## Abstract

A molecular understanding of coke formation during the methanol to olefins (MTO) reaction is of great importance in order to adopt strategies that can improve the lifetime of the catalyst. UV-Raman has proven to be a valuable characterization tool, because of the favorable resonance conditions achieved towards key coke components, e.g. aromatic and olefinic compounds. Still, the applicability of UV-Raman in MTO is limited by the high risk of inducing sample damage under the exposure to the intense UV excitation laser. This drawback has been addressed by specific experimental setups, exploiting the concept of sample movement under the laser beam during the measurement, so that the laser-sample interaction is minimized by averaging over a wider sample surface. In this work, the impact of two different experimental setups, both relying on sample movement, are evaluated for the operando investigation of the MTO reaction over a SAPO-34. While in one case the whole catalytic bed is moved (fluidized bed), in the other case the sample is pressed into a pellet and rotated. Due to the peculiar spatial evolution of the reaction zone during MTO in a fixed-bed reactor, each method provides valuable information, but at very different spatiotemporal scales.

## Keywords

Methanol-to-hydrocarbons; Raman; Operando; Zeolite; Deactivation

## 1 Introduction

The methanol to hydrocarbons (MTH) reaction represents an industrially applied alternative to crude oil based processes, enabling the production of light olefins (MTO), gasoline (MTG) or aromatics (MTA), from abundant and economically viable feedstocks (e.g. natural gas, biomass or coal) [1–3]. The sustainable advantages of these processes are however hampered by the relatively fast deactivation of the zeolite catalysts on which the process relies [4]. Deactivation occurs by blockage of the active sites in the microporous network of the catalyst, as a consequence of heavy hydrocarbons and extended carbon deposits, in a process usually referred to as coking [5–7]. A molecular level characterization of the hydrocarbons transformations occurring during deactivation, is essential for obtaining an understanding of coking mechanisms [8]. Another challenge for an accurate characterization of the deactivation phenomena is that instead of post-mortem [7–9], ideally one would like to perform the analysis under reaction (i.e. operando) conditions [10–20]. To tackle both of the aforementioned challenges, Raman spectroscopy has a considerable potential, but the number of literature reports dealing with the investigation of deactivation during MTH is still limited in comparison to other tools [10,11,13,14,21,22]. The advantages of Raman spectroscopy mostly relate to its capability in distinguishing among the several allotropic forms of carbon [23,24]. Furthermore, when wavelengths falling in the vicinity of the electronic transition of particular moieties are exploited, resonance conditions can be achieved for these ones. As a consequence, the intensities of some of the vibrational modes associated to these molecules are selectively enhanced by a factor  $10^5$ - $10^7$  [25–27]. However, experiments performed with conventional visible laser sources often fail because of the strong overlap of the Raman signal with the fluorescence emission proper of aromatic species formed during MTH. Such interference is effectively avoided through a careful choice of the excitation wavelength, which should fall in a spectral range free from emission processes. UV excitation is a very convenient option, since the resonance conditions for some deactivation species are achieved: in particular, polycyclic aromatic hydrocarbons (PAHs) and other aromatic/conjugated species show their electronic transition in the mid-UV range, thereby allowing the resonance enhancement [28–30].

Besides the aforementioned multiple advantages, the application of UV-Raman spectroscopy in the MTH reaction has been mainly limited because of possible sample damaging under the intense UV irradiation. Therefore, the few authors that have applied UV-Raman spectroscopy to study the MTH reaction, also presented technical solutions able to overcome the sample damaging issue. The general concept beyond the experimental setups is sample movement: by continuously changing the portion of specimen exposed to the laser beam during the measurement, the spurious degradation induced by the excitation source is mitigated. In this way, a catalyst performing MTH can be monitored for a reasonably long time-framework, still obtaining trustworthy data. Several devices have been presented in the literature, mostly taking advantage of a mechanical movement of the sample (i.e. by spinning it through an electric engine) [31–33]. At the beginning of 2000, Chua and Stair developed a fluid bed reactor specifically for the in-situ investigation of the MTH reaction [11,13]: their device takes advantage of the continuous movement of the catalysts particles under the laser beam obtained through electromagnetic shaking of the whole reactor. They showed the effectiveness of their setup by measuring the spectra of several hydrocarbons related to MTH (e.g. benzene and PAHs), which appear stable even after hours of exposure to the UV laser beam. More recently, Beato et al. developed a micro-reactor cell based on the commercial Linkam CCR1000 setup [10]. Again, this tool takes advantages of the catalytic bed fluidization to achieve the sample movement. With respect to the technical solution described previously, in this reactor fluidization is produced with a fully fluid-dynamical approach: a membrane pump connected to the outlet of the cell produces an oscillatory backpressure, which makes the catalyst powder moving in a volcano like fashion. Among the proposed test cases, this setup has been applied to the study of MTH over ZSM-5 and ZSM-22. Recently, we successfully exploited the same setup in the operando UV-Raman investigation of hydrocarbons transformations occurring during MTH as a function of the topology of different zeolite catalysts [22].

