14 **Abstract**

15 Fragipan is a dense and usually brittle subsurface soil horizon, limiting the penetration of roots and the infiltration of water. Genesis of fragipan is  
16 still unclear; however there is a general agreement on the importance of wet-dry cycles in its evolution. Furthermore, in addition to the effect of

17 water, in argillic Bx horizon, the presence of cations affecting the clay dispersion/flocculation behaviour might be a key factor in fragipan dynamics.

18 In order to gain knowledge on the specific effect of alternating moisture conditions on the evolution of aggregates collected from Btx horizon, we

19 evaluated the variations of physical properties caused by a wet-dry cycle using both deionized and Ca-enriched water on the 1-2 mm aggregate, and

20 on newly formed aggregates (i.e. 2-5 and >5 mm size classes) obtained after a lab experiment. The obtained results were compared with a Bt

21 horizon that did not show fragipan properties. Btx and Bt samples were collected from a Typic Fragiudalf on fluvio-glacial terraces in NW Italy. The

22 two horizons had comparable clay content (around 13%), and their mineralogical composition was dominated by hydroxy-interlayered vermiculite

23 and smectite.

24 The fragipan 1-2 mm aggregates before the treatments had low clay dispersion ratio (11.5%), and typically low volume of macropores ( $74 \text{ mm}^3 \text{ g}^{-1}$ ),

25 high volume of mesopores ( $111 \text{ mm}^3 \text{ g}^{-1}$ ), high slaking (30.1%), close packing of coarse particles and open arrangement of fine particles (0.82 and

26 0.31, respectively). The water treatment promoted the enrichment in flocculated-clay in the new-aggregates, and Ca-treatment enhanced clay

27 flocculation both in the newly formed and in the 1-2 mm aggregates. The clay flocculation induced a denser arrangement of clay particles ( $\geq 0.44$ ),

28 and a consequent reduction of mesopores (from 56.2 to 66.1  $\text{mm}^3 \text{ g}^{-1}$ ), combined with the opening of the coarser particles packing ( $\leq 0.78$ ). This

29 new particle arrangement did not correspond to the specific combination of coarse/fine particles arrangement of fragipan. The relative percentage of

30 slaking also decreased. Therefore, upon both deionized water and  $\text{CaCl}_2$  wetting and drying, the aggregates from fragipan changed and the specific

31 physical properties of fragipan, measurable in laboratory, tended to be attenuated.

32

33 **Highlights**

- 34 - In fragipan, physical properties changes induced by wetting/drying are studied in the lab
- 35 – Water and CaCl<sub>2</sub> wetting/drying promoted the enrichment in flocculated-clay
- 36 - Flocculation induced a denser arrangement of clay particles and mesopores reduction
- 37 - The new arrangement did not correspond to the specific fragipan particle arrangement
- 38 - Water and CaCl<sub>2</sub> wetting/drying attenuated the fragipan physical characteristics measurable in laboratory

## 43 **1. Introduction**

44 Fragipan is a subsurface soil horizon limiting the penetration of roots and infiltration of water because of its high bulk density, low porosity, and  
45 discontinuous void space (Soil Survey Staff, 2014). The occurrence of fragipan (Bx horizons) in a soil profile can strongly reduce soil physical  
46 quality and functionality. No specific analytical determinations are however required for fragipan recognition, i.e. the fragic properties are  
47 identified in the field (Soil Survey Staff, 2014). Fragipan shows a hard or very hard consistence when dry, but it is brittle when moist, and its air-  
48 dried clods undergo immediate slaking once immersed in water (e.g., Bockheim and Hartemink, 2013; Lindbo et al., 1994). Falsone and Bonifacio  
49 (2009) demonstrated that the low permeability and high bulk density of fragipan result from a specific arrangement of mineral particles that is not  
50 found in any other soil horizons, i.e. an open packing of the clay phase is associated to an extremely dense packing of silt and sand.

51 Fragipan horizons occur in all parts of the world and are common in North-American Alfisols (Bockheim and Hartemink, 2013), in Luvisols and  
52 Albeluvisols in Ukraine (Nikorych et al. 2014), in Udalfs in Northern Italy (Falsone and Bonifacio, 2006; Ajmone-Marsan et al., 1994). In these  
53 environments they typically occur within an argillic (argic) horizon (Btx). Bockheim and Hartemink (2013) reviewed the descriptive models for the  
54 genesis of fragipan, and subdivided them based on the approach used. The physical models emphasized either the role that lithologic discontinuities  
55 or pore size distribution have on water flow and material accumulation into the fragipan, or the hydrocollapse of soil or parent material that can  
56 form hard pans. The chemical models, on the other hand, point to the importance of water translocated weathering products such as clay and Fe, Al,  
57 Si phases, as bonding agents and bridges of coarser particles. Wet-dry cycles have been indicated as one of the driving factors for fragipan evolution  
58 (e.g., Wilson et al., 2010; Boulet et al., 1998; Bruckert and Bekkary, 1992), but the role of alternating moisture conditions is still not well-  
59 understood, and contrasting results have been reported. Szymański et al. (2011) and Nikorych et al. (2014) stated that the seasonal soil wetting and

60 drying cause fragipan degradation through the formation of vertical cracks. Weisenborn and Schaetzl (2005a) reported that, upon wetting, argillic  
61 fragipans can degrade because of clay and Fe leaching due to vertically percolating water, thus developing non-brittle E horizon features. Attou and  
62 Bruand (1998) found instead that fragipan originates from successive wetting and drying cycles, because of the effect that alternating water  
63 conditions have on clay; wetting favours clay dispersion within the soil matrix and the subsequent dry period allows the reorganization of clay  
64 particles into coatings and bridges over and between the skeleton grains. In addition to the effect of water, in argillic Bx horizon, the presence of  
65 cations affecting the clay dispersion/flocculation behaviour should be therefore a key factor in fragipan dynamics.

