## **Memo 24/2014-1**

This version November 2014

### **Abstract**

We estimate a dynamic discrete choice model of Registered Nurses' labor supply with random terms. A distinguished feature of our model is that random terms are correlated over time and jobs (habit persistence). Past options and not only the past optimal choices matter for the current choices. Given observed incentives, we find that nurses are mobile when they are young (less than physicians), but there is also a weak tendency of higher mobility again when they are approaching retirement age. Wage increases have a modest impact on labor supply. The overall elasticity for nurses is close to zero (like for physicians). These low elasticities shadow for stronger responses, shifting labor away from part time jobs in the public and private sector towards full time jobs in the private sector. A change in taxation away from the progressive tax system towards a flat tax of 28% gives Registered Nurses a very modest incentive to shift their job to private hospitals. For physicians the impact is stronger.

JEL classifications: J22, I10, C35

Keywords: Nurses' labor supply, multi-sector, panel data.

## 1. Introduction

The main motivation for the paper is that, as is the case with other OECD countries, Norway's population is ageing and the old-age dependency ratio, i.e. the ratio of the population aged 65 and over to the population aged 20-64 is estimated to nearly double: from 32.7% in 2011 to 62.2% in 2050<sup>4</sup> (OECD, 2013). This phenomenon implies that in the coming decades there will be many old people requiring care in hospitals and elderly homes (OECD 2005). There will thus be a growing demand for nurses and medical doctors. This increase in demand can be covered with more nurses and medical doctors educated at Norwegian universities or migrating from abroad. The latter might be a difficult option, since most other OECD countries have the same need for people working in the health sector (OECD 2103).

In this paper, we focus on another option. We study how nurses respond to incentives to work longer hours and we compare them with medical doctors. Almost 50% of Norwegian nurses work part time and their working hours are among the lowest in the European Union (see OECD 2005). There might be room for increasing labor supply of nurses. Specifically, we wish to understand to what degree wages and taxes affect the labor supply of nurses. We do this by estimating a longitudinal discrete choice model on panel data for Registered Nurses. Andreassen et al. (2013) estimate a longitudinal discrete choice model on panel data for physicians. The contribution of this paper is to estimate the same model for nurses and to compare the results for nurses with the results for physicians published in Andreassen et al. (2013). The available choices for nurses are different types of working loads in primary care and hospitals. In the model, we allow for taste or habit persistence that may slow down mobility across jobs and working loads when wages and taxes are changed to stimulate labor supply. The period of estimation is 1997 to 1999.

The main conclusion is that by cutting taxes and/or increasing wages nurses both start working and move to jobs with higher working loads. However, the impact is not strong. Wage increases have the greatest effect on labor supply among nurses aged 35-50, while less progressive taxes stimulates in particular medical doctors to move to jobs with higher working loads in the private sector. It should be noted that the impact of a wage increase on labour supply is in part absorbed by taxation. Because all details of a step-wise linear progressive tax system is accounted for when estimating the model, this absorption is explicitly taken into account. As mentioned

---

<sup>4</sup> This is in line with the average rise for the OECD area as a whole, although the increase in Norway is less dramatic than projected in most EU countries. In the EU21 countries, the ratio is projected to increase from 37.1% in 2011 to 76.1% in 2050.

above, a novel feature of the model is the estimate of habit persistence. We find that young nurses (like young medical doctors) have less habit persistence than the older ones.

Moreover we find that the preferences are rather similar for nurses and physicians, with the exception that the number of small children has a significant negative impact on labor supply for nurses, but not for physicians. Most of the physicians are males while almost all nurses are females. Another important finding is that the overall elasticities are close to zero and very similar to the ones for medical doctors.

Di Tommaso et al. (2009) estimate on the same data a static discrete choice model of labor supply on nurses. The estimates indicate that overall labor supply is rather inelastic with an average elasticity of 0.33. The results is similar to the results reported in Shields (2004). This paper shows, based on the longitudinal approach and with habit persistence, that the labor supply of nurses becomes even more inelastic.

In the next section we give a brief but self-contained review of the model. Data is presented in Section 3. Estimates, elasticities and the result of a policy simulation are reported in the following sections.

