#### Abstract

We report the observation of the $X(3823)$ state in the process $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823) \rightarrow \pi^{+} \pi^{-} \gamma \chi_{c 1}$ with a statistical significance of $6.2 \sigma$, in data samples at center-of-mass energies $\sqrt{s}=4.230,4.260,4.360$, 4.420 , and 4.600 GeV collected with the BESIII detector at the BEPCII electron positron collider. The measured mass of the $X(3823)$ state is $(3821.7 \pm 1.3 \pm 0.7) \mathrm{MeV} / c^{2}$, where the first error is statistical and the second systematic, and the width is less than 16 MeV at the $90 \%$ confidence level. The products of the Born cross sections for $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$ and the branching ratio $\mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1, c 2}\right]$ are also measured. These measurements are in good agreement with the assignment of the $X(3823)$ state as the $\psi\left(1^{3} D_{2}\right)$ charmonium state.

Since its discovery, charmonium-meson particles which contain a charm and an anticharm quark-has been an excellent tool for probing quantum chromodynamics (QCD), the fundamental theory that describes the strong interactions between quarks and gluons, in the nonperturbative (low-energy, long-distance effects) regime, and remains of high interest both experimentally and theoretically. All of the charmonium states with masses that are below the open-charm threshold have been firmly established [1,2]; open-charm refers to mesons containing a charm quark (antiquark) and either an up or down antiquark (quark), such as $D$ or $\bar{D}$. However, the observation of the spectrum that is above the open-charm threshold remains unsettled. During the past decade, many new charmoniumlike states have been discovered, such as the $X(3872)$ [3], the $Y(4260)$ [4,5] and the $Z_{c}(3900)$ [5-7]. These states provide strong evidence for the existence of exotic hadron states [8]. Although charged charmoniumlike states like the $Z_{c}$ (3900) provide convincing evidence for the existence of multiquark states [9], it is more difficult to distinguish neutral candidate exotic states from conventional charmonium. Moreover, the study of transitions between charmonium(like) states, such as the $Y(4260) \rightarrow \gamma X(3872)$ [10], is an important approach to probe their nature, and the connections between them. Thus, a more complete understanding of charmonium(like) spectroscopies and their relations is necessary and timely.

The lightest charmonium state above the $D \bar{D}$ threshold is the $\psi(3770)$ [2], which is currently identified as the $1^{3} D_{1}$ state [1], the $J=1$ member of the $D$-wave spin-triplet charmonium states. Until now there have been no definitive observations of its two $D$-wave spin-triplet partner states, i.e., the $1^{3} D_{2}$ and $1^{3} D_{3}$ states. Phenomenological models predict that the $1^{3} D_{2}$ charmonium state has large decay widths to $\gamma \chi_{c 1}$ and $\gamma \chi_{c 2}$ [11]. In 1994, the E705 Collaboration reported a candidate for the $1^{3} D_{2}$ state with a mass of $3836 \pm 13 \mathrm{MeV} / c^{2}$ and a statistical significance of $2.8 \sigma$ [12]. Recently, the Belle Collaboration reported evidence for a narrow resonance $X(3823) \rightarrow \gamma \chi_{c 1}$ in $B$ meson decays with $3.8 \sigma$ significance and mass $3823.1 \pm 1.8$ (stat) $\pm 0.7$ (syst) $\mathrm{MeV} / c^{2}$, and suggested that this is a good candidate for the $1^{3} D_{2}$ charmonium state [13]. In the following, we denote the $1^{3} D_{2}$ state as $\psi_{2}$ and the $\psi(3686)[\psi(2 S)]$ state as $\psi^{\prime}$.

In this Letter, we report a search for the production of the $\psi_{2}$ state via the process $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X$, using $4.67 \mathrm{fb}^{-1}$ data collected with the BESIII detector operating at the BEPCII storage ring [14] at center of mass (c.m.) energies that range from $\sqrt{s}=4.19$ to 4.60 GeV [15]. The $\psi_{2}$ candidates are reconstructed in their $\gamma \chi_{c 1}$ and $\gamma \chi_{c 2}$ decay modes, with $\chi_{c 1, c 2} \rightarrow \gamma J / \psi$ and $J / \psi \rightarrow \ell^{+} \ell^{-}(\ell=e$ or $\mu)$. A geant4based [16] Monte Carlo (MC) simulation software package is used to optimize event selection criteria, determine the detection efficiency, and estimate the backgrounds. For the signal process, we generate $40000 e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$ events at each c.m. energy indicated above, using an EVTGEN [17] phase space model, with $X(3823) \rightarrow \gamma \chi_{c 1, c 2}$. The initial state radiation (ISR) is simulated with ккмс [18], where the Born cross section of $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$ between 4.1 and 4.6 GeV is assumed to follow the $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}$ line shape [19]. The maximum ISR photon energy is set to correspond to the $4.1 \mathrm{GeV} / c^{2}$ production threshold of the $\pi^{+} \pi^{-} X(3823)$ system. The final state radiation is handled with Рнотоs [20].