66 This paper aims at understanding the role of wet-dry cycles on aggregates dynamics in Btx horizon, hypothesizing that the wet-dry cycle and the  
67 presence of flocculating cation, such as calcium, should differently affect the Bx physical properties. In laboratory conditions, the presence of  
68 calcium would favour clay flocculation enhancing the Bx properties both in pre-existing and newly-formed soil aggregates. To obtain a deeper  
69 insight into the mechanisms occurring upon wetting and drying in argillic fragipan we performed a laboratory experiment to evaluate the changes in  
70 those physical properties that are controlled by clay flocculation/dispersion behaviour and interactions between particles. The specific goals were:  
71 (i) to study the evolution of aggregates from a Btx horizon during a laboratory controlled wet-dry cycle, using both deionized water and a solution  
72 containing calcium (i.e.,  $\text{CaCl}_2$ ); (ii) to investigate the physical properties of newly-formed aggregates obtained from the Btx horizon upon wet-dry  
73 cycle in the laboratory. The results were compared to those of the upper Bt horizon (i.e. non-fragipan argillic).

74 .

75

76 **2. Materials and Methods**

77 *2.1. The study area*

78 In the catchment of the Stura di Lanzo River (45° 13.366' N, 7° 31.399' E), NW Italy, a fine-loamy mixed Typic Fragiudalf (Soil Survey Staff,  
79 2014) was selected for this study. It develops on fluvio-glacial terraces of the Fiano Unit (Middle Pleistocene, i.e. Mindel-Riss interglacial in the  
80 Alps) according to Forno et al. (2007). The dominant lithologies of the area eroded by the Pleistocene glacier are prasinites, serpentinites,  
81 lherzolites, amphibolites, micaceous and chlorite schists, eclogites, and gneiss. The vegetation is dominated by *Robinia pseudoacacia* L. and  
82 *Corylus avellana* L. The morphological description of a representative soil profile of the area is reported in Table 1. At the sampling site, the  
83 fragipan horizon was identified at 165-190 cm depth by brittleness and morphology, including vertical seams, coarse prismatic structure, and  
84 absence of roots in prisms (Soil Survey Staff, 2014).

85 Samples (~1 kg) of the argillic fragipan (Btcx) and the overlying argillic non-fragipan (Btc2) horizons were collected, air-dried and sieved to pass a  
86 2-mm screen. The main properties of the <2 mm fraction of Btc2 and Btcx horizons are reported in Table 2. An aliquot of <2 mm air-dried of Btc2  
87 and Btcx samples was further dry-sieved at 1 mm and the 1-2 mm aggregate class was separated.

88

89 *2.2. Sample preparation and treatment conditions*

90 One hundred grams of the <2 mm air-dried samples of each soil horizon were evenly distributed in a container and sprayed with 25 ml of deionized  
91 water or 0.25M CaCl<sub>2</sub> (Figure 1). Four tests were thus performed: Btcx horizon plus deionized water, Btcx plus 0.25M CaCl<sub>2</sub>, Btc2 horizon plus  
92 deionized water, and Btc2 plus 0.25M CaCl<sub>2</sub>. The samples were allowed to dry for 2 weeks at room temperature, ensuring the occurrence of both  
93 new-aggregates formation and clay flocculation, i.e. the two main processes considered in this study. Both processes are in fact relatively rapid, and

94 in controlled conditions the formation of aggregates via particle interactions and/or clay flocculation can quickly occur (Fortun et al., 1989; Falsone  
95 et al., 2007; Falsone et al. 2016). The experiment was replicated three times, originating therefore 12 samples. At the end of the treatment, the  
96 samples were sequentially dry sieved on 5-, 2- and 1-mm sieves. Three fraction of aggregates were thus obtained: 1-2, 2-5 and >5 mm. The weight  
97 of each aggregate class was recorded and the result was expressed as percentage. The >2 mm aggregate classes (i.e., 2-5 and >5 mm fractions) were  
98 considered as newly formed aggregates (NEW-aggregates).

99 Three samples of 1-2 mm aggregates obtained by dry-sieving of <2 mm of Btc2 and Btcx samples were also put in the same laboratory conditions as  
100 described above, but without any treatment.

101

102 The analyses were performed on the 1-2 mm aggregates without any treatment (FRG and NFRG), on the 1-2 mm aggregate fraction after the  
103 treatment (FRG-WAT, FRG-CA, NFRG-WAT and NFRG-CA), and on the 2-5 (FRG<sub>2-5</sub>-WAT, FRG<sub>2-5</sub>-CA, NFRG<sub>2-5</sub>-WAT and NFRG<sub>2-5</sub>-CA) and  
104 >5 mm NEW-aggregates (FRG<sub>5</sub>-WAT, FRG<sub>5</sub>-CA, NFRG<sub>5</sub>-WAT and NFRG<sub>5</sub>-CA).

105

### 106 *2.3. Chemical and physical analyses*

107 The organic carbon was measured by dry combustion (CE Instruments NA2100 elemental analyser, Rodano, Italy). The contents of pedogenic iron  
108 oxides (FeDCB) were estimated through extraction with Na-dithionite-citrate-bicarbonate (Mehra and Jackson, 1960) and subsequent determination  
109 of Fe by AAS (Perkin Elmer Analyst 400, Waltham, USA). The particle size distribution (PSD) was determined by the pipette method (Gee and  
110 Bauder, 1986) after: (i) dispersion with deionized water only; (ii) dispersion with (NaPO<sub>3</sub>)<sub>6</sub>; (iii) dispersion with (NaPO<sub>3</sub>)<sub>6</sub> after H<sub>2</sub>O<sub>2</sub> oxidation of

111 organic matter and Na-dithionite-citrate-bicarbonate removal of Fe-cements. The PSD data were used to calculate the clay dispersion ratio (CDR)  
112 according to Dong et al. (1983) as follows:

$$113 \quad CDR = \frac{\text{Clay obtained with deionized water}}{\text{Clay obtained with } (NaPO_3)_6} \cdot 100 \quad (1)$$

