Abstract

Adsorption of H$_2$S on the Ni$_2$(dhtp)(H$_2$O)$_2$ ·8H$_2$O metal-organic framework (known as CPO-27-Ni or MOF-74-Ni) is characterized by in-situ technique (PXRD, FTIR, Raman and Uv-visible spectroscopy) and by first principles periodic boundary conditions calculations. Powder X-ray diffraction results show very high stability of CPO-27-Ni framework in presence of H$_2$S. Nevertheless, as evidenced by change in color of the sample from pale yellow to dark green, the adsorption of H$_2$S strongly affects the coordination of Ni sites. FTIR results show the reversible molecular adsorption of H$_2$S. Experimental and computed energies of interaction reveal good agreement. Quantitative data considering energetic aspects (calorimetric measurements) are also included. This work highlights the fundamentals of H$_2$S adsorption onto the CPO-27-Ni framework.

Introduction

Over the last decade, metal-organic frameworks have received large interest due to their high porosity with astounding internal surface areas, and framework modularity (both chemical and morphological).[1-3] These well-defined crystalline networks have suggested several potential applications such as gas separation, gas storage, catalysis, drug delivery, and sensors. Currently, the most feasible practical application of MOFs seems to be gas storage and separation.[4-8] As gas storage is concerned, MOFs' most appealing properties refer to their huge surface area (with reported values up to 4500 m^2 g^{-1} for MOF-177[2]) and to their extreme low density. This implies that within such large pore spaces a significant amount of gas can be

stored. However, high surface area is not a sufficient requirement to guarantee high performance in gas separation or purification, where high affinity towards the selected molecule/s is also necessary. In this regard the capability of the material to selectively operate with respect to a specific guest molecules, has to be tuned by carefully considering operational thermodynamic conditions (pressure, temperature) and gas feed components [9, 10]. Organic ligands that constitute most of the MOF structure do not provide strong electrostatic and dispersive forces which are required for the retention of small gas molecules. However, unlike other adsorbents such as activated carbons and polymers, MOFs benefit from a very well-developed structural chemistry which arises from the presence of metallic sites and possible facile functionalization of organic ligands.[11-13] Therefore, each unit in MOFs (metals or ligands) can be considered as a potential coordination–adsorption site for the target gas. Moreover, gas adsorption via physisorption, chemisorption and/or reactive adsorption on a MOF under control condition have been recently studied. A well-documented example is that of NH_3 adsorption on HKUST-1, with and without the presence of H_2O[14] or the separation of O_2 from O_2/N_2 mixture, at liquid nitrogen temperature (reversible) or at room temperature (irreversible).[15] In both cases it was found that only in specific conditions adsorption was reversible, allowing multi-cycles use of the materials; on the contrary, in other ranges of temperature/gas mixtures, a partial or total collapse of the framework was observed. Framework damage is an easy risk especially in case of interaction with reactive gases like H_2S as was observed in previous studies performed on HKUST-1.[16-18]

Recent studies of H_2S adsorption on rigid and flexible MILs frameworks were performed.[19-21] In particular, Mil-53(Al) has shown high performance and reversibility towards H_2S adsorption.[22] Allan et al. observed good adsorption properties towards H_2S, both in term of stored capacity and framework stability on a MOF with densely exposed metal sites CPO-27-Ni.[23] Their data indicate that the framework structure is retained throughout the dehydration/gas loading process and only a small loss of deliverable gas capacity over a six month period was observed. In the present study we report a detailed characterization of H_2S adducts on CPO-27-Ni described by IR, Raman, UV-Visible spectroscopy, microcalorimetry and PXRD and ab-initio periodic calculations. First, attempts in the evaluation of the reversibility of the adsorption/desorption processes, effects of aging in H_2S are reported.

2 Experimental and computational methods

2.1 Materials and experimental methods

CPO-27-Ni synthesis: Following the procedure reported into the literature[24] the CPO-27-Ni material was prepared from a nickel(II) acetate and 2,5-dihydroxyterephthalic acid reaction in a THF–water mixture giving an ochre substance $Ni_2(dhtp)(H_2O)_2 \cdot 8\ H_2O$. X-ray powder data showed the high crystallinity of the sample for which a BET surface area of 1200 $m^2\ g^{-1}$ was evaluated (Langmuir surface area of 1315 $m^2\ g^{-1}$). The sample was stable to moisture and aging, maintaining its high crystallinity and porosity.