Events with four charged tracks with zero net charge are selected as described in Ref. [6]. Showers identified as photon candidates must satisfy the fiducial and shower quality as well as timing requirements as described in Ref. [21]. At least two good photon candidates in each event are required. To improve the momentum and energy resolution and to reduce the background, the event is subjected to a four-constraint (4C) kinematic fit to the hypothesis $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \gamma \gamma \ell^{+} \ell^{-}$, that constrains the total four-momentum of the detected particles to the initial fourmomentum of the colliding beams. The $\chi^{2}$ of the kinematic fit is required to be less than 80 (with an efficiency of about $95 \%$ for signal events). For multiphoton events, the two photons returning the smallest $\chi^{2}$ from the 4C fit are assigned to be the radiative photons.

To reject radiative Bhabha and radiative dimuon ( $\gamma e^{+} e^{-}$ and $\gamma \mu^{+} \mu^{-}$) backgrounds associated with photon conversion, the cosine of the opening angle of the pion-pair candidates is required to be less than 0.98 . This restriction removes almost all Bhabha and dimuon background events, with an efficiency loss that is less than $1 \%$ for signal events. The background from $e^{+} e^{-} \rightarrow \eta J / \psi$ with $\eta \rightarrow \pi^{+} \pi^{-} \pi^{0}$ or $\gamma \pi^{+} \pi^{-}$is effectively rejected by the invariant mass requirement $M\left(\gamma \gamma \pi^{+} \pi^{-}\right)>0.57 \mathrm{GeV} / c^{2}$. MC simulation shows that this requirement removes less than $1 \%$ of the signal
events. In order to remove possible backgrounds from $e^{+} e^{-} \rightarrow \gamma_{\mathrm{ISR}} \psi^{\prime} \rightarrow \gamma_{\mathrm{ISR}} \pi^{+} \pi^{-} J / \psi$, accompanied with a fake photon or a second ISR photon, $e^{+} e^{-} \rightarrow \eta \psi^{\prime}$ with $\eta \rightarrow \gamma \gamma$, and $e^{+} e^{-} \rightarrow \gamma \gamma \psi^{\prime}$, the invariant mass of $\pi^{+} \pi^{-} J / \psi$ is required to satisfy $\left|M\left(\pi^{+} \pi^{-} J / \psi\right)-m\left(\psi^{\prime}\right)\right|>6 \mathrm{MeV} / c^{2}$ [22]. The signal efficiency for the $\psi^{\prime}$ mass window veto is $85 \%$ at $\sqrt{s}=4.420 \mathrm{GeV}$ and $\geq 99 \%$ at other energies.

After imposing the above requirements, there are clear $J / \psi$ peaks in the $M\left(\ell^{+} \ell^{-}\right)$invariant mass distributions for the data. The $J / \psi$ mass window is defined as $3.08<M\left(\ell^{+} \ell^{-}\right)<3.13 \mathrm{GeV} / c^{2}$. The mass resolution is determined to be $9 \mathrm{MeV} / c^{2}$ by MC simulation. In order to evaluate non- $J / \psi$ backgrounds, we define $J / \psi$ mass sidebands as $3.01<M\left(\ell^{+} \ell^{-}\right)<3.06 \mathrm{GeV} / c^{2}$ or $3.15<M\left(\ell^{+} \ell^{-}\right)<3.20 \mathrm{GeV} / c^{2}$, which are twice as wide as the signal region. The combination of the higher energy photon $\left(\gamma_{H}\right)$ with the $J / \psi$ candidate is used to reconstruct $\chi_{c 1, c 2}$ signals, while the lower one is assumed to originate from the $X(3823)$ decay. We define the invariant mass range $3.490<M\left(\gamma_{H} J / \psi\right)<$ $3.530 \mathrm{GeV} / c^{2}$ as the $\chi_{c 1}$ signal region, and $3.536<$ $M\left(\gamma_{H} J / \psi\right)<3.576 \mathrm{GeV} / c^{2}$ as the $\chi_{c 2}$ signal region $\left[M\left(\gamma_{H} J / \psi\right)=M\left(\gamma_{H} \ell^{+} \ell^{-}\right)-M\left(\ell^{+} \ell^{-}\right)+m(J / \psi)\right]$.