114 The wet aggregate stability (WAS) was evaluated after 10 min in rotating 0.2-mm sieves (Kemper and Rosenau, 1986). The material remaining on  
115 the sieves was then dried and weighed. Then, the amount of stable aggregates (>0.2 mm) was corrected for the content of coarse sand determined  
116 after H<sub>2</sub>O<sub>2</sub> oxidation and Na-dithionite-citrate-bicarbonate extraction. The WAS index was calculated as follows:

$$117 \quad WAS = \frac{\text{weight retained} - \text{weight of coarse sand}}{\text{total sample weight} - \text{weight of coarse sand}} \cdot 100 \quad (2)$$

118 And the percentage of aggregate loss (Loss) as

$$119 \quad Loss = 100 - WAS \quad (3)$$

120 To test the wet cohesion independently from slaking, thus regardless of the ruptures due to water saturation, 10 g of aggregates were gently  
121 immersed into 95% ethanol solution for 10 min (Le Bissonnais, 1996) before being wet sieved for 10 min. Then, the amount of aggregates that had  
122 resisted the sieving (WAS<sub>et</sub>) and the percentage of aggregate loss (Loss<sub>et</sub>) was determined according to the equations (2) and (3). The relative  
123 percentage of slaking (RPS; Falsone and Bonifacio, 2006) was calculated as:

$$124 \quad RPS = \frac{Loss - Loss_{et}}{Loss} \cdot 100 \quad (4)$$

125 The specific surface area was determined by N<sub>2</sub> gas adsorption at 77 K in the relative pressure (p/p<sup>o</sup>) range of 0.05-0.30 (Gregg and Sing, 1982) with  
126 a Sorptomatic 1900 surface area analyser (CE instruments, Rodano, Italy) by applying the Brunauer-Emmett-Teller (BET) equation. Enough

127 sample was used for measurement to ensure a total surface area  $>10 \text{ m}^2$  (corresponding to around 1.2 g of sample). All samples were initially  
128 degassed for 16 hours at  $50^\circ\text{C}$ . The micropore ( $<2 \text{ nm}$ ) volume and surface area were evaluated from the adsorption-desorption isotherms, using the  
129 t-plot method ( $V_{\text{MICRO}}$  and  $S_{\text{MICRO}}$ , respectively; de Boer et al., 1966), while mesopores (2-50 nm;  $V_{\text{MESO}}$  and  $S_{\text{MESO}}$ ) were derived from the  
130 desorption branch according to Pierce's (1953) model.

131 Porosity characteristics were evaluated by Hg intrusion using a 2000 WS porosimeter equipped with a 120 Macropore unit (CE Instruments,  
132 Rodano, Italy). The total volume of intruded Hg (i.e. total pore volume) was expressed on a mass basis ( $V_{\text{TOT}}$ ,  $\text{mm}^3 \text{ g}^{-1}$ ). The cumulative curve of  
133 intruded Hg volume as a function of the pore radius was used to calculate the variation of the pore volume following Bruand and Prost (1987):

$$134 \quad \text{slope}_{ij} = \frac{V_i - V_j}{\log_{10} R_j - \log_{10} R_i} \quad (5)$$

135 where the volumes  $V_i$  and  $V_j$  correspond to the radii  $R_i$  and  $R_j$  at two successive positions  $i$  and  $j$ . The values of the slope were then plotted against  
136 the mean log radius, thus the relative maxima of the slope curve indicated the most represented classes of pores and corresponded to a modal radius  
137 (expressed in  $\mu\text{m}$ ). The volume of each modal class of pores was thus included between two minimum values of the slope, which defined the limits  
138 of the class. This data treatment returns a bimodal distribution: two modal pore radii attributed to the packing of finer (clay) and coarser (sand and  
139 silt) fractions, according to Fiès and Bruand, (1998). The corresponding volumes of pores were labelled as  $V_f$  and  $V_c$ . The modal pore size  
140 corresponding to the coarser particles ranged between 0.152 to 1.565  $\mu\text{m}$ , while the modal pore size corresponding to the finer particles ranged  
141 between 0.005 and 0.022  $\mu\text{m}$  (data not shown). The modal smaller pores were therefore in the range size of mesopores measured by  $\text{N}_2$  adsorption  
142 (Echeverría et al., 1999) and in this study we chose to use the  $\text{N}_2$  adsorption data for finer pore size measurements.

143 The packing density of particles, i.e. the volume occupied by solid particles with respect to the total volume (space occupied by solid plus void  
144 space), was calculated according to Falsone and Bonifacio (2009) as:

$$145 \text{ packing density} = \frac{\text{particle mass}}{\text{particle density}} \cdot \frac{1}{\frac{\text{particle mass}}{\text{particle density}} + \text{volume of pores}} \quad (6)$$

146 where particle density was taken equal to  $2.65 \times 10^{-3} \text{ g mm}^{-3}$ , the mass was expressed in g ( $100 \text{ g}^{-1}$ ), the volume of pores in  $\text{mm}^3 \text{ g}^{-1}$ , and the  
147 resulting packing density was dimensionless. We calculated both the packing density of the sand-silt phase and of clay, using the particle size data  
148 obtained after dispersion of sample with  $(\text{NaPO}_3)_6$  for particle mass, and the modal coarse volume ( $V_c$ ) and the mesopores volume ( $V_{\text{MESO}}$ ),  
149 respectively, for sand-silt and clay-clay interactions (Zong et al., 2015; Fiès and Bruand, 1998).

150 All the statistical analyses were carried out using SPSS 20 (SPSS Inc., Chicago, IL). Differences among samples were evaluated using the analysis  
151 of variance (ANOVA and Duncan's test). The threshold used for significance in all statistical tests was set at 0.05.