## 2. Model

The model we use in this section is similar to the model estimated for physicians by Andreassen et al (2013) so that it is possible to show similarities and differences between nurses and physicians.

The model we employ allows for habit persistence and therefore correlation in utilities across time. Let  $U_{jn}(t)$  be the utility of nurse  $n$  when working in job type  $j$  at time  $t$ . The utility function is assumed to be random because there are job attributes that affect preferences that we do not observe. Let  $v_{jn}(t)$  be the systematic part of the utility function and let  $\varepsilon_{jn}(t)$  be the random taste shifter, assumed to be independent and identical extreme value distributed. Following Dagsvik (2002), we assume that

$$(1) \quad U_{jn}(t) = \max_j \left[ U_{jn}(t-1) - \rho, v_{jn}(t) + \varepsilon_{jn}(t) \right]$$

The coefficient  $\rho$  is a preference discount factor. If  $\rho = 0$  there is a complete strong taste or habit persistence, and if  $\rho = \infty$  there is no taste persistence at all and  $U_{jn}(t) = v_{jn}(t) + \varepsilon_{jn}(t)$ . The inclusion of taste or habit persistence is a behavioural assumption and it implies that individuals' past options (and not only past optimal choices) matter for current choices. This implies that the current choice depends on all the utility functions associated with each alternative in the past, not only the optimal one. If  $\rho = \infty$ , the model degenerates to a standard multinomial logit model that can be estimated on panel data, see Train (2003). If  $\rho = 0$ , then utilities are perfectly correlated across time.

From the model we can derive transition probabilities, which will be estimated on panel data. We will assume that nurse  $n$  will choose the state that maximizes utility, given his or her choice set. Nurses can choose between 10 states, which vary with respect to type of institution (hospitals versus primary care), sector (public versus private) and hours offered by the institutions in the health care sector (part time versus full time). Part time is defined as a number of hours of work less than 30. We will assume that the choice set is related to availability of jobs, characterized by offered hours. Thus, in our model the nurses are not free to choose any hours they like to work. We will assume that

$$(2a) \quad g_{jnt}(h_{jnt}) = \exp(d_{1j}z_{jnt}); \quad z_{jnt} = 1 \text{ if } h_{jnt} \leq 30; = 0 \text{ otherwise, (part-time)}$$

$$(2b) \quad g_{jnt}(h_{jnt}) = \exp(d_{2j}z_{jnt}); \quad z_{jnt} = 1 \text{ if either } h_{jnt} \geq 30; = 0 \text{ otherwise, (full-time)}$$

Note that the  $g(\cdot)$  function captures the rationing of full time jobs and  $d_{kj}$  are parameters to be estimated for each sector  $j$  and working loads  $k$ . The  $g(\cdot)$  function capture the availability of full time and part hours in the different jobs.<sup>5</sup> For physicians there are only a rationing of full time jobs while for nurses there is a rationing of part time as well as full time jobs.

Let  $Q_{ijnt}$  denote the probability that doctor or nurse  $n$  moves from state  $i$  in period  $t-1$  to state  $j$  in period  $t$ , and  $Q_{iint}$  denotes the probability that doctor or nurse  $n$  stays in state  $i$  also in period  $t$ .

With the assumed probability distribution for  $\varepsilon_{jnt}$ , we get (Dagsvik (2002):

$$(3) \quad Q_{ijnt} = \frac{V_{jnt}}{\sum_{r=t_0}^t \left\{ \left[ \exp(-(t-r)\rho) \right] \sum_{k=0}^9 V_{knr} \right\}}; \quad \forall i, j = 0, 1, 2, \dots, 9$$

$$Q_{iint} = 1 - \sum_{\substack{j=0 \\ j \neq i}}^9 Q_{ijnt}; \quad \forall i, j = 0, 1, 2, \dots, 9$$

<sup>5</sup> See Dagsvik and Strøm (2006) for further details about rationing of jobs in labor supply models.

where  $V_{jnt} = \exp(v_{jnt})g_{jnt}$

The different job types that the employed nurse can choose between are:

0 = not working

1 = working part time in a hospital in the private sector;

2 = working full time in a hospital in the private sector;

3 = working part time in primary care in the private sector;

4 = working full time in primary care in the private sector;

5 = working part time in a hospital in the public sector;

6 = working full time in a hospital in the public sector;

7 = working part time in primary care in the public sector;

8 = working full time in primary care in the public sector;

9 = working in other sectors<sup>6</sup>.