To investigate the possible existence of resonances that may decay to $\gamma \chi_{c 1, c 2}$, we examine two-dimensional scatter plots of $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$versus $M\left(\gamma_{H} J / \psi\right)$. Here, $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)=\sqrt{\left(P_{e^{+} e^{-}}-P_{\pi^{+}}-P_{\pi^{-}}\right)^{2}}$ is the recoil mass of the $\pi^{+} \pi^{-}$pair, where $P_{e^{+} e^{-}}$and $P_{\pi^{ \pm}}$are the 4-momenta of the initial $e^{+} e^{-}$system and the $\pi^{ \pm}$, respectively. For this, we use the $\pi^{+} \pi^{-}$momenta before the 4 C fit correction because of the good resolution for low momentum pion tracks, as observed from MC simulation. Figure 1 shows $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$versus $M\left(\gamma_{H} J / \psi\right)$ for data at different energies, where $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime} \rightarrow \pi^{+} \pi^{-} \gamma \chi_{c 1, c 2}$ signals are evident in almost all data sets. In addition, event accumulations near $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right) \simeq 3.82 \mathrm{GeV} / c^{2}$ are evident in the $\chi_{c 1}$ signal regions of the $\sqrt{s}=4.36$ and 4.42 GeV data sets. A scatter plot of all the data sets combined is shown in Fig. 1(f), where there is a distinct cluster of events near $3.82 \mathrm{GeV} / c^{2}$ [denoted hereafter as the $X(3823)$ state] in the $\chi_{c 1}$ signal region.

The remaining backgrounds mainly come from $e^{+} e^{-} \rightarrow\left(\eta^{\prime} / \gamma \omega\right) J / \psi$, with $\left(\eta^{\prime} / \omega\right) \rightarrow \gamma \gamma \pi^{+} \pi^{-}$or $\gamma \pi^{+} \pi^{-}$, and $\pi^{+} \pi^{-} \pi^{+} \pi^{-}\left(\pi^{0} / \gamma \gamma\right)$. The $e^{+} e^{-} \rightarrow\left(\eta^{\prime} / \gamma \omega\right) J / \psi$ backgrounds can be measured and simulated using the same data sets. The $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \pi^{+} \pi^{-}\left(\pi^{0} / \gamma \gamma\right)$ mode can be evaluated with the $J / \psi$ mass sideband data. All these backgrounds are found to be small, and they produce flat contributions to the $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$mass distribution. There also might be $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}$ events with $\psi^{\prime} \rightarrow \eta J / \psi$ and $\pi^{0} \pi^{0} J / \psi$, but such kind of events would not affect the $\psi^{\prime}$ mass in the $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$distribution.

An unbinned maximum likelihood fit to the $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$distribution is performed to extract the $X(3823)$ signal parameters. The signal shapes are

FIG. 1 (color online). Scatter plots of $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$vs $M\left(\gamma_{H} J / \psi\right)$ at (a) $\sqrt{s}=4.230$, (b) 4.260 , (c) 4.360 , (d) 4.420, and (e) 4.600 GeV . The sum of all the data sets is shown in (f). In each plot, the vertical dashed red lines represent $\chi_{c 1}$ (left two lines) and $\chi_{c 2}$ (right two lines) signal regions, and the horizontal lines represent the $\psi^{\prime}$ mass range (bottom two lines) and 3.82 GeV (top line), respectively.
represented by MC-simulated $\psi^{\prime}$ and $X(3823)$ (with input mass of $3.823 \mathrm{GeV} / c^{2}$ and a zero width) histograms, convolved with Gaussian functions with mean and width parameters left free in the fit to account for the mass and resolution difference between data and MC simulation, respectively. The background is parameterized as a linear function, as indicated by the $J / \psi$ mass sideband data. The $\psi^{\prime}$ signal is used to calibrate the absolute mass scale and the resolution difference between data and simulation, which is expected to be similar for the $X(3823)$ state and $\psi^{\prime}$. A simultaneous fit with a common $X(3823)$ mass is applied to the data sets with independent signal yields at $\sqrt{s}=4.230$, $4.260,4.360,4.420$, and 4.600 GeV (data sets with small luminosities are merged to nearby data sets with larger luminosities), for the $\gamma \chi_{c 1}$ and $\gamma \chi_{c 2}$ modes, respectively.