152

153

### 154 **3. Results**

#### 155 *3.1. 1-2 mm aggregates properties before treatments (without any treatment)*

156 The 1-2 mm aggregate class of both fragipan (FRG) and non-fragipan (NFRG) horizons had low organic C content ( $<2 \text{ g kg}^{-1}$ ; Table 3). The content  
157 of pedogenic Fe oxides was high ( $\text{Fe}_{\text{DCB}} > 60 \text{ g kg}^{-1}$ ; Table 3). FRG had high coarse sand content (CS: 49.4%; Table 3), while NFRG was rich in fine  
158 sand (FS: 44.4%; Table 3). The difference in coarse sand content among FRG and NFRG was also observed in the content of primary coarse sand-  
159 size particles ( $\text{CS}_{\text{ox}}$ : 7.4 and 24.9% for NFRG and FRG). The amount of clay was instead similar in the two horizons (10.7 and 13.0% for NFRG

160 and NFRG, respectively), as well as the clay dispersion ratio (CDR). The fragmentation behaviour in water of the 1-2 mm aggregate class of FRG  
161 showed a relative percentage of slaking of 30.1% (RPS; Table 4), giving a contribution to the wet-aggregate losses, as in general observed in  
162 fragipan horizons (Falsone et al., 2006). The N<sub>2</sub> adsorption at 77 K and Hg porosity data clearly evidenced the peculiarity of pores size distribution  
163 of FRG-aggregates: FRG had more mesopores than macropores ( $V_{\text{MESO}}$  and  $V_c$ , respectively, Figure 2A; Lamotte et al., 1997; Ajmone-Marsan et  
164 al., 1994), in opposition to NFRG. Because of high mesoporosity volume, the corresponding mesopores surface areas ( $S_{\text{MESO}}$ ) were large in FRG  
165 (Figure 2B). The packing density of the coarser particles showed that typically FRG had a closer arrangement than NFRG (PDc: 0.82 and 0.73;  
166 Table 5). The packing density of the clay fraction showed instead a slightly more open arrangement in FRG than NFRG (PDf values: 0.31 and 0.39  
167 for FRG and NFRG samples, Table 5). Before treatments, the 1-2 mm FRG aggregates had thus the highest PDc/PDf ratio (Table 5) as typical of  
168 fragipans i.e. an open packing of the clay phase associated to an extremely dense packing of sand and silt (Falsone and Bonifacio, 2009).

169

### 170 3.2. 1-2 mm aggregates properties after the wet-dry cycle

#### 171 3.2.1. Fragipan

172 The amount of FRG aggregates maintaining the 1-2 mm size after one wet-dry cycle with deionized water was around 20% of the total mass (Figure  
173 3A), while a lower percentage of 1-2 mm aggregates was obtained after CaCl<sub>2</sub> treatment (10.6%, Figure 3B). The clay fraction was the most  
174 affected by the presence of Ca, as expected, and the FRG-CA sample was enriched in flocculated clay with respect to both the untreated and  
175 water-treated samples (i.e. the CDR decreased, Table 3;  $p < 0.05$ ). The experiments destabilised all the treated-aggregates, as visible from the  
176 increase of the aggregate losses due to wet sieving (Loss and Loss<sub>et</sub> increased up to 68.8 g (100) g<sup>-1</sup> in the case of FRG-CA,  $p < 0.05$ ; Table 4). The

177 losses due to slaking instead decreased (RPS,  $p < 0.05$ ; Table 4). Finally, also the pore system changed (Figure 2A): the treatments slightly increased  
178 the coarser pores volume ( $V_c$ ) and reduced the mesopores volume ( $V_{MESO}$ ). The volume of micropores also decreased following the Ca-treatment.  
179 As a result of the change in pore distribution, the finer particles in the treated-aggregates became more closely packed, especially in the Ca-treated  
180 sample, while the arrangement of coarser particles was slightly looser than those of untreated-FRG (PDF increased and PDc slightly decreased,  
181 respectively; Table 5), and the PDc/PDf ratio strongly decreased ( $p < 0.05$ ).

182

### 183 3.2.2. *Non-fragipan*

184 The amounts of NFRG aggregates that maintained the 1-2 mm size after wet-dry cycle with both deionized water and  $CaCl_2$  were around 20% of the  
185 total mass (Figure 3A-B). Differently from FRG samples, the 1-2 mm aggregate class of NFRG samples had lower  $CS_{ox}$  content than the samples  
186 before the treatment (Table 3;  $p < 0.05$ ). The clay fraction appeared again more affected (Table 3): the NFRG-CA sample had higher clay content  
187 and lower clay dispersibility (i.e., lower CDR value;  $p < 0.05$ ) than NFRG before treatment, in contrast to NFRG-WAT that had similar clay content  
188 and higher dispersability (i.e., higher CDR value;  $p < 0.05$ ) than NFRG.

189 The treatments increased the aggregate losses by wet sieving ( $Loss$  and  $Loss_{et}$ ,  $p < 0.05$ : Table 4), but, after the Ca-treatment and differently from  
190 FRG sample, the losses due to slaking increased (i.e., RPS value increased,  $p < 0.05$ ; Table 4). As regards to the aggregate porosity, the mesopores  
191 volume and surface ( $V_{MESO}$  and  $S_{MESO}$ ) increased after treatment (Figure 2A-B), while the volume and the surface of the micro ( $V_{MICRO}$  and  $S_{MICRO}$ )  
192 and the volume of coarser pores ( $V_c$ ) decreased, especially after  $CaCl_2$ -treatment. As a result, the arrangement of finer particles appeared denser,  
193 while the packing density of coarser particles did not change with respect to those of NFRG (PDF increased and PDc did not vary, respectively;

194 Table 5). After the treatments, the packing density of the aggregates from NFRG and FRG became more similar than it was before, as visible also  
195 by the PDc/PDf ratio (Table 5).