Powder X-ray diffraction: In situ powder X-ray diffraction patterns were collected with a PW3050/60 X'Pert PRO MPD diffractometer (PAN analytical) in Debye–Scherrer geometry. The sample was placed inside 1.0 mm boron-silicate capillaries, exposed to 60 mbar H_2S, and then sealed.

IR spectroscopy: FTIR spectra were collected in transmission mode on self-supporting wafer, and in controlled atmosphere using a home build IR cell. The spectra were recorded at 2 cm^{-1} resolution on a Bruker IFS 66 FTIR spectrometer equipped with a MCT detector.

Raman spectroscopy Raman spectra were recorded using a Renishaw Raman Microscope spectrometer. An Ar^+ laser emitting at 514 nm was used, where the output power was limited to 1% (100% power = 8.2 mW at the sample). This constraint was necessary in order to avoid sample damage. The photons scattered by the sample were dispersed by a 1800 lines/mm grating monochromator and simultaneously collected on a CCD camera; the collection optic was set at 20X objective. The spectra were obtained by collecting 50 acquisitions (each of 10 seconds) on a self-supporting wafer put in a home-made cell with a suprasil quartz cuvette that allowed measurements in controlled atmosphere.

Uv-Visible spectroscopy: DR-UV-vis-NIR measurements were performed on a Varian Cary 5000 spectrometer equipped with a reflectance sphere on thick self-supported pellets. In all experiments, samples were put inside an ad hoc cell that allowed thermal treatments under high vacuum conditions, dosage of probe molecules, and in situ spectra collection.

Calorimetry: Calorimetric isotherm data were obtained on a Tian-Calvet-type (Setaram), a calorimeter provided with a calibrated gas-volumetric glass manifold. Pressure was measured by means of a Barocell (Edwards) transducer gauge (0-100 mbar). Adsorption-desorption cycles of H_2S at CPO-27-Ni were studied at room temperature on 56.4 mg of the CPO-27-Ni powder sample by following different regeneration methods (by outgassing at RT and at

473K). For all the experiments, prior to the adsorption of H_2S, CPO-27-Ni was activated (outgassed) at 473K for 3 hours in order to reveal coordinatively unsaturated M^{2+} centers.

2.2 Computational Methods

Theoretical investigation was carried out using periodic density functional theory (DFT) calculations employing the hybrid B3LYP[25-27] functional empirically corrected to include a long-range dispersion term, as proposed by Grimme[28] and modified for crystalline systems.[29] All calculations were performed with the CRYSTAL09 code.[30, 31]

All-electron Gaussian-type basis sets were used for all of the atoms. A TZVP basis set was chosen for Ni (Gaussian basis functions' exponents lower than 0.1 au were removed) while a TZP basis set was employed for the adsorbed molecules (vide infra Table 3 for details).

For the numerical integration of the exchange–correlation term a (75,974) pruned grid, was adopted.[31] The condition for the SCF convergence was set to 10-8 and 10-10 Hartrees during geometry optimization and vibration frequencies calculation, respectively. The Pack-Monkhorst/Gilat shrinking factors for the reciprocal space sampling were set to 2, corresponding to 4 k-points at which the Hamiltonian matrix was diagonalized. The tolerances for one- and two-electron integrals calculation was set to 7 7 7 7 18 (see Ref [31] for details).

A full relaxation of the structures (both lattice parameters and atomic positions) was performed by keeping the symmetry of the system; that is, one molecule was placed on each Ni atom of the unit cell (1:1 molecular loading). All the results refer to Ni in high-spin electronic configuration within a ferromagnetic unit cell. For geometry optimization, the default convergence criteria were used.[31] Equilibrium structures were used to compute the binding energies for the adsorbed molecules (H_2O and H_2S):

$$\Delta E = E_{MOF/X} - E_{MOF} - nE_X \qquad (1)$$

where n=6 and X indicates the molecule (i.e. $X = H_2S$, H_2O). Basis set superposition error (BSSE) was taken into account by using the counterpoise correction (CP) method.

The enthalpy of interaction was computed as:

$$\Delta H(T) = \Delta E^{CP} + \Delta ZPE + \Delta H_T \qquad (3)$$

Where, ΔZPE and ΔH_T are the contribution from the zero-point energy and the thermal correction to enthalpy a given temperature, T, respectively. The corresponding value of T was taken to be T = 298 K.