Figure 2 shows the fit results, which return $M[X(3823)]=$ $M[X(3823)]_{\text {input }}+\mu_{X(3823)}-\mu_{\psi^{\prime}}=3821.7 \pm 1.3 \mathrm{MeV} / c^{2}$ for the $\gamma \chi_{c 1}$ mode, where $M[X(3823)]_{\text {input }}$ is the input $X(3823)$ mass in MC simulation, $\mu_{X(3823)}=1.9 \pm$ $1.3 \mathrm{MeV} / c^{2}$ and $\mu_{\mu^{\prime}}=3.2 \pm 0.6 \mathrm{MeV} / c^{2}$ are the mass shift values for $X(3823)$ and $\psi^{\prime}$ histograms from the fit. The fit yields $19 \pm 5 X(3823)$ signal events in the $\gamma \chi_{c 1}$ mode. The statistical significance of the $X(3823)$ signal in the $\gamma \chi_{c 1}$ mode is estimated to be $6.2 \sigma$ by comparing the difference between the log-likelihood value [ $\Delta(\ln \mathcal{L})=27.5]$ with or without the $X(3823)$ signal in the fit, and taking the change of the number of degrees of freedom $(\Delta \mathrm{ndf}=6)$ into account, and its value is found to be larger than $5.9 \sigma$ with various systematic checks. For the $\gamma \chi_{c 2}$ mode, we do not observe an $X(3823)$ signal and provide

FIG. 2 (color online). Simultaneous fit to the $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$ distribution of $\gamma \chi_{c 1}$ events (left) and $\gamma \chi_{c 2}$ events (right), respectively. Dots with error bars are data, red solid curves are total fit, dashed blue curves are background, and the green shaded histograms are $J / \psi$ mass sideband events.
an upper limit on its production rate (Table I). The limited statistics preclude a measurement of the intrinsic width of $X(3823)$ state. From a fit using a Breit-Wigner function (with a width parameter that is allowed to float) convolved with Gaussian resolution, we determine $\Gamma[X(3823)]<$ 16 MeV at the $90 \%$ confidence level (C.L.) (including systematic errors).

The $X(3823)$ is a candidate for the $\psi_{2}$ charmonium state with $J^{\mathrm{PC}}=2^{--}$[13]. In the $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi_{2}$ process, the $\pi^{+} \pi^{-}$system is very likely to be dominated by an $S$ wave. Thus, a $D$ wave between the $\pi^{+} \pi^{-}$system and $\psi_{2}$ is expected, with an angular distribution of $1+\cos ^{2} \theta$ for $\psi_{2}$ in the $e^{+} e^{-}$c.m. frame. Figure 3(a) shows the angular distribution $(\cos \theta)$ of $X(3823)$ signal events selected by requiring $\quad 3.82<M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)<3.83 \mathrm{GeV} / c^{2}$. The inset shows the corresponding $M\left(\pi^{+} \pi^{-}\right)$invariant mass distribution per $20 \mathrm{MeV} / c^{2}$ bin. A Kolmogorov [23] test to the angular distribution gives the Kolmogorov statistic $D_{14 \text {,obs }}^{D}=0.217$ for the $D$-wave hypothesis and $D_{14, \mathrm{obs}}^{S}=0.182$ for the $S$-wave hypotheses. Because of limited statistics, both hypotheses can be accepted ( $D_{14, \mathrm{obs}}^{D}, D_{14, \mathrm{obs}}^{S}<D_{14,0.1}=0.314$ ) at the $90 \%$ C.L.