## 2.1 The deterministic part of the utility function

We will assume that the systematic or deterministic part of the utility function is given by:

$$(4) \quad \log v_{jnt} = \left( A + \sum_{s=1}^4 a_s X_{snt} \right) \frac{(C_{jnt} 10^{-5})^\lambda - 1}{\lambda} + \left( B + \sum_{s=5}^7 b_s X_{snt} \right) \frac{(L_{jnt} - L_0)^\gamma - 1}{\gamma}$$

Here  $C_{jnt}$  is disposable annual income, and it is given by

$$(5) \quad C_{jnt} = f_t(w_{jnt}h_{jnt} + SI_{nt}) + I_{nt},$$

$w_{jnt}$  is the hourly wage rate,  $h_{jnt}$  denotes annual hours of work,  $SI_{nt}$  is the wage income from secondary jobs and  $I_{nt}$  is non-labor income, including the after-tax income of a spouse, child benefits and other benefits. The functional form of  $f_t(\cdot)$  depends on the characteristics of the tax function,  $T_t(\cdot)$ , which is a step-wise linear tax function at time t, see tables A.1-A.3 in Appendix A.

---

<sup>6</sup> The classification of sectors is based on the standard used by Statistics Norway, which is based on the statistical Classification of Economic Activities (NACE) used in the European Community. The sector "Other sectors" consists of all types of jobs that do not fall in under either hospital or health care services. It thereby includes nurses doing a wide variety of work outside the traditional health care sectors, such as administrative work in government and in the private sector.

Annual leisure is denoted  $L_{jnt}$ . We assume 12 hours a day for rest and sleep and 48 weeks of work a year. Therefore, leisure in this definition is equal to the total number of hours in a year (8760) minus sleeping time in a year minus hours of work. Leisure includes therefore hours in the week-ends and in vacation time:

$$(6) \quad L_{jnt} = \frac{8760 - (12 \times 365) - 48h_{jnt}}{8760}$$

Moreover  $X_{1nt}$  is age and  $X_{2nt}$  is age squared. We account for the possibility that there is an impact on hours supplied when spouses are working in jobs where shift work is very common like in the health sector. We have thus included a dummy variable  $X_{3nt}$  which equals 1 if the nurse is married to a person in the health sector, and equal 0 otherwise. Other observed covariates that are included to account for observed heterogeneity are the dummy variables  $X_{4nt}$  that equals 1 if more than one job, and equal to 0 otherwise;  $X_{5nt}$  equals 1 if number of children  $\leq 6$ ; and  $X_{6nt}$  equals 1 if number of children  $\{>6, \leq 11\}$  and finally  $X_{7nt}$  equals 1 if female, and equal to 0 otherwise.

To account for the possibility that habit persistence may increase with age (a lower preference discount parameter) we let the preference discount parameter  $\rho$  depend on the age and age squared of the nurse:

$$(7) \quad \rho_n = \rho_0 + \rho_1 X_{1n} + \rho_2 X_{2n}$$

To estimate the model we need estimates of the wage equation. How this is done and how the models is estimated (through simulated maximum likelihood) are described in Appendix B.

### 3. Data

The data used in this study are the result of merging register data from Statistics Norway with data on physicians and nurses collected by The Norwegian Association of Local and Regional Authorities (from the PAI<sup>7</sup> register). The register data from Statistics Norway consists of

---

<sup>7</sup> The PAI register consists of data on workers in public enterprises, including physicians and nurses working in hospitals and health care.

demographic, educational, income and labor market data. The income data is taken from tax returns, while the labor market data consist of employee data merged with data on employers.

The resulting panel data set covers *all* employed registered nurses in Norway in the period 1997 – 1999. Appendix C shows the data for nurses and compare them with the data for physicians as reported in Andreassen et al. (2013). We only use observations of married individuals who did not change their marital status during the observation period. Table C.1 in Appendix C shows the sample selection. The final sample has 28,578 married nurses.