3. Results and discussion

3.1 Vibrational spectroscopy: FTIR and Raman

Vibrational features of CPO-27-Ni have been extensively described previously.[11, 32-34] For sake of clarity Figure 1 reports only the ranges where major changes are occurring upon H_2S adsorption (60 mbar equilibrium pressure). The high frequency range of the IR spectrum is reported where stretching modes of H_2S occur (Parts a and b). On the other hand, the low frequency range for the active Raman modes is reported (Part c) where some of the framework modes are perturbed and some direct evidence of H_2S coordination could be singled out. The IR spectrum of CPO-27-Ni in contact with 60 mbar of H_2S is reported as a red curve in Figure 1, while the effects of progressive outgassing at room temperature are reported as grey curves. The last spectrum, obtained after 3 h of outgassing does not show clear evidence of significant amount of irreversibly adsorbed H_2S.

Molecular H_2S is characterised by three IR active vibrational mode at 2626, 2614 and 1182 cm^{-1} corresponding to the asymmetric, symmetric stretching, and bending vibrational modes.[35] The presence of H_2S adsorbed on CPO-27-Ni is indicated in the IR spectrum by the presence of a doublet at 2565 and 2524 cm^{-1}. These asymmetric and symmetric (S-H) stretching vibrations of the adsorbed H_2S are red shifted by 61 and 90 cm^{-1} respectively with respect to the gas phase values. Due to the fact that upon H_2S adsorption most of the framework bands are slightly shifted, any attempt to magnify specific features of the adsorbed H_2S performing spectra subtraction, was not satisfactory.

In comparison, IR spectrum for H_2S adsorbed on MIL-47(V) shows a broad absorption band centred at 2585 cm^{-1} with shoulder at 2560 cm^{-1}.[19] These dramatic shifts in the (S-H) stretch observed on CPO-27-Ni and the change from yellow to dark green of the activated sample upon H_2S adsorption indicate the involvement of Ni^{2+} sites into the adsorption mechanism. The mentioned change in colour is further investigated by Uv-Visible spectroscopy as described in the next section.
Figure 1: FTIR (a and b) and Raman spectra (c) of CPO-27-Ni: As prepared (blue curve); activated at 473K for 3h (black), in contact with H_2S (red curve at 60 mbar); and following desorption of H_2S (grey curves) at ambient temperature.

Figure 1c compares the Raman spectrum of the activated CPO-27-Ni (black curve) and when in interaction with H_2S (red curve). The blue curve represents the hydrated sample, which is reported for further comparison. The dehydrated form of CPO-27-Ni shows bands at 1625, 1561 and 586 cm^{-1}. They are due to benzene ring vibrations; the former two refer to stretching modes, the latter to a ring deformation.[32] Features at 1495 and 1428 cm^{-1} are assigned to $\nu(COO^-)_{asym}$ and $\nu(COO^-)_{sym}$. The intense band at 1277 cm^{-1} is attributed to $\nu(CO)$ vibration due to the deprotonated species derived from the hydroxyl group. The minor feature at 835 cm^{-1} is ascribed to ring C–H bending modes. At lower frequency, the band at 430 cm^{-1} is attributed to the $\nu(Ni–O_{Ligand})$ mode.[36, 37] Upon H_2S coordination, some relevant changes occur in the framework vibrational region in both the frequency and the relative intensities of the Raman bands. The spectra are reported only in the low frequency region due to the very low intensity of $\nu(HS)$ modes. As far as the frequency shifts are concerned, most of the components are sensibly red-shifted (the bands at 1625, 1561, 1427, 1278, 833, 586 and 430 cm^{-1} shift down to 1618, 1558, 1415, 1273, 827, 570 and 410 cm^{-1}, respectively). Exception is made for the band around 1500 cm^{-1} that remains almost un-shifted. The additional component, observed at 327 cm^{-1} and absent in both activated and hydrated CPO-27-Ni, could be associated to the vibration of the Ni-S bond of the coordinated H_2S. Due to its very low Raman intensity, no evidence is recorded of the $\nu(HS)$ mode. For this reason, the hypothesis

of H_2S decomposition under the laser beam and the consequence formation of S deposition cannot be totally discarded.