Aiming to overcome some of the limitation of the previous devices (mostly related to the instability of the focus over the sample upon fluidization), some of us recently developed a mechanical-based setup, where the movement is produced through a magnetic stirring [34,35]. The latter has been exploited in a carefully

controlled study of some relevant molecular species taking part to the deactivation in MTH (i.e. PAHs) [36], as well as in the characterization of pristine [37] and fully deactivated MTH catalysts with different topologies [8].

From the previous paragraph, the only reason driving the choice of a specific setup seems to be the necessity to avoid decomposition during the measurement. Actually, the choice of a different configuration can affect the observed process: this fact is of particular relevance for MTH, since the deactivation has a spatial pattern determined by the type of reactor adopted. In fix bed designs, the deactivation proceeds following the direction of the flow, in a way pictorially described as a “burning cigar” [19,20,38,39]. Conversely, in fluidized bed reactors, deactivation reasonably occurs homogeneously over the whole catalyst, due to the continuous exchange of the position of particles with respect to the flow direction [40].

In the next sections, the UV-Raman characterization of SAPO-34 under MTO reaction conditions is reported. SAPO-34 represents the most applied catalyst for the MTO reaction because of its peculiar topology (see Figure 1).

Figure 1. Topology (CHA) of SAPO-34. The main types of rings forming the framework are highlighted: 8-membered ring (green), 6-membered ring (red) and 4-membered ring (blue).

The SAPO-34 framework belongs to the CHA topology: the network of double six rings includes quite large *cha* cages interconnected by small 8-membered ring windows. The latter allow the diffusion of molecules with dynamic radius smaller than 3.72 Å, whereas species up to 7.37 Å can be hosted in the cages [41]. Such features explain the superior selectivity of SAPO-34 toward light olefins (mostly ethylene and propylene) highly desirable in MTO, whereas bulkier hydrocarbons (including higher alkenes and aromatics) are trapped in the cages. The latter moieties, if not further able to react within the cages, become deactivating species which cause a progressive decrease of the catalysts activity down to complete deactivation. The aim of this work is to take advantage of the favorable resonance conditions achieved with UV-Raman towards key coke components and to characterize their formation/transformations under MTO conditions. Furthermore, the observed reactivity will be discussed on the basis of the specific reactor setup adopted for the measurement.

## 2 Materials and Methods

The SAPO-34 ((P+Al)/Si = 11) sample deeply characterized in ref. [8] has been studied under operando conditions in this work. UV-Raman spectra have been collected with a Renishaw inVia Raman Microscope spectrometer, whose excitation source is a Coherent MotoFred 300C frequency doubled Ar<sup>+</sup> laser, emitting at 244 nm. A 15× objective focused the excitation beam over the sample and recollected the backscattered light,

then the Rayleigh peak was removed by a dielectric edge filter. The Raman signal was dispersed by a 3600 lines mm<sup>-1</sup> grating and finally collected by a Peltier cooled CCD detector.

The operando UV-Raman measurements reported in this work have been performed taking advantage of two of the setups described in the Introduction section: the “magnetic stirring” and the modified Linkam CCR1000 setups. The key features of both setups are graphically outlined in Figure 2 and described thereafter.