We have coded the data so that we ended up with 10 different sectors of work described above (including not working). Table C.2 gives the distribution of physicians and nurses across sectors. Most nurses work in hospitals and primary care. Among working nurses, 59 percent work part-time in 1999, while only 31 percent of working physicians work part time.

Our data only included hours worked per year, so weekly hours are calculated by dividing hours worked in a year by 48 (weeks in a year minus vacation). Table C.3 shows the number of hours worked in the different sectors. Working hours for full time jobs are longer in the private sector compared to the public sector, while working hours for part time jobs are longer in the public sectors. Table C.4 reports also the distribution between short part-time and long-part time for nurses.

Table C.5 shows the mean of the explanatory variables for married physicians and married registered nurses. Women constitute around 27 per cent of physicians and 95 per cent of nurses. The average age of nurses increases from 43 in 1997 to 45 in 1999. Also the average age of physicians increases in the same period. 13 percent of nurses are married with somebody in the health sector and 43 percent of physicians are married with somebody in the health sector. The percentage of nurses with an external job decreases from 7 percent in 1997 to 6 percent in 1999. For physicians, the percentages changes from 10 to 8 percent.

Our model is based on the assumption that we can simulate the different levels of consumption and leisure which could be achieved by each individual in each sector if they chose to work there. Our calculations are based on estimated wage equations done independently for the three years 1997, 1998 and 1999. The resulting levels of possible consumption and leisure are reported in Table C.6 and C.7 respectively. For the states which are observed chosen by an individual we use observed leisure, while for other potential, but not chosen states, we use average leisure among those observed in the state. Consumption is determined by wage income, capital income, transfer

income and the income of the spouse. All income variables were deflated by the consumer price index. Leisure is expressed as a percentage of available time. Available time includes time over the week-ends and vacation time but excludes 12 hours per day of sleeping and personal care time.

In Appendix D, Tables D.1-D.4, we report the observed transitions across states. Although “stayers” are dominating there are also a considerable amount of “movers”.

In order to estimate the model of Section 2, we need to estimate the wage equations. Appendix E report the data and the estimates of the wage equation following the methodology explained in Appendix B.

#### **4. Estimates**

In this section we report the results for the labor supply of nurses alongside with the results for physicians estimated by Andreassen et al (2013). The estimate of the utility function is given in Table 1 and the estimates of the rationing function, the availability of jobs, is given in Table 2 below.

(Table 1 and 2 approximately here)

The exponents in the Box-Cox utility function are both less than 1 which implies that the utility function is strictly concave. For nurses, the part of the utility that is related to leisure is not significantly different from a log linear function. For both medical doctors and nurses, the marginal utility of consumption is declining in consumption. Its variation with age is shown in Figure 1.

(Figure 1 approximately here)

The marginal utility of consumption is a concave function of age with a peak around 40 year of age for nurses and 45 for medical doctors. For both nurses and physicians, the marginal utility is shifted upwards if the spouse also works in the health sectors. This implies that health workers married to health workers have stronger incentives to work longer hours in the health sector than other health workers.

The impact of having children below the age of 7 on the leisure term is not significantly different from zero for physicians but positive for nurses. Thus nurses with small children have lesser incentives to work long hours compared to physicians, which may be due to the fact that most of the nurses are women while most physicians are men. As in most countries women takes more

care of small children than men. It is interesting to note that the impact of older children on the marginal utility of leisure is positive and similar for both nurses and physicians.

The estimate of the habit persistence parameters implies that the young are more mobile than the old, given wages, taxes and other incentives. As seen on Figure 2 this is particular the case for medical doctors.

(Figure 2 approximately here)

Mobility as captured by the habit persistence parameters are declining with age, more strongly for physicians than for nurses, and with a weak tendency of increasing again when the health workers are approaching retirement age.

How well the model fits data is illustrated on Figures 3 and 4. With a few exceptions, in particular for private hospitals where the observations are few, the model fits data pretty well.

(Figure 3 and 4 approximately here)

## 5. Elasticities

In Table 3 we report the impact of an overall wage increase in all years from 1997 to 1999 on labor supply in 1999. In Table 4 we report similar elasticities based on some selected characteristics.