196

### 197 *3.3. NEW- aggregates properties obtained by wet-dry cycle*

#### 198 *3.3.1. Fragipan*

199 After the treatment with deionized water, the 2-5 and >5 mm newly formed aggregates (FRG<sub>2-5</sub>-WAT and FRG<sub>5</sub>-WAT) composed 23.1 and 45.3%  
200 of the total mass of FRG samples (Figure 3A), while after CaCl<sub>2</sub>-treatment they represented 16.5 and 66.5%, (FRG<sub>2-5</sub>-CA and FRG<sub>5</sub>-CA; Figure  
201 3B). The NEW-aggregate classes of FRG sample had low organic C content and high Fe<sub>DCB</sub> amount (Table 6), as already observed for 1-2 mm  
202 aggregates before and after treatments. The amount of coarse sand decreased in all NEW-aggregates with respect to the aggregates before treatments  
203 ( $p < 0.05$ ; CS values in NEW-aggregates ranged from 29.2 to 40.1 g kg<sup>-1</sup>, CS content was 49.4 g kg<sup>-1</sup> in untreated-FRG aggregates; Table 6 and Table  
204 3, respectively), as well as the content of primary coarse sand particles (CS<sub>ox</sub>,  $p < 0.05$  Tables 3 and 6). As already observed for 1-2 mm aggregates,  
205 after CaCl<sub>2</sub>-treatment the clay content increased and this again corresponded to a slightly lower water dispersibility of the clay fraction, as CDR  
206 decreased in NEW-aggregates after Ca-treatment ( $p < 0.05$ ; Table 6). In FRG the NEW-aggregates were extremely water fragile, and after wet  
207 sieving their losses varied from 64.3 to 76.4% (Loss; Table 7). Similar values were found for Loss<sub>et</sub>. However, the incidence of slaking on FRG  
208 losses was extremely low, and for >5 mm NEW-aggregates the RPS values were even <2% (Table 7). The volume corresponding to the larger  
209 pores, V<sub>c</sub>, did not show any specific trend with the treatment (Figure 4A), as well as the PDc values (Table 8). However, the packing density of  
210 coarser particles was lower than that of the FRG aggregates before treatments ( $p < 0.05$ ; for FRG, the PDc values in NEW-aggregates ranged from

211 0.70 to 0.78, while in 1-2 aggregates before treatments it was 0.82; Table 8 and 5, respectively). The FRG NEW-aggregate  $V_{\text{MESO}}$  ranged from 56.7  
212 and 66.1  $\text{mm}^3 \text{g}^{-1}$  and  $S_{\text{MESO}}$  from 30.8 to 34.3  $\text{m}^2 \text{g}^{-1}$  (Figure 4A and B), thus a strong mesoporosity decline has occurred after treatments ( $p < 0.05$ ;  
213  $V_{\text{MESO}}$  and  $S_{\text{MESO}}$  of the 1-2 mm aggregates before treatments were 111.0  $\text{mm}^3 \text{g}^{-1}$  and 42.6  $\text{m}^2 \text{g}^{-1}$ , Figure 2A-B). The Ca-treatment strongly affected  
214 the microporosity, as visible from the very low volume and surface area of micropores in Ca-treated NEW-aggregates (Figure 4A-B). As a  
215 consequence of the modification occurring in meso and microporosity, the Pdf values increased in NEW-aggregates with respect to the 1-2 mm  
216 aggregates before treatments ( $p < 0.05$ ; Pdf values always  $\geq 0.44$  in NEW-aggregates vs. 0.31 in aggregates before treatments; Tables 8 and 5,  
217 respectively), especially in the Ca-incubated samples.

### 218 3.3.2. *Non-fragipan*

219 After treatment of NFRG with deionized water, the 2-5 and  $>5$  mm newly formed aggregates composed 25.0 and 20.1% of the total mass, while  
220 after  $\text{CaCl}_2$ -treatment they represented 21.4 and 43.4%, respectively (Figure 3A-B). The organic C content was similar in all NFRG NEW-  
221 aggregates (0.6-0.8  $\text{g kg}^{-1}$ , Table 6), as well as the amount of pedogenic Fe oxides (50.5-53.0  $\text{g kg}^{-1}$ , Table 6), even if the  $\text{Fe}_{\text{DCB}}$  content in NEW-  
222 aggregates was lower than before treatments ( $p < 0.05$ ;  $\text{Fe}_{\text{DCB}}$  was 62.8  $\text{g kg}^{-1}$  in the untreated-NFRG aggregates; Table 3). Similarly to the NEW-  
223 aggregates of FRG, the coarse sand content decreased in the NEW-aggregates of NFRG with respect to the aggregates before treatments ( $p < 0.05$ ;  
224 CS values in NF-aggregates ranged from 8.2 to 15.0  $\text{g kg}^{-1}$ , CS content was 24.8  $\text{g kg}^{-1}$  in untreated-NFRG aggregates; Table 6 and Table 3,  
225 respectively), as well as the content of primary coarse sand particles ( $p < 0.05$ ;  $\text{CS}_{\text{ox}}$ ; Tables 3 and 6). The clay behaviour was similar to that of FRG  
226 samples: the Ca-treated samples were enriched in flocculated clay (higher clay content and lower CDR values than water-treated samples; Table 6).  
227 The NEW-aggregates were unstable to water stresses, and high losses of aggregates occurred (Loss and  $\text{Loss}_{\text{et}}$  always  $> 52\%$ ; Table 7), even if the

228 incidence of slaking was low (RPS always <13%; Table 7). The NFRG NEW-aggregates were still more stable than FRG ones but the differences  
229 were less marked. In the NFRG NEW-aggregates, the  $V_c$  values ranged from 97 to 123 mm<sup>3</sup> g<sup>-1</sup> (Figure 4A) and the corresponding PDc varied from  
230 0.73 to 0.76 (Table 8). Similar  $V_c$  and PDc values were thus found in both FRG and NFRG NEW-aggregates. No specific effect of the treatment  
231 conditions on the coarser porosity was found. Instead, similarly to FRG samples, the  $V_{MICRO}$  and  $S_{MICRO}$  strongly decreased after the Ca-treatment  
232 (Figure 4A-B). With respect to the sample before treatments, also in the case of NFRG NEW-aggregates, the PDf values increased especially in the  
233 Ca-incubated samples ( $p < 0.05$ ; PDf values varied from 0.42 to 0.54 in NEW-aggregates, and in aggregates before treatments PDf was 0.39; Tables  
234 8 and 5, respectively).