3.2 Uv-Visible-NIR spectroscopy

Despite from the observation derived from IR and Raman spectra one might expect the adsorption of H_2S to show features similar to that of water, the macroscopic change in colour of the sample (from yellow to dark green) indicates that H_2S has a much stronger effect on the electronic structure of Ni sites than H_2O. Figure 2 compares the electronic spectra of CPO-27-Ni as prepared (blue curve), activated (black curve), and upon H_2S adsorption (red curve). The spectrum of the hydrated sample (in which water is coordinated to the Ni site) is characterized by the presence of three main features: a band at 9300 cm^{-1}, a doublet at 13605 and 15080 cm^{-1} and an intense absorption with an edge at about 21500 cm^{-1}. This latter component is associated with the lowest π-π* energy transition due to the organic linker. Three spin allowed d-d excitations are expected for a Ni^{2+} ion in O_h symmetry. However, due to the low lying charge transfer region of the MOF-linker, the optical spectrum clearly shows only the two dd-excitations ($^3A_{2g}(^3F) \rightarrow {}^3T_{2g}(^3F)$ and $^3A_{2g}(^3F) \rightarrow {}^3T_{1g}(^3F)$) at low energy[32] while the expected d-d at high energy ($^3A_{2g}(^3F) \rightarrow {}^3T_{1g}(^3P)$) appears just as a shoulder. The position of this d-d transition has been reported only recently to be at 24800 cm^{-1} by Gallo et al.[38] using resonant inelastic X-ray scattering (RIXS).[39-41] The technique, being element selective at the Ni K-edge, does not detect the $\pi \rightarrow \pi$* transition of the ligand (as UV-Vis does) and so the Ni^{2+} d-d transitions emerges clearely.[42]

The thermal treatment *in vacuo* at 473 K produces a blue shift for all the components and the appearance of a new band at 5730 cm^{-1}. Remaining components are observed at 10160, 14200 and 25000 (the latter clearly observed in RIXS experiments only), see Table 1. This profile has been interpreted on the basis of a five-coordinated Ni^{2+} species in a squared-pyramidal geometry (C_{4V} space group: the assignment of the electronic transitions is as it follows: $^3B_1(^3F) \rightarrow {}^3E(1)(^3F)$, $^3B_1(^3F) \rightarrow {}^3A_2(^3F)$, $^3B_1(^3F) \rightarrow {}^3B_2(^3F)$, $^3B_1(^3F) \rightarrow {}^3E(2)(^3P)$, $^3B_1(^3F) \rightarrow {}^3A_2(^3P)$.[32, 43] H_2S adsorption (60 mbar equilibrium pressure at RT, red curve) on activated CPO-27-Ni causes the erosion of the component at 5730 cm^{-1}, while the other *d-d* transitions now appear at 9430, 15400and 25500 cm^{-1} respectively(the latter visible in RIXS experiments, only); finally, the component due to the organic linker (lowest π-π*) is slightly red shifted at about 19500 cm^{-1}. The fact that the same number of major components are observed in the spectrum obtained in presence of coordinated water (blue curve) implies that the Ni^{2+} sites are in octahedral symmetry also when coordinating with H_2S. Furthermore, the

consistent change in color, even more dramatic than that observed for NO,[32] is reflected by the significantly different positions of the bands. The data are summarized in Table 1.

Table 1. Maximum of the Ni^{2+} d-d bands observed by UV-Vis spectroscopy, in cm^{-1} and corresponding assignment according to literature, [32, 43] supposing an O_h- or a C_{4v}-like local symmetry for Ni^{2+} in presence and absence of adsorbents (H_2O or H_2S), respectively.

System	Band position (cm^{-1})	assignment
CPO-27-Ni hydrated	25000^a	$^3A_{2g}(^3F) \rightarrow ^3T_{1g}(^3P)$
	15082-13605	$^3A_{2g}(^3F) \rightarrow ^3T_{1g}(^3F)$
	9300	$^3A_{2g}(^3F) \rightarrow ^3T_{2g}(^3F)$
CPO-27-Ni de-hydrated	25000^a	$^3B_1(^3F) \rightarrow ^3E(1)(^3F)$
	14200	$^3B_1(^3F) \rightarrow ^3A_2(^3F)$
	10160	$^3B_1(^3F) \rightarrow ^3B_2(^3F)$
	5730	$^3B_1(^3F) \rightarrow ^3A_2(^3P)$
CPO-27-Ni + H_2S	25500^b	$^3A_{2g}(^3F) \rightarrow ^3T_{1g}(^3P)$
	15400	$^3A_{2g}(^3F) \rightarrow ^3T_{1g}(^3F)$
	9430	$^3A_{2g}(^3F) \rightarrow ^3T_{2g}(^3F)$