(Table 3 and 4 approximately here)

We observe that the labor supply of both nurses and doctor are rather inelastic. An overall wage increase of 1 percent increases labor supply in terms of total hours of work in 1999 by only 0.03-0.04 percent. However an overall wage increase is predicted to have a stronger impact on the distribution of physicians and nurses across job types. An overall wage increase is predicted to shift in particular physicians to full time jobs in hospitals.

Table 4 shows that the labor supply elasticities of physicians do not vary much according to either age or to their original state. On the other hand, the wage elasticities of nurses vary greatly, being higher if they are not working, than if they are working full or part-time. The elasticities for those not working are higher for nurses than for physicians. Having young children does not affect the labor supply of physicians (the coefficient is not significantly different from zero), but has a relatively strong effect on the wage elasticities of nurses. These results indicate that for nurses the work/not work decision is more important than for physicians (especially if they have young children), while income plays a greater role for physicians.

## 6. Policy simulation

In Table 5 we report the impact of change in taxation away from the current progressive tax system towards a flat tax of 28%. The change in taxation is implemented for the whole period 1997-1999. This change in taxation gives the medical doctors an incentive to shift their work from part time jobs to full time jobs, in particular to jobs in the private sector. The reason for this is that wage levels and wage dispersion is much higher in the private than in the public sector. By moving to the private sector and by increasing their working loads the medical doctor can keep more of their gross gain due to lower taxes. For nurses the impact of lower taxes is much weaker. Most of them have lower income in potential new jobs, even in the private sector, than physicians and therefore they don't benefit that much from shifting jobs. Some of the nurses have so low potential income that the flat tax of 28% increases their taxes. Moreover, their spouses get higher disposable income and this also has a negative impact on their labor supply. We therefore find that some quit working.

(Table 5 approximately here)

## 7. Conclusion

We have estimated a discrete choice model with random terms where we allow for these terms to be correlated over time and jobs (habit persistence). Past options and not only the past optimal choices matter for the current choices. Given observed incentives we find that both nurses and in particular medical doctors are mobile when they are young, but there is a weak tendency of higher mobility again when physicians and nurses are approaching retirement age.

Wage increases have a modest impact on labor supply. The overall elasticity for both physicians and nurses are close to zero. These low elasticities shadow to some extent for stronger responses, shifting labor away from part time jobs in the public and private sector towards full time jobs in the private sector. This latter result accords well with the fact that in recent years when the real wages in Norway have increased substantially there are more physicians and nurses working in private hospitals. The regulation of hours is more rigid in the public than in the private sector.

Our results indicate that a reform that may help in increasing the labor supply of nurses is to remove some of the constraints related to the availability of full time jobs for nurses.

A change in taxation away from the progressive tax system towards a flat tax of 28% gives the medical doctor an incentive to shift their job to private hospitals. The reason for this is that the wage level and dispersion is much higher in the private than in the public sector. With a lower and flat tax rate they can reap more of these private benefits. For nurses the impact is much more modest. Their potential wage when moving is not that much higher than in the public sector, at least compared with the situation for physicians.

## Appendix B. Estimation procedures

### The wage equations

In order to estimate the model we need estimates of the wage equations. Log wage is assumed to depend on observed covariates (the  $Z$ -vector to be defined below) and a random term. The random term consist of two parts; one that is distributed across job types, individuals and time, and one that is distributed only across individuals. The latter random component accounts for correlation in wages across type of jobs at each point in time. The wage equations are the following:

$$(A.1) \left\{ \begin{array}{l} \log W_{it} = Z_{it}\beta_{it} + \eta_{it} \\ \eta_{it} = \tilde{e}_{it} + \kappa_{it}\tau_n \\ \tau_n \sim L(0,1) \\ \tilde{e}_{it} = \sigma_{it}e_{it}, \text{ where } e_{it} \sim L(0,1) \end{array} \right.$$

$L(0,1)$  is the standard logistic distribution

We then get

$$(A.2) \quad \log W_{it} = Z_{it}\beta_{it} + \sigma_{it}e_{it} + \kappa_{it}\tau_n; \quad i = 1, 2, \dots, 9$$