235

236

#### 237 **4. Discussion**

238 In this work, we wanted to evaluate the variations caused by a wet-dry cycle carried out in laboratory controlled conditions, using both deionized  
239 and Ca-enriched water on the 1-2 mm aggregate properties of a Btx horizon, and to investigate the physical properties of newly formed aggregates  
240 (i.e. 2-5 and >5 mm size classes) obtained after the experiment. This was performed in order to investigate the specific effect of alternating  
241 moisture conditions on the evolution of aggregates collected from Btx horizon. The same soil properties were monitored for the reference Bt  
242 horizon that did not show fragipan properties.

243

244 *4.1. 1-2 mm aggregates properties of fragipan and non-fragipan before treatments*

245 The characterisation of the 1-2 mm aggregates before the treatment experiments confirmed the typical physical properties of fragipans detectable in  
246 laboratory and reported in Figure 6: high aggregate fragility against slaking (e.g., Soil Survey Staff, 2014; Falsone and Bonifacio, 2006; Lindbo and  
247 Rhoton, 1996), low volume of macropores and high volume of micropores (e.g., Lamotte et al., 1997; Ajmone-Marsan et al., 1994), high density  
248 (e.g., Falsone and Bonifacio, 2009; Weisenborn and Schaetzl, 2005b). Conversely, non-fragipan aggregates showed higher resistance to water-  
249 breakdown and lower slaking susceptibility, had more macropores than micropores, and showed a more open arrangement of the coarse fraction  
250 (Figure 6). The particle size distribution was however similar between the two horizons, and the low CDR values were in agreement with the  
251 presence of flocculated clays in argillic horizons formed by lessivage (e.g., Schaetzl and Anderson 2005) and suggested a similar dispersion  
252 behaviour of the clay fraction (Dong et al., 1983).

253

#### 254 *4.2. Evolution of fragipan and non-fragipan 1-2 mm aggregates during laboratory controlled wet-dry cycle (deionized water and CaCl<sub>2</sub> effect)*

255 The wet-dry cycle affected the properties of the 1-2 mm aggregates from the fragipan, even if they maintained their size after the treatment and thus  
256 did not take part in the formation of larger NEW-aggregates. Different effects of deionized and Ca-enriched water on aggregate dynamics were  
257 observed. After treatment with deionized water, FRG 1-2 mm aggregates were enriched in easily dispersible clay (CDR values >20%; Table 3),  
258 while the CaCl<sub>2</sub>-treatment slightly increased the clay flocculation status (CDR values <10%). This means that, as expected, Ca addition enhanced  
259 clay flocculation. In the presence of Ca<sup>2+</sup> ions, the clay outer layer is thinner and electrostatic repulsion among clay particles is lower, allowing for  
260 van der Waals' forces to promote the formation of small stacks of clay platelets (i.e., clay domains; Sposito, 1989). This arrangement favours face-  
261 to-face association between clay particles (van Olphen, 1977), which might have caused the denser packing of the clay fraction indicated by the

262 increase of the Pdf values. In contrast, water treatment had a lower effect on clay associations because clay arrangement was unaffected, as  
263 indicated by the similarity of Pdf values between FRG treated and untreated 1-2 mm aggregates. As a result the PDC/Pdf ratio, which can be used  
264 as a simple index of the combination of the coarser and finer particle density, decreased. Ramos et al. (2015) stated that the face-to-face association  
265 of kaolinite platelets favoured fragipan formation, but in our Ca-treated samples it causes the closure of clay packing minimising the differences  
266 between coarser and finer particle density. The aggregates after treatment did not thus show anymore the contrasting coarser-finer particles  
267 arrangement typical of fragipan (Falsone and Bonifacio, 2009). Moreover, the 1-2 mm aggregates of both treated-FRG were more water fragile after  
268 treatment, but they showed a higher relative resistance to slaking. It appeared therefore that the fragipan aggregates that did not take part in the  
269 formation of NEW-aggregates markedly lost the typical properties of fragipan investigated in this lab study (Figure 6).

270

271 *4.3. Physical properties of newly-formed aggregates obtained from fragipan and non-fragipan horizons upon the laboratory wet-dry cycles*  
272 *(deionized water and CaCl<sub>2</sub> effect)*

273 The formation of new aggregates in fragipan seems to have occurred through the interaction of clay floccules, and other soil coarse particles, likely  
274 sand grains and/or already existing aggregates, as indicated by clay quantity and quality in the NEW-aggregates. In fact, after both deionized water  
275 and CaCl<sub>2</sub> addition, the clay amount increased in FRG NEW-aggregates and its dispersibility decreased or was steady. The involvement of coarse  
276 particles, and thus the formation of aggregates due to clay floccules covering sand particles or already existing aggregates is in agreement with  
277 Falsone et al. (2007). They found that in the presence of poorly dispersible clay, the low electrostatic barrier allowed clay sized aggregates to form  
278 and subsequently cover sand grains during a wet-dry cycle with deionized water. Although in the present study we did not measure the surface

279 charge of clay fraction, both the low CDR values of the 1-2 mm aggregates before treatments and the selection of samples from argillic horizons  
280 suggested a low surface charge of clay fraction. In these conditions, the addition of  $\text{Ca}^{2+}$  would further enhance clay flocculation, and the similarity  
281 between samples (i.e., water and Ca-treated) in quantitative and qualitative clay data suggest the same pathway of aggregates formation in both  
282 deionized water and  $\text{CaCl}_2$  treated samples. The NEW-aggregates obtained after the treatments had a lower resistance to water stress than the  
283 samples before treatments. This further confirmed the hypothesized aggregation pathway (i.e., clay-clay associations covering coarse particles), as  
284 aggregate stability is lower when coarse particles are linked to an already flocculated clay phase (Attou et al., 1998; Falsone et al., 2007). As a  
285 consequence of the new particle association, in FRG NEW-aggregates coarser particles had a more open arrangement (i.e., PDc values decreased).  
286 The volume of mesopores instead decreased and, again, in the Ca-incubated samples the enhancement of clay flocculation affected the packing  
287 density of clay with a closer arrangement after treatment (i.e., PDF values increased). In this study, the aggregates after treatments showed thus a  
288 progressive decrease of PDc/PDF ratio. Considering the investigated physical parameters, it appeared therefore that also the FRG NEW-aggregates  
289 did not show the typical properties of fragipan after both water and Ca-treatment (Figure 6).