^{a} The exact band position has been observed by RIXS and reported in Ref.[38], for the hydrated sample. RIXS data of the de-hydrated sample and after interaction with H_2S have been kindly supplied by E. Gallo and P. Glatzel (ESRF), prior publication.

Figure 2: DIR-Uv-Visi-NIR spectra of CPO-27-Ni: As prepared (blue curve), activated (black curve) and with H_2S adsorbed (red curve, 60 Torr equilibrium pressure).

3.3 Microcalorimetry

Enthalpy of H_2S adsorption at exposed nickel sites and the adsorption capacity of the CPO-27-Ni were evaluated by measuring calorimetric adsorption isotherms. Volumetric isotherms as a function of equilibrium pressure are illustrated in Figure 3. The primary adsorption isotherm (filled red square) was measured on a pristine CPO-27-Ni sample activated under vacuum at 473 K. This sample was regenerated following the H_2S desorption at room temperature (303K) and secondary adsorption isotherm was measured (empty red square). Difference between primary and secondary isotherms clearly indicates that, some amount of H_2S is not removed by outgassing the sample at room temperature. With the aim of providing evidence about the potential of the material in recyclable cycles, the same CPO-27-Ni sample was regenerated by desorbing H_2S at 473K for 12h after secondary isotherm. Re-adsorption of H_2S on this regenerated sample (filled black square) shows more uptake than that observed for the freshly activated one (filled red square). A subsequent 3 h H_2S desorption at 473K was performed before to run another H_2S adsorption isotherm (black empty square); no significant changes could be appreciated with respect to the previous scenario.

All the reported isotherms show type I behavior in which the saturation is reached at low pressure (< 1 mbar); *i.e.*, the suitable pressure range for natural gas purification, which contains H_2S in ppm level. Considering a 1:1 stoichiometry between adsorbed H_2S and nickel site, and taking into account all the nickel atoms available for the adsorption, the adsorbed moles of H_2S (n_a) are normalized to the moles of the activated CPO-27-Ni (empirical formula of CPO-27-Ni: C_4HO_3Ni, 155.7401g.mol^{-1}). The weight % is calculated over the sum of the mass of H_2S adsorbed and mass of the activated CPO-27-Ni. The maximum 17 wt% uptake corresponds to the formation of a 1:1 complex. For freshly activated sample (filled red squares) and samples regenerated at 473 K, (filled and empty black squares) an uptake of ~0.68 moles of H_2S per mole of C_4HO_3Ni is observed; this corresponds to 13 wt% of H_2S. Note that this value is in complete agreement with the one obtained in previous studies performed on CPO-27-Ni in presence of other probes (NO and CO [32, 34]). Independently to the strength of the interaction, the 1:1 ratio was never observed for this material. This aspect can be linked to the fact that not all the Ni^{2+} sites are available for adsorption. In fact, the presence of a large amount of packed sample inside the calorimenter cell will limit the complete desorption of the solvent. Note that such an effect does not occur in IR experiments, where the spectra are acquired by employing very thin sample pellets.
Figure 3: Plot of the volumetric isotherms obtained for H_2S adsorption on the CPO-27-Ni activated at 473K, as the function of the equilibrium pressure P_e (■: adsorption isotherm on freshly activated; □: adsorption isotherm on sample regenerated under vacuum at 303K, ■: adsorption isotherm on sample regenerated at 473K for12h, □: adsorption isotherm on sample regenerated at 473K for 3h). The adsorbed moles of H_2S (n_a) are normalized to the moles of Ni atoms present in the MOF sample, supposing all the Ni atoms available to the interaction with H_2S. The inset shows the zoom in the P_e = 0-3 mbar range.