The correlations in wages across jobs are given by:

$$(A.3) \left\{ \begin{array}{l} \text{cov}(\eta_{int}, \eta_{jnt}) = E[\eta_{int}\eta_{jnt}] = \kappa_{it}\kappa_{jt} \\ \text{corr}(\eta_{int}, \eta_{jnt}) = \frac{\kappa_{it}\kappa_{jt}}{\sqrt{\sigma_{it}^2 + \kappa_{it}^2} \sqrt{\sigma_{jt}^2 + \kappa_{jt}^2}} \end{array} \right.$$

The wage equations are estimated separately, but we account for selection in the following way. We estimate a set of coefficients for every year. Hence we are using 3 (1997-1999) cross-section datasets to estimate the coefficients. In the estimation of the wage equation we use a larger data set. Unmarried physicians and nurses are included and the justification is that there are no reasons to expect wages to differ with respect to marital status. The coefficients vary across the 9 job types and over time. The vector of the explanatory variables  $Z_{nt}$  is (1, age, gender, centrality index education)

Let  $\varphi$  be the density for the normalized (0,1) logistic density distribution. And let

$$(A.3) \left\{ \begin{array}{l} L_t = \prod_{j=1}^9 \frac{1}{\sigma_{jt} w_{jnt}} \varphi \left( \frac{\log w_{jnt} - Z_{nt} \beta_{jt} - \kappa_{jt} \tau_n - \lambda_{jt} \log P_{jnt}}{\sigma_{jt}} \right) \\ \text{and} \\ \hat{\varphi}(\cdot) = \frac{1}{S} \sum_{s=1}^S \varphi \left( \frac{\log w_{jnt} - Z_{nt} \beta_{jt} - \kappa_{jt} \tau_n - \lambda_{jt} \log P_{jnt}}{\sigma_{jt}} \right) \\ \text{and} \\ \log \hat{L}_t = \sum_{n=1}^{N_t} \sum_{j=1}^9 -\log \sigma_{jt} - \log \hat{\varphi}(\cdot) \end{array} \right.$$

The latter  $\log \hat{L}_t$  is used to estimate coefficients in the wage equations. Here  $s$  is a random draw for each individual from a standard logistic distribution, number of draws are  $S=20$ .  $P_{jnt}$  is a standard multinomial logit probability (for doctor or nurse  $n$ , working in job type  $j$  at time  $t$ ) used to capture selection effects, see Strøm and Wagenhals (1991) for an outline of selection effects in wage equations with logistic distributed error terms.

$$(A.4) \left\{ \begin{array}{l} P_{jnt} = \frac{v_{jnt}}{\sum_{k=0}^9 v_{knt}}; j = 0, 1, 2, \dots, 9 \\ v_{jnt} = y_{nt} \alpha_{jt} \end{array} \right.$$

Here the vector  $y_{nt}$  is (1, age, education, number of children above and below 6 years of age, dummy for married or cohabiting, dummy for married to a person working in the health sector or not, spouse income). Note that the coefficients, both in the wage equations and in the probabilities capturing selection effects,  $P_{jnt}$ , vary across alternatives and over time. Not working is among the alternatives in the probabilities. The estimates of the wage equations and the probabilities related to selection effects, as well as summary statistics, are given in Appendix C.

### Estimation of the utility function and rationing of jobs

To proceed with the estimation of the utility function we first have to calculate the disposable income function, here called consumption, in each of the 10 states. For all states, irrespective of the fact that we have observed the wage in the job chosen by the agent, we use the wage equation, including all terms, also the error terms. For the working states we have done the following:

$$(A.5) \quad \left\{ \begin{array}{l} C_{int} = f_t(w_{int}h_{jnt} + I_{nst}) + I_{nt}, \quad i=1,2,,9 \\ f_t(w_{int}h_{int} + I_{nst}) = w_{int}h_{int} + I_{nst} - T(w_{int}h_{int} + I_{nst}) \\ \log W_{int} = Z_{nt}\beta_{it} + \hat{\sigma}_{it}e_{int} + \hat{\kappa}_i\tau_n; \quad i=1,2,,9 \end{array} \right.$$

