between 0 and 10 cmH<sub>2</sub>O [20].

In patients with ARDS, the increase of  $E_{\text{RS}}$  is mainly attributed to  $E_{\text{L}}$  [31]. However, alterations in  $E_{\text{CW}}$  have been also described in these patients [13, 15]. Moreover, *influenza* A (H1N1)-associated ARDS frequently occurs in obese subjects [32], a category of patients that often present a compromised  $E_{\text{CW}}$  [33]. Under these circumstances: (a) part of  $P_{\text{PLATRS}}$  may be “wasted” to distend the chest wall and only a fraction of the pressure applied at the airways will inflate the lung [14]; (b) the amount of pressure that will result in lung recruitment depends on the  $E_{\text{CW}}/E_{\text{RS}}$  ratio [16]. In normal adults the  $E_{\text{CW}}/E_{\text{RS}}$  ratio is approximately 0.4 [16]. In patients with ARDS, Gattinoni and coworkers [13] described patients with a normal chest wall and a  $E_{\text{CW}}/E_{\text{RS}}$  ratio of 0.2 and patients with a substantial impairment of the elastic properties of the chest wall and a  $E_{\text{CW}}/E_{\text{RS}}$  ratio of 0.5 [16]. Mergoni [34], Ranieri [15], and Grasso [14] later confirmed these findings. We show that in 7 of our patients, the impairment of the elastic properties of the respiratory system ( $E_{\text{RS}}=38.4\pm 5.2$  cmH<sub>2</sub>O/L) was due to a profound and substantial alteration of the lung parenchyma. In these patients the  $E_{\text{CW}}/E_{\text{RS}}$  ratio was  $0.16\pm 0.03$  and  $P_{\text{PLATL}}$  during conventional ventilation was  $27.2\pm 1.2$  cmH<sub>2</sub>O (**Table 2**). In these patients, hypoxemia was refractory to conventional treatments and ECMO was required to re-establish oxygenation. In the remaining patients, chest wall mechanics substantially contributed to the observed values of  $E_{\text{RS}}$  ( $37.4\pm 4.2$  cmH<sub>2</sub>O/L) with an  $E_{\text{CW}}/E_{\text{RS}}$  ratio of  $0.47\pm 0.08$  (**Table 2**). In these patients,

during conventional ventilation and with a PEEP of  $17.9 \pm 1.2$  cmH<sub>2</sub>O, baseline  $P_{PLATL}$  was  $16.6 \pm 2.9$  cmH<sub>2</sub>O. Raising PEEP to  $22.3 \pm 1.4$  cmH<sub>2</sub>O to target the upper physiological limit of  $P_{PLATL}$  ( $25.3 \pm 1.7$  cmH<sub>2</sub>O) decreased oxygenation index (from  $37 \pm 4$  to  $16 \pm 1$ ;  $P=0.0001$ ) reverting the indication for ECMO and allowing treatment with conventional ventilation. The significant improvement in oxygenation (**Table 2**) with a relatively small increase of PEEP ( $4.4 \pm 1.4$  cmH<sub>2</sub>O, range 4 -6 cmH<sub>2</sub>O) suggests a high potential for alveolar recruitment in the *NO ECMO* group [35].

Recent evidences [36] account for significant alveolar hyperinflation at  $P_{PLATRS}$  levels higher than 28 cmH<sub>2</sub>O. Several arguments support the lack of any direct or indirect evidence of hyperinflation observed in the present study even if we did not directly assess recruitment and hyperinflation. **First**,  $P_{PLATL}$  was significantly lower than  $P_{PLATRS}$ , due to high  $Est_{cw}$ . **Second**, *stress index* went from the range of values associated to tidal recruitment ( $0.922 \pm 0.033$ ) to the range of values associated to protective ventilation ( $1.052 \pm 0.032$ ;  $P=0.0001$ ). **Third**, although a decrease in cardiac output could have *per se* decreased shunt and improved oxygenation [37], we found that cardiac output remained unchanged. **Fourth**, the slight but significant increase of  $E_L$  with the higher PEEP strategy may be explained assuming that in these patients the increase of PEEP shifted tidal ventilation close to upper inflection point of the pulmonary volume-pressure curve [39-41] as also supported by recent evidence suggesting that “regional elastance” of lung tissue previously collapsed and re-expanded by applied pressure is higher than the elastance of the normally patent lung regions [42].

The observational nature of the present study limits the interpretation of its

results. **First**, alterations of  $E_{CW}$  in patients with ARDS have been associated to excessive and unopposed abdominal pressure [43] or to pleural effusions due to a positive fluid balance [14]. Moreover, in normal subjects  $E_{RS}$  increases with age, due to an increase of  $E_{CW}$  [44]. Although we found that patients with an impaired chest wall mechanics were older ( $53.3 \pm 11.7$  vs.  $35.4 \pm 11.1$  years;  $P=0.01$ ) and had a more pronounced positive fluid balance ( $1384 \pm 332$  vs.  $718 \pm 270$  ml;  $P=0.01$ ) than the patients that had a normal chest wall, the small number of patients included in study does not allow to identify clinical or physiological variables that could predict alteration of impairment of chest wall mechanics. **Second**, we report on a cohort of patients with a particularly diffuse and recruitable form of ARDS. **Third**, portioning  $E_{RS}$  between  $E_{CW}$  and  $E_L$  is based on the measurement of  $P_{ES}$  and on the assumption that this measurement (**a**) represents the average pleural pressure [45], (**b**) is insensitive to changes in lung volume [46] and to local gradients in pleural pressure [12]. Unfortunately none of these assumptions have never been verified in patients with ARDS [47]. **Fourth**: Several other methods have been proposed to set up an open lung approach [48, 49]. Borges and coworkers showed that applying distending pressures up to 60 cmH<sub>2</sub>O could successfully recruit the lung in ARDS patients considered not responders to conventional lung distending pressures [50]. Therefore it is conceivable that targeting a  $P_{PLAT_L}$  higher than 25 cmH<sub>2</sub>O would have successfully recruited patients also in the ECMO group. Finally, we must point out that reducing tidal volume from 6 to 4 ml/Kg would have allowed higher PEEP levels at baseline in both groups [51].

May our data influence physicians' attitudes to implement ECMO in patients with ARDS? Unfortunately, available data come from case series [1-5, 18, 52] and only one randomized clinical trial tested the efficacy of ECMO in patients with severe ARDS [53]. **Table 4** presents the main ECMO criteria of these studies together with the ECMO criteria proposed by the Extracorporeal Life Support Organization guidelines [54]. As can be seen all our patients would have been treated with ECMO according to the existing criteria. Results of the present study may therefore suggest that (*a*) liberal and inclusive criteria for centralizing patients with H1N1-induced ARDS to center with ECMO facility [1-5, 18, 52] should not be considered "prima facie" grounds to actually implement ECMO; (*b*) titrating PEEP to target a  $P_{PLATL}$  value of 25 cmH<sub>2</sub>O [14, 15, 17] instead of  $P_{PLATRS}$  of 30 cmH<sub>2</sub>O [27, 28] may optimize oxygenation and prevent unappropriate use of ECMO in those patients with influenza A (H1N1)-associated ARDS that have an abnormal chest wall mechanics. Further studies are required to evaluate whether these conclusions may apply to a general population of ARDS patients.