The product of the Born-order cross section and the branching ratio of $X(3823) \rightarrow \gamma \chi_{c 1, c 2}$ is calculated using $\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)\right] \mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1, c 2}\right]=$ $N_{c 1, c 2}^{\mathrm{obs}} /\left[\mathcal{L}_{\text {int }}(1+\delta)\left(1 /|1-\Pi|^{2}\right) \epsilon \mathcal{B}_{c 1, c 2}\right]$, where $N_{c 1, c 2}^{\mathrm{obs}}$ is the number of $X(3823) \rightarrow \gamma \chi_{c 1, c 2}$ signal events obtained
from a fit to the $M_{\text {recoil }}\left(\pi^{+} \pi^{-}\right)$distribution, $\mathcal{L}_{\text {int }}$ is the integrated luminosity, $\epsilon$ is the detection efficiency, $\mathcal{B}_{c 1, c 2}$ is the branching fraction of $\chi_{c 1, c 2} \rightarrow \gamma J / \psi \rightarrow \gamma \ell^{+} \ell^{-}$, and $(1+\delta)$ is the radiative correction factor, which depends on the line shape of $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$. Since we observe large cross sections at $\sqrt{s}=4.360$ and 4.420 GeV , we assume the $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$ cross section follows that of $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}$ over the full energy range of interest and use the $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}$ line shape from published results [19] as input in the calculation of the efficiency and radiative correction factor. The vacuum polarization factor $\left(1 /|1-\Pi|^{2}\right)$ is calculated from QED with $0.5 \%$ uncertainty [24]. The results of these measurements for the data sets with large luminosities at $\sqrt{s}=4.230$, $4.260,4.360,4.420$, and 4.600 GeV are listed in Table I. Since at each single energy the $X(3823)$ signal is not very significant, upper limits for production cross sections at the $90 \%$ C.L. based on the Bayesian method are given [systematic effects are included by convolving the $X(3823)$ signal events yield ( $n$ yield ) dependent likelihood curves with a Gaussian with mean value zero and standard deviation $n^{\text {yield }} \sigma_{\text {sys }}$, where $\sigma_{\text {sys }}$ is the systematic uncertainty of the efficiencies]. The corresponding production ratio of $\mathcal{R}_{\psi^{\prime}}=\left\{\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)\right] \mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1}\right]\right\} /$ $\left\{\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}\right] \mathcal{B}\left[\psi^{\prime} \rightarrow \gamma \chi_{c 1}\right]\right\}$ is also calculated at $\sqrt{s}=4.360$ and 4.420 GeV .

We fit the energy-dependent cross sections of $e^{+} e^{-} \rightarrow$ $\pi^{+} \pi^{-} X(3823)$ with the $Y(4360)$ shape or the $\psi(4415)$ shape with their resonance parameters fixed to the Particle Data Group (PDG) values [2]. Figure 3(b) shows the fit results, which give $D_{5, \mathrm{obs}}^{\mathrm{H} 1}=0.151$ for the $Y(4360)$ hypothesis $(\mathrm{H} 1)$ and $D_{5, \mathrm{obs}}^{\mathrm{H} 2}=0.169$ for the $\psi(4415)$ hypothesis (H2), based on the Kolmogorov test. Thus, we accept both the $Y(4360)$ and the $\psi(4415)$ hypotheses $\left(D_{5, \mathrm{obs}}^{\mathrm{H1}}\right.$, $\left.D_{5, \mathrm{obs}}^{\mathrm{H} 2}<D_{5,0.1}=0.509\right)$ at the $90 \%$ C.L.

The systematic uncertainties in the $X(3823)$ mass measurement include those from the absolute mass scale, resolution, the parameterization of the $X(3823)$ signal, and the background shape. Since we use the $\psi^{\prime}$ signal to calibrate the fit, we conservatively take the uncertainty

TABLE I. Number of observed events ( $N^{\text {obs }}$ ), integrated luminosities $(\mathcal{L})$ [15], detection efficiency $(\epsilon)$ for the $X(3823) \rightarrow \gamma \chi_{c 1}$ mode, radiative correction factor $(1+\delta)$, vacuum polarization factor $\left(1 /|1-\Pi|^{2}\right)$, measured Born cross section $\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)\right]$ times $\mathcal{B}_{1}\left[X(3823) \rightarrow \gamma \chi_{c 1}\right]\left(\sigma_{X}^{B} \mathcal{B}_{1}\right)$ and $\mathcal{B}_{2}\left[X(3823) \rightarrow \gamma \chi_{c 2}\right]\left(\sigma_{X}^{B} \mathcal{B}_{2}\right)$, and measured Born cross section $\sigma^{B}\left(e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} \psi^{\prime}\right)\left(\sigma_{\psi^{\prime}}^{B}\right)$ at different energies. Other data sets with lower luminosity are not listed. The numbers in the brackets correspond to the upper limit measurements at the $90 \%$ C.L. The relative ratio $\mathcal{R}_{\psi^{\prime}}=\left\{\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)\right] \mathcal{B}\left(X(3823) \rightarrow \gamma \chi_{c 1}\right)\right\} /\left\{\sigma^{B}\left[e^{+} e^{-} \rightarrow\right.\right.$ $\left.\left.\pi^{+} \pi^{-} \psi^{\prime}\right] \mathcal{B}\left(\psi^{\prime} \rightarrow \gamma \chi_{c 1}\right)\right\}$ is also calculated. The first errors are statistical, and the second systematic.