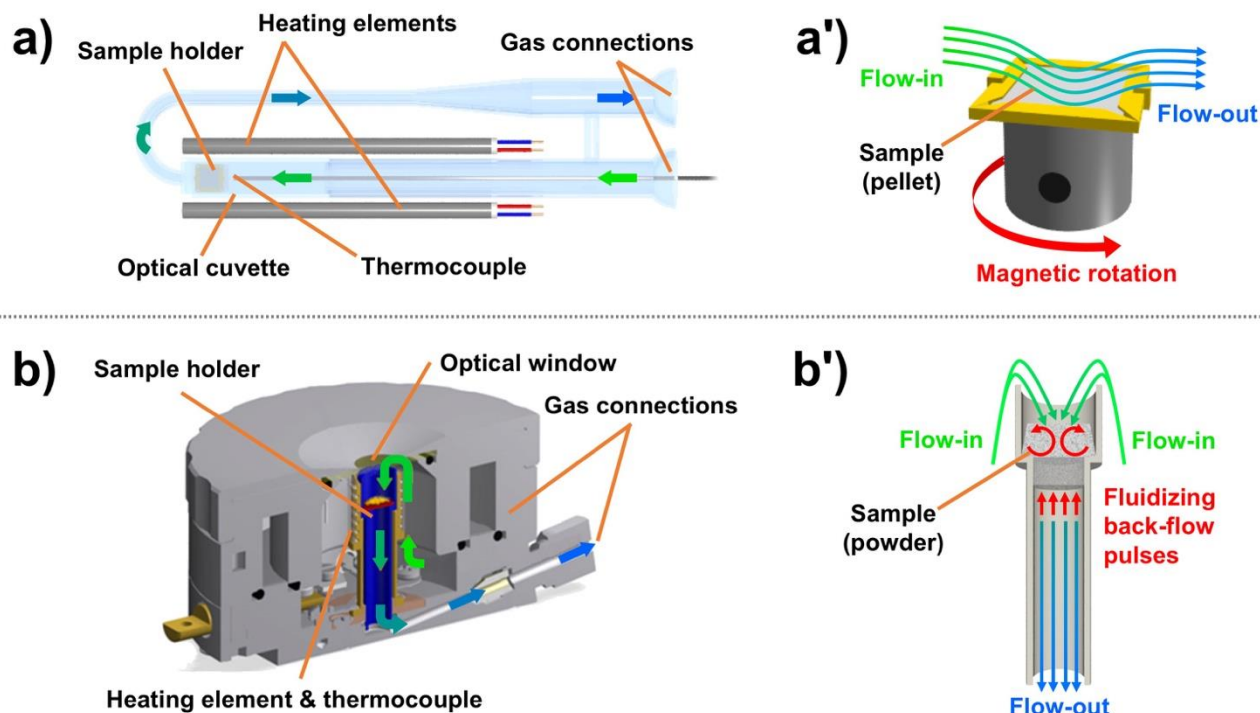

Figure 2. Schematics of a) magnetic stirring and b) modified CCR1000 setups. Panels a') and b') report details of the corresponding sample holders, highlighting the mechanism producing the sample movement during the measurements. Panel b) adapted from ref [10].

The magnetic stirring setup (Figure 2a) is derived from the house-made cell described in ref. [34,35], originally developed for ex situ studies [8,36,37], and is a simple U-shaped quartz-glass reactor, where a portion of the inlet channel is an optical grade quartz cuvette, allowing the measurement of UV-Raman spectra. Furthermore, with respect to the parent cell, two external electrical heating elements are placed on the sides of the cuvette, allowing to span the 50-500 °C temperature range. The heating elements are controlled by a PID system driven by a K-type thermocouple, inserted in the cell nearby the sample and thus keeping constant the desired reaction temperature. The catalyst is mounted over a magnetic sample holder as a self-supported pellet of ~ 2 mg (Figure 2b): by applying an external magnetic field, the sample is put in rotation in order to perform reliable measurements. The gas flow crossing the cell tangentially hits the upper surface of the pellet, i.e. the same fraction of sample probed by UV-Raman. This measurement geometry can be thus regarded as a model for the top layers of a fixed bed catalyst.

The CCR1000 reactor is supplied by Linkam Scientific Instruments and has been modified according to ref. [10]. In brief, the gas flow through the sample is from top to bottom, while the outlet of the reactor is connected to a membrane pump delivering back-flow pulses with a frequency of 40-100 Hz. The pulses induce pressure fluctuations which lift the catalyst particles at the same pulse frequency. Due to the net downwards gas flow, the particles are kept in the sample cup and the oscillatory pressure profile causes the movement of the catalytic bed in a “volcano like” manner. The continuous and homogeneous particle movement allows focusing the laser beam with a 10x objective onto the surface of the moving bed, thus providing reliable UV-Raman measurements. The catalyst sample (~ 20 mg) is loaded as a sieve fraction of 150-300 µm to ensure that all the sample is moving homogeneously, thereby simulating a continuously stirred tank reactor (CSTR).