Figure 4 illustrates the dependence of the differential molar adsorption heat q_{diff} as a function of H_2S coverage. Except from the isotherm obtained after prolonged re-activation (12 h in dynamic vacuum at 473 K, filled black squares), which is significantly higher (72 kJ mol^{-1}) than the initial q_{diff} (56-58 kJ mole^{-1}). This value remains almost constant up to the loading of ~0.7 mole of H_2S per mole of CPO-27-Ni in case of freshly activated (filled red squares) and samples re-generated at 473 K (full and empty black squares). In case of sample regenerated by outgassing at room temperature, the heat drop is observed at 0.5 moles of H_2S per mole of CPO-27-Ni. The decreases in heat of adsorption observed in all cases show similar behavior with drops of about ~ 30 kJ mol^{-1} (typical of weak physisorption with no specific interaction between the host/guest species).

The fact that the initial heat of adsorption obtained for the sample regenerated at 473 K for 12 h (figure 4 filled black squares) is significantly higher than in all the other cases and, knowing that all the Ni sites in CPO-27-Ni are equivalent, suggests that this treatment causes some damage to the framework with the consequent formation of defects. We think that, this small fraction (0.1 mol of H_2S/mol of CPO-27-Ni) of H_2S is not reversible even after outgassing at 473 K for 3 h (empty black squares).

Compared to other MOFs so far investigated for H_2S adsorption, CPO-27-Ni has shown the highest uptake and high enthalpy of adsorption while maintaining its structure and porosity. In the case of HKUST-1, the interaction with H_2S is so strong to be able to cause framework decomposition[17]; on the other hand, many cluster- based MOFs show very weak interaction.[19, 20]

Figure 4: Dependence of the differential molar adsorption heat $q$diff as a function of H_2S coverage on CPO-27-Ni activated at 473K (■: adsorption isotherm on freshly activated; □: adsorption isotherm on sample regenerated under vacuum at 303K, ■: adsorption isotherm on sample regenerated at 473K for12h, □: adsorption isotherm on sample regenerated at 473K for 3h). The adsorbed moles of H_2S n_a are normalized to the moles of Ni atoms present in the MOF sample, supposing all the Ni atoms available to the interaction with H_2S.

3.4 Periodic DFT calculations

The main geometrical and energetic results obtained by periodic calculations at the B3LYP-D*/TZVP level of theory with the CRYSTAL09 code[31] are summarized in Table 2. The optimized structures are shown in Figure 5, as viewed along the [001] direction. All the results refer to CPO-27-Ni with nickel atoms in high-spin electronic configuration within a ferromagnetic unit cell and a molecular loading of 1:1 (*i.e.*, one molecule per metal atom) with respect to experimental data of Dietzel et al.[24] As expected, upon hydration or upon interaction with hydrogen sulfide, the volume of the unit cell increases in agreement with experimental evidence. For CPO-27-Ni in interaction with H_2S, structural features are in good agreement with the recently reported synchrotron X-ray data at room temperature[23], with values for lattice parameters and volume lying within 1% and 2.5%, respectively. For the

three structures, the average of the Ni-O bond distance in the framework and the Ni-Ni distances are also in good agreement with experimental data from different techniques[24, 32], despite a slight overestimation.

Table 2. Summary of the main geometrical and energetic features obtained by periodic calculations at the B3LYP-D*/TZVP level of theory. For comparison also the experimental values for $-\Delta H_{ads}^{expt}$ are reported.

	Dehydrated	+ H_2O	+ H_2S	Exp +H_2S value from [23]
$a = b$ (Å)	25.894	25.897	25.908	25.745
c (Å)	6.843	6.891	6.877	6.8057
V (Å^3)	3973.3	4002.2	3997.5	3906.6
<R_O> (Å)	2.029	2.060	2.054	
R_{Ni1} (Å)	2.935	3.013	3.002	
R_{Ni2} (Å)	4.921	4.990	4.977	
R_{ads} (Å)	–	2.156	2.633	2.590
$\Delta d_{AB}/\Delta d_{BC}$ (Å) ^{a}	–	+ 0.005/ + 0.006	< +0.001	
θ_{Ni-A-B} (°)	–	99.6/ 111.0	91.5/93.7	
-ΔE^c (BSSE) (kJ mol^{-1}) ^{b}	–	75.5 (11.4)	-55.9 (6.5)	
ΔZPE (kJ mol^{-1})	–	9.7	9.4	
ΔH_T(298K) (kJ mol^{-1})	–	-2.2	-1.5	
-ΔH^0(298K) (kJ mol^{-1})	–	68.0	47.9	
$-\Delta H_{ads}^{expt}$ (kJ mol^{-1}) ^{c}		> 100	57±1	