290

#### 291 *4.4. The overall experimental effect*

292 There was a general trend upon treatments that was independent from the type of horizon (FRG and NFRG) and the aggregate size (1-2 mm, 2-5  
293 NF-aggregates, >5 mm NF-aggregates): the wet-dry cycle modified the spatial arrangements of both clay and coarser particles, with a denser  
294 packing of the clay phase and an opening of the coarser particles arrangement. This was likely caused by the formation of face-to-face clay  
295 associations and by associations between coarse particles and flocculated clays. The new particle arrangement worsened the aggregate water

296 resistance, and all the aggregates after treatments were indeed less water stable. However, our results suggested that this new particle arrangement  
297 contributed to limit the breakdown due to slaking, as the relative percentage of slaking decreased ( $r^2$  always  $>0.5$ ; Figure 5). This suggests that the  
298 opening of the coarse particles arrangement coupled to the closure of the clay particles packing limited aggregate breakdown due to slaking, thus  
299 further confirming that FRG samples obtained after treatments moved away from the typical physical behaviour of fragipans measurable in  
300 laboratory.

301

## 302 **5. Conclusions**

303 The water treatment promoted the enrichment in flocculated-clay in the NEW-aggregates, and Ca-treatment enhanced clay flocculation both in the  
304 NEW- and in the 1-2 mm aggregates that maintained their size. However, the hypothesized enhancement of fragipan properties (such as slaking,  
305 particle density and porosity), due to the increase in clay flocculation did not take place in our samples. The clay flocculation in fact induced a  
306 denser arrangement of clay particles, and a consequent reduction of mesopores, combined with the opening of the coarser particles packing. This  
307 new particle arrangement did not correspond to the specific combination of coarse/fine particles arrangement of fragipans detectable in laboratory  
308 conditions. These results point to the importance of the clay fraction, and particularly of the dispersible clay fraction, but more research is needed to  
309 understand its role in driving argillic Bx properties.

400

401 Figure 6. Qualitative evolution of fragipan properties upon wetting and drying in lab conditions, depicted on an arbitrary scale (from 1 to 5) after A)  
402 deionized water cycle and B) CaCl<sub>2</sub>-treatment in the different aggregate classes compared to soil fragipan and non-fragipan before treatments. The  
403 investigated fragipan properties are slaking (Soil Survey Staff, 2014; Falsone and Bonifacio, 2006; Lindbo and Rhoton, 1996), macroporosity  
404 (Lamotte et al., 1997; Ajmone-Marsan et al., 1994), particle density (Falsone and Bonifacio, 2009; Weisenborn and Schaetzl, 2005b) and  
405 microporosity (Lamotte et al., 1997; Ajmone-Marsan et al., 1994) measured in this study by high values of RPS values, low amount of V<sub>c</sub>, high  
406 values of PDc and high amount of V<sub>MESO</sub>, respectively. The highest is the rank, the best expressed the property. Note that in B) there are  
407 overlapping lines for FRG-CA and FRG<sub>2-5</sub>-CA samples.

#### 408 **Tables**

409 Table 1. Main morphological properties of the soil profile. Codes according to Schoeneberger et al. (2012)

Horizons	depth	Boundary	Munsell colour (dry)	Mottles	Structure	Coatings	Concentration	Rock fragments	Roots
	cm	D_T	Q_S_C	colour	G_S_T	Q_K	Q_S_K	volume%	Q_S

Oi	1-0	A_S	-	-	-	-	-	-	-	-	-
A	0-10	A_S	2.5Y6/4	-	-	2_f_gr	-	1	3_f

410 Horizon boundary: (D) Distinctness: A=abrupt, C=clear, G=gradual; (T) Topography: S=smooth, W=wavy, U=unknown

411 Mottles: (Q) Quantity: f=few, c=common; (S) Size class: 1=fine, 2=medium; 3=coarse; (C) Contrast: d=distinct, p=prominent

412 Texture: SCL=sandy clay loam, SL=sandy loam. L=loam, C=clay

413 Structure: (G) Grade: 2=moderate, 3=strong; (S) Size class: f=fine, m=medium, co=coarse; (T) Type: gr=granular, abk= angular blocky, pr=prismatic

414 Coatings: (Q) Quantity: 1=few, 2=common; (K) Kind: c= clay

415 Concentrations: (Q) Quantity: 1=few, 2=common, 3=many; (S) Size class: 3=coarse; (K) Kind: FMN= iron-manganese masses

416 Roots: (Q) Quantity: 0=absent/very few, 1=few, 3=many; (S) Size class: f=fine

417

418 Table 2. Main properties of the <2 mm fraction of the selected Btc2 and Btcx soil horizons

Horizon	pH	Organic C	CS	FS	S	C	Fe <sub>DCB</sub>	Ca	Total	V <sub>TOT</sub>	SSA	Clay mineralogy
										saturation	porosity	

		g kg <sup>-1</sup>	g kg <sup>-1</sup>	g kg <sup>-1</sup>	g kg <sup>-1</sup>	g kg <sup>-1</sup>	g kg <sup>-1</sup>	%	%	mm <sup>3</sup> g <sup>-1</sup>	m <sup>2</sup> g <sup>-1</sup>	
Btc2	6.1	1.2	57.7	29.5	29.5	12.7	56.0	27.6	40	265	34.5	HIV (44%), Sm (28%), IV (15%), I (13%)
Btcx	6.1	2.2	59.5	26.2	26.2	14.2	77.3	21.3	38	240	48.4	HIV (37%), Sm (34%), IV (15%), I (14%)