With both the setups, samples have been pre-oxidized at 550 °C under 20 ml min<sup>-1</sup> of pure O<sub>2</sub> to remove the pre-existing carbonaceous residuals. After 30 min, the temperature has been decreased to 400 °C and, after purging with 20 ml min<sup>-1</sup> of He for 5 min, the reaction has been started exposing the catalyst to methanol vapors (weight hourly space velocity, WHSV, of 2 g<sub>MeOH</sub> g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>). In order to keep the WHSV to the desired value, the temperature of the methanol evaporator has been decreased to 0 °C in the case of the CCR1000 reactor and down to -20 °C for the magnetic stirring one. Since its onset, the reaction has been monitored for approximately 90 min of time on stream (TOS), with a continuous collection of spectra (~10 min accumulation each). The qualitative composition of the flow outgoing the reactors has been monitored with a Pfeiffer OmniStar GSD 320 O quadrupole mass spectrometer (MS) during the whole experiment. Ex situ measurements have been performed for the sake of comparison on the fully deactivated SAPO-34 as characterized in ref. [8]: the whole amount of catalyst recovered from the reactor has been milled and homogenized prior the measurement, in order to obtain a spatially averaged picture of deactivating species.

### 3 Results and Discussion

#### 3.1 Magnetic stirring reactor

The operando UV-Raman characterization of SAPO-34 during MTH within the magnetic stirring reactor cell is shown in Figure 3.

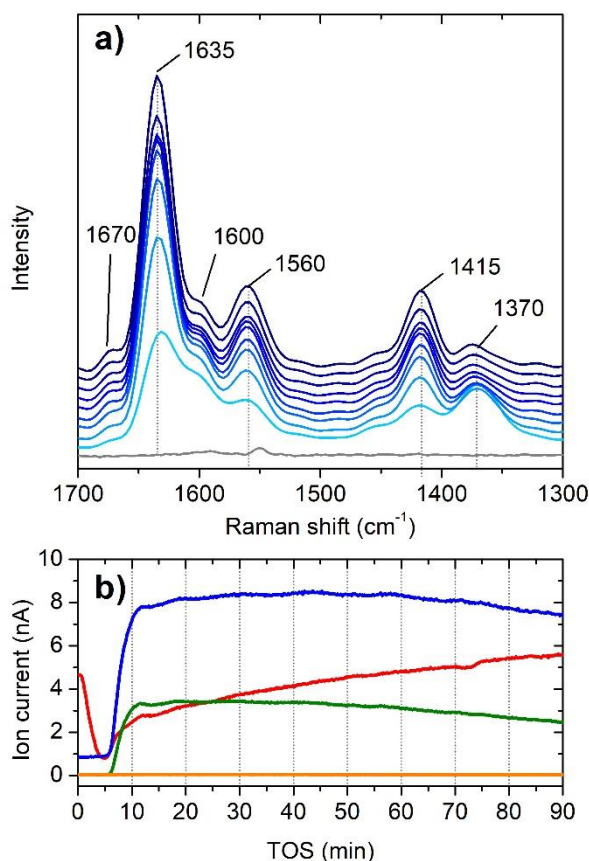

Figure 3. a) UV-Raman spectra of SAPO-34 along 90 min of MTH reaction (400 °C, 2 g<sub>MeOH</sub> g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>) collected every 10 min (time evolution from cyan/bottom to blue/top) exploiting the magnetic stirring reactor cell. The spectrum of the bare SAPO-34 before starting the reaction is shown for the sake of comparison (gray curve). b) online MS charts for selected reagents/products: methanol (red, m/z = 31), ethylene (blue, m/z = 27), higher alkenes (green, m/z = 41) and aromatics (orange, m/z = 91).

Along the 90 min of reaction investigated in this study, a clear evolution of the spectroscopic features is observed. The spectrum of the bare SAPO-34 does not show major features in the range of interest, just a

single, weak band ascribable to framework modes at  $1550\text{ cm}^{-1}$ . Upon methanol dosage, the peak with maximum at  $1635\text{ cm}^{-1}$  rapidly grows (by a factor 4 during the whole experiment), in particular during the first 30 min. The same band is actually red-shifted by approximately  $5\text{-}10\text{ cm}^{-1}$  at the earliest stages. The bands at  $1560\text{ cm}^{-1}$  and  $1415\text{ cm}^{-1}$  grow simultaneously, with a similar intensity *versus* TOS trend. The two weak bands at approximately  $1600\text{ cm}^{-1}$  and  $1670\text{ cm}^{-1}$ , grow also with TOS but comparatively slower and to minor extent. The only band observed to decrease in intensity is the one at  $1370\text{ cm}^{-1}$ , with a trend that seems to be directly inverse to the  $1635\text{ cm}^{-1}$  band. Interestingly, the band at  $1370\text{ cm}^{-1}$  also blue-shifts ( $\sim 5\text{ cm}^{-1}$ ) with increasing TOS.