^{a} Intra-molecular distances of the adsorbed Ni$^{2+}\cdots$AB(C) molecule: AB(C) = OH$_2$; H$_2$S For the unperturbed molecules B3-LYP-D*/TZVP distances are: d_{AB} =d_{BC} = 0.963 (OH$_2$); d_{AB} =d_{BC} = 1.345 (SH$_2$)

^{b} Lateral interaction between H$_2$O (or H$_2$S) adjacent molecules is about -2.0 kJ/mol (Ni) on average, thus indicating a somewhat weak attractive interaction

^{c} $-\Delta H_{ads}^{expt}$ values are obtained by microcalorimetry.

Figure 5: H_2O (left) and H_2S (right) molecules as arranged in the CPO-27-Ni channels. Metal, sulfur, oxygen, carbon, and hydrogen atoms are blue, yellow, red, gray, and white, respectively.

As shown in Figure 5, computed results confirm that the principal interaction is observed between the Ni atom and oxygen and sulfur, even if the molecules are tilted toward a nearby oxygen atom of the framework thus indicating a weaker secondary interaction. This resembles what it was observed for the adsorption of CO_2 in CPO-27-Mg which was explained due to the presence of a negative potential around the oxygen belonging to the carboxylate group of the organic ligand.[44]

The computed Ni---S bond distance of 2.633 Å is close to the experimental value as reported by Allan et al.[23] (2.590 (1) Å), and similar to bond lengths observed in H_2S loaded into Ni-zeolites.[45]. For H_2O, a good agreement is observed with respect to the Ni---O bond length (*i.e.*, 2.10 ± 0.04 Å) from the EXAFS spectrum.[32]The computed enthalpies of adsorption of H_2O and H_2S are underestimated with respect to microcalorimetry results. Indeed, experimentally determined $-\Delta H_0(298K)$ is more than 100 kJ/mol per Ni atom for water and 57 kJ/mol per Ni atom for hydrogen sulfide. This underestimation can be ascribed to a general drawback of the DFT methods in describing the interaction of adsorbate with the Ni atom. However, computed data can be considered in semi-quantitative agreement with experiment.

3.5 Structure stability of CPO-27-Ni upon adsorption of H_2S

In situ powder X-ray diffraction patterns were measured to check the structure stability of CPO-27-Ni in contact with H_2S for increasing times. The results are reported in Figure 6. A

very small decrease in intensity of first diffraction peak is observed at the very initial exposure of H_2S, as it is evident by comparing bold black curve and successive black curves; after this first evolution, no further changes were observed until 72h (red pattern). Finally, the pattern obtained after 2 months shows a further small decrease in intensity. This does not affirm any loss of crystallinity, as the first diffraction peaks are sensitive to pore filling and packing of the sample inside the capillary. Moreover, no additional peaks are observed and those at higher angle well match in intensity with those recorded for pristine the CPO-27-Ni sample. This results show the high stability of CPO-27-Ni with respect to H_2S exposure.

Figure 6: *in situ* powder X-ray diffraction patterns of CPO-27-Ni in contact with H_2S(60 mbar) monitored as a function of time.

4 Conclusions

Combined use of spectroscopic with microcalorimetric data and computational evidences were able to characterize the properties of adsorbed H_2S on Ni sites of CPO-27-Ni. H_2S forms stable adducts at Ni sites, giving rise to species which are totally reversible only upon outgassing at 473 K. Macroscopic change in colour of the sample that turns from yellow to dark green, indicates that H_2S has a much more strong effect on the electronic structure of Ni sites than H_2O. Heat of adsorption (q_{diff}), obtained for H_2S adsorption isotherms on an activated sample is maintained in case of a reactivated CPO-27-Ni. The measured value of 56-58 kJ mole^{-1} (almost constant up to the loading of ~0.7 mole of H_2S per mole of CPO-27-Ni) indicates the formation of a medium-strong physisorptive interaction. Compared to other MOFs investigated so far for H_2S adsorption, CPO-27-Ni shows the highest uptake and high enthalpy of adsorption while maintaining its original structure and porosity. These key aspects

make CPO-27-Ni a promising material for application in biogas or natural gas stream purification.