419 CS: coarse sand (2-0.2 mm); FS: fine sand (0.2-0.05 mm); S: silt (0.05-0.002 mm); C: clay (<2 μm); Ca saturation: percentage of exchangeable  
420 Ca/cation exchange capacity; V<sub>TOT</sub>: total volume of Hg intruded; SSA: specific surface area; Clay mineralogy was evaluated by X-ray diffraction  
421 (Co-Kα radiation) on Mg-saturated, ethylene glycol solvated and 550°C-heated oriented clay fraction-mounts - scans were made from 3 to 35°2θ at  
422 a speed of 1.5°2θ min<sup>-1</sup> and a semi-quantitative evaluation of mineral abundance was performed as described in Stanchi et al. (2017): HIV,  
423 hydroxy-interlayered vermiculite; Sm, smectite; IV, randomly interstratified illite-vermiculite mixed layers; I, illite; numbers inside brackets are the  
424 relative abundance

425

426

427 Table 3. Organic C, pedogenic Fe oxides and particle size distribution of the 1-2 mm aggregate  
 428 class of FRG and NFRG (Btcx and Btc2 soil horizon) before treatments and after the wet-dry cycle.

sample code	treatment	Organic C	Fe <sub>DCB</sub>	Particle size distribution after dispersion				CS <sub>ox</sub>	CDR
				with (NaPO <sub>3</sub> ) <sub>6</sub>					
				CS	FS	S	C		
		g kg <sup>-1</sup>	g kg <sup>-1</sup>	%				g kg <sup>-1</sup>	%
FRG	before treatments (without any treatment)	1.9±0.1	86.8±3.2	49.4±2.4	17.4±1.2	20.1±0.8	13.0±0.4	24.9±0.7	11.5±0.2
FRG- WAT	water treatment	1.7±0.2	88.3±1.1	51.0±0.1	16.2±0.1	23.2±3.0	9.6±3.2	33.0±0.4	20.8±4.3
FRG- CA	CaCl <sub>2</sub> -treatment	1.4±0.2	94.8±3.9	39.1±0.7	16.6±0.7	25.5±0.2	18.7±0.2	31.5±3.3	9.1±0.8
NFRG	before treatments (without any treatment)	1.3±0.1	62.8±1.8	24.8±5.4	44.4±8.8	20.1±3.3	10.7±0.1	7.4±0.5	12.1±1.8
NFRG- WAT	water treatment	1.1±0.2	61.5±2.8	20.5±0.3	37.2±7.6	32.0±2.4	10.4±4.9	4.1±0.2	25.0±3.2
NFRG- CA	CaCl <sub>2</sub> -treatment	0.9±0.3	53.5±0.7	15.6±3.1	30.2±2.9	34.5±0.8	19.6±0.5	4.4±0.5	9.2±1.4

429 CS: coarse sand (2-0.2 mm); FS: fine sand (0.2-0.05 mm); S: silt (0.05-0.002 mm); C: clay (<2 µm); CS<sub>ox</sub>:

430 coarse sand obtained after H<sub>2</sub>O oxidation and Na-dithionite-citrate-bicarbonate extraction followed by

431 (NaPO<sub>3</sub>)<sub>6</sub> dispersion; CDR: clay dispersion ratio

432

433 Table 4. Wet stability of the 1-2 mm aggregate class of Btcx and Btc2 soil horizon before  
 434 treatments (horizon codes: FRG and NFRG) and after the wet-dry cycle.

sample code	treatment	Loss	Loss <sub>et</sub>	RPS
		%	%	%
FRG	before treatments (without any treatment)	30.2±1.1	21.1±0.5	30.1±0.9
FRG-WAT	water treatment	58.1±0.2	44.5±4.1	23.4±4.2
FRG-CA	CaCl <sub>2</sub> -treatment	68.8±3.6	58.5±2.9	15.0±8.7
NFRG	before treatments (without any treatment)	20.7±2.5	16.2±1.2	21.7±2.4
NFRG-WAT	water treatment	41.7±1.7	34.8±2.7	16.5±3.0
NFRG-CA	CaCl <sub>2</sub> -treatment	44.7±1.0	32.6±0.5	27.1±1.8

435 Loss: percentage of aggregates lost after 10 min of wet sieving; Loss<sub>et</sub>: percentage of aggregates  
 436 lost after pre-wetting in ethanol and 10 min of wet sieving; RPS: relative percentage of slaking

437

438

439 Table 5. Packing density of coarser (sand and silt) and finer (clay) particles (PDc and PDf,  
 440 respectively) of the 1-2 mm aggregate class of Btcx and Btc2 soil horizons before treatments  
 441 (horizon codes: FRG and NFRG) and after the wet-dry cycle.

sample code	treatment	PDc	PDf	PDc/PDf
FRG	before treatments (without any treatment)	0.82±0.01	0.31±0.01	2.65±0.06
FRG-WAT	water treatment	0.79±0.01	0.39±0.08	2.02±0.16
FRG-CA	CaCl <sub>2</sub> -treatment	0.79±0.01	0.54±0.01	1.47±0.01
NFRG	before treatments (without any treatment)	0.73±0.01	0.39±0.01	1.87±0.02
NFRG-WAT	water treatment	0.73±0.01	0.34±0.10	2.16±0.06
NFRG-CA	CaCl <sub>2</sub> -treatment	0.74±0.01	0.53±0.01	1.39±0.02

442

443 Table 6. Organic C, pedogenic Fe oxides and particle size distribution of newly formed 2-5 and >5 mm aggregates of FRG and NFRG (Btcx and  
 444 Btc2 soil horizons) obtained after the wet-dry cycle.

NF-aggregate class	sample code	treatment	Organic C g kg <sup>-1</sup>	Fe <sub>DCB</sub> g kg <sup>-1</sup>	Particle size distribution after dispersion with (NaPO <sub>3</sub> ) <sub>6</sub>				CS <sub>ox</sub> g kg <sup>-1</sup>	CDR %
					CS	FS	S	C