Concerning the assignment of the observed UV-Raman signals, the concerted intensity trend suggests that the bands at  $1635\text{ cm}^{-1}$ ,  $1560\text{ cm}^{-1}$  and  $1415\text{ cm}^{-1}$  are related to the same or same group of chemical species. These can be related to alkenes [22,42]: this assignment is supported by the known retention of  $\text{C}_{4+}$  alkenes within the cages of SAPO-34, since the small 8-membered windows do not allow them to out-diffuse from framework [43]. The  $1600\text{ cm}^{-1}$  is assigned to the G band of amorphous carbon, whereas the usually observed D band is suppressed due the use of UV excitation in its measurement [24]. The high frequency shoulder at  $\sim 1670\text{ cm}^{-1}$  falls in the region typical of carbonyl stretching, thus it can testify the presence of oxygenated compounds. However, some branched olefins can give signals up to this frequency value [42]. Finally, the  $1370\text{ cm}^{-1}$  band is found in the frequency region typical of PAHs fingerprints [36]. Small PAHs give intense features close to this frequency, e.g. naphthalene ( $1380\text{ cm}^{-1}$ ), anthracene ( $1400\text{ cm}^{-1}$ ) and phenanthrene ( $1350\text{ cm}^{-1}$ ), however none of them exactly match this band. It is important to highlight that the signal is rather broad (FWHM of  $\sim 40\text{ cm}^{-1}$ , i.e. roughly the double of ones of pure PAHs), indicating the overlap of the features of more than a single molecule. Furthermore, according to dissolution-extraction experiment performed on the same catalyst [8] and to modelling results [22], these PAHs are most probably methylated and their skeletal vibration can be affected by such substitutions. The more abundant presence of PAHs at early TOS (according to the larger intensity of the  $1370\text{ cm}^{-1}$  band) is further supported by the observed lower frequency of the most intense, band at about  $1625\text{ cm}^{-1}$ : this frequency is characteristic for the small PAHs listed above.

The online MS signals reported in Figure 3b are a further piece of information useful in interpreting the chemical behavior of the catalyst during reaction. The most peculiar pattern is associated to methanol: at the beginning of the reaction, the ion current associated to it rapidly drops, while no products appear in the gas phase. As the signals from products start to appear, also the methanol signal starts to increase again, for a short time lapse with very high slope and then with a much slower rate until the end of the experiment. This peculiar evolution of the methanol signal is ascribed to the physisorption of methanol at the cold glass parts of the reactor cell and the concurrent build-up of the hydrocarbon pool in the pores of the zeolite. As all the glass parts are saturated by the methanol vapors, a higher fraction of it is able to pass through the whole reactor and is then measured by MS, causing the fast increase described above. On the other hand, the observed induction time before products are detected (typically between 5-10 min of TOS) has been discussed in the literature as a function of the primary size of the SAPO-34 particles [44]. At longer TOS, a progressive decrease in the catalysts activity is observed, according to the increase of the methanol signal and the simultaneous decrease of ethylene/propylene signals. Such gradual deactivation behavior has been previously reported for this specific topology [8]. Aromatics are never observed along the whole experiment, in agreement with the selectivity over the only small alkenes imposed by the small-pore topology of CHA.

The combination of all the pieces of information above finally allows to describe the key hydrocarbons transformations occurring at the catalyst during the explored TOS. At early stages, when catalyst is still poorly productive, the dominating spectral features are ascribed to small, eventually methylated PAHs (the hydrocarbon pool) and a fraction of amorphous carbon. The latter is most probably formed at early reaction stage by active sites sitting on the external surfaces of the catalysts particles, which are rapidly deactivated thus preventing the further growth of the extended carbonaceous phase. In fact, its Raman signals (in particular the G band at  $1600\text{ cm}^{-1}$ ) only slightly increase along TOS. Despite the amount of amorphous carbon is expected to be low at this stage, it is effectively probed by UV-Raman according to its low penetration depth, thus highlighting more effectively near-surface species. When products start to be observed by MS, the features