FIG. 3 (color online). (a) The $X(3823)$ scattering angle distribution for $X(3823)$ signal events, the inset shows the corresponding $M\left(\pi^{+} \pi^{-}\right)$invariant mass distribution per $20 \mathrm{MeV} / c^{2} \mathrm{bin}$; and (b) fit to the energy-dependent cross section of $\sigma^{B}\left[e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)\right] \mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1}\right]$ with the $Y(4360)$ (red solid curve) and the $\psi(4415)$ (blue dashed curve) line shapes. Dots with error bars are data. The red solid (blue dashed) histogram in (a) is MC simulation with a $D$ wave ( $S$ wave).
of $0.6 \mathrm{MeV} / c^{2}$ in the calibration procedure as the systematic uncertainty due to the mass scale. The resolution difference between the data and MC simulation is also estimated by the $\psi^{\prime}$ signal. Varying the resolution parameter by $\pm 1 \sigma$, the mass difference in the fit is $0.2 \mathrm{MeV} / c^{2}$, which is taken as the systematic uncertainty from resolution. In the $X(3823)$ mass fit, a MC-simulated histogram with the width of $X(3823)$ state set to zero is used to parameterize the signal shape. We replace this histogram with a simulated $X(3823)$ resonance with a width of 1.7 MeV [13] and repeat the fit; the change in the mass for this fit, $0.2 \mathrm{MeV} / c^{2}$, is taken as the systematic uncertainty due to the signal parameterization. Likewise, changes measured with a background shape from MC-simulated $\left(\eta^{\prime} / \gamma \omega\right) J / \psi$ events or a second-order polynomial indicate a systematic uncertainty associated with the background shape of $0.2 \mathrm{MeV} / c^{2}$ in mass. Assuming that all the sources are independent, the total systematic uncertainty is calculated by adding the individual uncertainties in quadrature, resulting in $0.7 \mathrm{MeV} / c^{2}$ for the $X(3823)$ mass measurement. For the $X(3823)$ width, we measure the upper limits with the above systematic checks, and report the most conservative one.

The systematic uncertainties in the cross section measurement mainly come from efficiencies, signal parameterization, background shape, decay model, radiative correction, and luminosity measurement. The luminosity is measured using Bhabha events, with an uncertainty of $1.0 \%$. The uncertainty in the tracking efficiency for high momentum leptons is $1.0 \%$ per track. Pions have momenta that range from 0.1 to $0.6 \mathrm{GeV} / c$, and the momentumweighted uncertainty is $1.0 \%$ per track. In this analysis, the radiative transition photons have energies from 0.3 to 0.5 GeV . Studies with a sample of $J / \psi \rightarrow \rho \pi$ events show that the uncertainty in the reconstruction efficiency for photons in this energy range is less than $1.0 \%$.

The same sources of signal parameterization and background shape as discussed in the systematic uncertainty of
$X(3823)$ mass measurement would contribute $4.0 \%$ and $8.8 \%$ differences in $X(3823)$ signal events yields, which are taken as systematic uncertainties in the cross section measurement. Since the $X(3823)$ is a candidate for the $\psi_{2}$ charmonium state, we try to model the $e^{+} e^{-} \rightarrow$ $\pi^{+} \pi^{-} X(3823)$ process with a $D$ wave in the MC simulation. The efficiency difference between the $D$-wave model and three-body phase space is $3.8 \%$, which is quoted as the systematic uncertainty for the decay model. The $e^{+} e^{-} \rightarrow$ $\pi^{+} \pi^{-} X(3823)$ line shape affects the radiative correction factor and detection efficiency. The radiator function is calculated from QED with $0.5 \%$ precision [25]. As discussed above, both $Y(4360)$ line shapes $[19,26]$ and the $\psi(4415)$ line shape describe the cross section of $e^{+} e^{-} \rightarrow$ $\pi^{+} \pi^{-} X(3823)$ reasonably well. We take the difference for $(1+\delta) \epsilon$ between $Y(4360)$ line shapes and the $\psi(4415)$ line shape as its systematic uncertainty, which is $6.5 \%$.