The consumption that we will use in the estimation of the utility function is:

$$(A.6) \quad C_{int} = \frac{1}{SR} \sum_{s=1}^S \sum_{r=1}^R \left[ \exp(Z_{nt}\beta_{it} + \hat{\sigma}_{it}e_{int} + \hat{\kappa}_i\tau_n) h_{int} + I_{nst} \right], \quad i=1,2,,9$$

Here the coefficients in the wage equations are estimated from the previous step.  $s=1,2,,S$  and  $r=1,2,,R$ , are draws from the standard logistic distribution. We have used  $S=R=20$ . Instead of integrating out the error terms in the wage equations in the disposable income function, we could have integrated them out in the final likelihood function. Due to the complexity of the model we have chosen to do the former. Due to the random variables in the wage equations which are present in the transition probabilities, the assumption of IIA is avoided.

The parameters of the utility function, including the habit persistence parameter  $\rho$ , are estimated in a maximum likelihood approach where the likelihood depends on the transition probabilities. The initial year,  $t_0$ , is 1997, and the years where transitions can take place are 1998 and 1999. Let the vector of coefficients to be estimated be  $\pi$ .

Suppressing the observed variables and the random variables that are integrated out, the transition probabilities can be written

$$(A.7) \quad Q_{jnt} = Q_{jnt}(\pi)$$

The likelihood for our sample is:

$$(A.8) \quad L = \prod_{t=1997}^{1999} \prod_{n=1}^{N_t} \prod_{i=1}^9 \prod_{j=1}^9 Q_{ijnt}(\pi)^{y_{i(t-1),j(t),n}}$$

$y_{i(t-1),j(t),n} = 1$  if  $n$  transit from state  $i$  in year  $t-1$  to state  $j$  in year  $t$   
 otherwise

$$y_{i(t-1),j(t),n} = 0$$

## Appendix C. Data

In this appendix the data and estimates for physicians are copied from Andreassen et al (2013).

**Table C.1 Sample selection**

|   | Physicians   | Nurses        |
|---|--------------|---------------|
| Norwegian physicians and nurses in 2000, original data set  | 12,376       | 55,180        |
| Dropped due to missing sector or missing gender             | 688          | 1,122         |
| Dropped if not a doctor or nurse in 1997, 1998 or 1999      | 2,172        | 9,458         |
| Dropped if not married throughout 1997 to 1999              | 2,934        | 16,022        |
| Dropped if occupation not relevant                          | 18           | 0             |

Note: The column to the left gives the states in 1998. Bold value indicates that the individual does not change state.

**Appendix E. Wage equations and selection effects for nurses, for physicians see Andreassen et al (2013).**

We estimate wage equations for all individuals for the three years 1997, 1998 and 1999. The wage equations for physicians are documented in Andreassen et al (2013). The wage equations for nurses are documented below. We take sample selection into account by including the predicted choice probabilities,  $Pr_1 - Pr_9$ , as explanatory variables in the wage equations. These probabilities were the predictions resulting from a simple multinomial logit estimation of sector choice. We show the mean of the explanatory variables used in the estimation of the choice probabilities in Table E.1. The estimates of the choice probabilities are given in Table E.2 and the resulting average predicted probabilities are given in Tables E.3, along with the means of the other variables used in the wage equations. The logit estimations were done on all nurses in a given year, while the wage equations were estimated on all working nurses with observations of wage income. The estimates of the wage equations are given in Table E.5. The wage equations for all nine work sectors have been estimated simultaneously using maximum likelihood, allowing for correlation between the different wages. The parameters  $\sigma_1$  to  $\sigma_9$  are the variance parameters mentioned in the main paper, and the parameters  $\kappa_1$  to  $\kappa_9$  are the parameters allowing for correlation between sectors. As can be seen from the tables these correlation factors are not found to be significant, indicating that there is not much residual correlation between the different wages after correcting for the other explanatory variables. In general being a woman reduces wages, while wages increase with age. Table E.6 shows the mean and predicted hourly wages for nurses and derived from predictions using the estimated wage equations reported above. Table E.7 shows the predicted wages for physicians based on the wage equations documented in Andreassen et. al. (2013). The wages for doctors are higher and vary more than the wages of nurses.

**Table E.1. Mean of the explanatory variables for the logit estimation. All nurses.**