Since the event topology in this analysis is quite similar to $e^{+} e^{-} \rightarrow \gamma \pi^{+} \pi^{-} J / \psi$ [10], we use the same systematic uncertainties for the kinematic fit ( $1.5 \%$ ) and the $J / \psi$ mass window (1.6\%). The uncertainties on the branching ratios for $\chi_{c 1, c 2} \rightarrow \gamma J / \psi(3.6 \%)$ and $J / \psi \rightarrow \ell^{+} \ell^{-}(0.6 \%)$ are taken from the PDG [2]. The uncertainty from MC statistics is $0.3 \%$. The efficiencies for other selection criteria, the trigger simulation [27], the event-start-time determination, and the final-state-radiation simulation are very high ( $>99 \%$ ), and their systematic uncertainties are estimated to be less than $1 \%$.

Assuming that all the systematic uncertainty sources are independent, we add all of them in quadrature. The total systematic uncertainty in the cross section measurements is estimated to be $13.8 \%$.

In summary, we observe a narrow resonance, $X(3823)$, through the process $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X(3823)$ with a statistical significance of $6.2 \sigma$. The measured mass of the $X(3823)$ state is $(3821.7 \pm 1.3 \pm 0.7) \mathrm{MeV} / c^{2}$, where the first error is statistical and the second systematic, and the width is less than 16 MeV at the $90 \%$ C.L. Our measurement agrees well with the values found by the Belle Collaboration [13]. The production cross sections of $\sigma^{B}\left[e^{+} e^{-} \rightarrow\right.$ $\left.\pi^{+} \pi^{-} X(3823)\right] \mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1}, \gamma \chi_{c 2}\right]$ are also measured at $\sqrt{s}=4.230,4.260,4.360,4.420$, and 4.600 GeV .

The $X(3823)$ resonance is a good candidate for the $\psi\left(1^{3} D_{2}\right)$ charmonium state. According to potential models [1], the $D$-wave charmonium states are expected to be within a mass range of 3.82 to 3.85 GeV . Among these, the $1^{1} D_{2} \rightarrow \gamma \chi_{c 1}$ transition is forbidden due to $C$-parity conservation, and the amplitude for $1^{3} D_{3} \rightarrow \gamma \chi_{c 1}$ is expected to be small [28]. The mass of $\psi\left(1^{3} D_{2}\right)$ is in the $3.810-3.840 \mathrm{GeV} / c^{2}$ range that is expected for several phenomenological calculations [29]. In this case, the mass of $\psi\left(1^{3} D_{2}\right)$ is above the $D \bar{D}$ threshold but below the $D \bar{D}^{*}$ threshold. Since $\psi\left(1^{3} D_{2}\right) \rightarrow D \bar{D}$ violates parity, the $\psi\left(1^{3} D_{2}\right)$ state is expected to be narrow, in agreement with our observation, and $\psi\left(1^{3} D_{2}\right) \rightarrow \gamma \chi_{c 1}$ is expected to
be a dominant decay mode $[29,30]$. From our cross section measurement, the ratio $\left(\mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 2}\right] /\right.$ $\left.\mathcal{B}\left[X(3823) \rightarrow \gamma \chi_{c 1}\right]\right)<0.42$ (where systematic uncertainties cancel) at the $90 \%$ C.L. is obtained, which also agrees with expectations for the $\psi\left(1^{3} D_{2}\right)$ state [30].

[22] In this Letter, $\quad M\left(\pi^{+} \pi^{-} J / \psi\right)=M\left(\pi^{+} \pi^{-} \ell^{+} \ell^{-}\right)-$ $M\left(\ell^{+} \ell^{-}\right)+m(J / \psi)$ is used to partly cancel the mass resolution of the lepton pair. Here $m(J / \psi)$ and $m\left(\psi^{\prime}\right)$ are the nominal masses of $J / \psi$ and $\psi^{\prime}$ [2].