of certain PAHs ( $1370$  and  $1625\text{ cm}^{-1}$ ) decrease in intensity and signals related to alkenes ( $1635$ ,  $1560$  and  $1415\text{ cm}^{-1}$ ) start to rise. Finally, a low amount of carbonyl-containing species/branched alkenes is observed at late TOS. The observed MS and Raman signals evolution suggests that PAHs are part of the HCP under these reaction conditions: they are in fact observed with maximum abundance at the beginning of the reaction (while catalyst activity is increasing), then their amount decreases suggesting a transformation into other chemical species, probably larger PAHs (which are difficult to detect because of their decreased resonance with respect to smaller ones) [36]. The small increase of the features associated to an extended carbon phase (i.e. the typical G band signal at  $1600\text{ cm}^{-1}$ ), further confirms that PAHs are converted into other molecular species rather than into extended coke, consistent with their hindrance to diffuse through the small 8-membered rings of SAPO-34 toward the external surface (where amorphous carbon is formed). Instead, the growth and conservation of Raman signals related to long-chain and branched olefins, which cannot diffuse out of the framework, indicate that they are not able to further react and consequently could act as deactivating-like species in SAPO-34. Such combination of aromatics and alkenes driving to deactivation in SAPO-34 is in line with the previous findings of Rojo-Gama et al.[8] and Hereijgers and co-workers [43].

### 3.2 Linkam CCR1000 reactor

The same operando experiment reported above has been repeated using a different reaction cell, i.e. the Linkam CCR1000, operated in a fluidized bed mode: the corresponding operando Raman spectroscopic and MS results are reported in Figure 4.

Figure 4. a) UV-Raman spectra of SAPO-34 along 90 min of MTH reaction ( $400\text{ }^{\circ}\text{C}$ ,  $2\text{ g}_{\text{MeOH}}\text{ g}_{\text{cat}}^{-1}\text{ h}^{-1}$ ) collected every 10 min (time evolution from orange/bottom to red/top) exploiting the Linkam CCR1000 reactor cell. The spectrum of the bare SAPO-34 before starting the reaction is shown for the sake of comparison (gray curve). b) online MS charts for selected reagents/products: methanol (red,  $m/z = 31$ ), ethylene (blue,  $m/z = 27$ ), higher alkenes (green,  $m/z = 41$ ) and aromatics (orange,  $m/z = 91$ ).

At a first look, the spectra reported in Figure 4a present similar spectral components as the ones previously discussed for Figure 3a. Nevertheless, their relative intensities are significantly different, with the exception of the first spectrum in the set reported in Figure 3a. At early TOS the dominating feature is the  $1600\text{ cm}^{-1}$  component, which is however part of a broad band tailed toward higher frequencies. The only other clear band is located at  $1370\text{ cm}^{-1}$ , and slightly increases in intensity with TOS. Concurrently, the maximum of the band at  $1600\text{ cm}^{-1}$  is slowly masked with TOS by another band, significantly blue-shifted at a frequency of  $1625\text{ cm}^{-1}$ . At the same time two weak bands at  $1560\text{ cm}^{-1}$  and  $1415\text{ cm}^{-1}$  increase in intensity.

It is reasonable to assign the bands to the same chemical species that were identified in the previous section for the magnetically stirred reactor. Accordingly, the band at  $1600\text{ cm}^{-1}$  is related to amorphous carbon, the bands at  $1370$  and  $1625\text{ cm}^{-1}$  to PAHs (probably methylated), and the two bands at  $1560$  and  $1415\text{ cm}^{-1}$  to alkenes (including branched ones).

The whole dataset reported in Figure 4a appears to be dominated by the features of amorphous carbon. Nevertheless, it is worth noticing that this observation does not necessarily relate to a higher amount of extended coke in the experiment performed in the Linkam cell with respect to the one operated with the magnetic stirring reactor, since the intensities of the two datasets cannot be mutually normalized in a rigorous way. The prevalence of the amorphous carbon signals in Figure 4a is thus ascribed to a slower deactivation process, since the features of the true deactivating species (i.e. of molecular nature) are still scarcely observable. In fact, the very intense band related to alkenes (at  $\text{cm}^{-1}$ ), dominating the spectra reported in Figure 3a, is not clearly discernable in the set of data collected with the Linkam reactor. However, the presence of this band can be inferred from the strongly asymmetric shape of the complex band between  $1500 - 1700\text{ cm}^{-1}$ , which extends towards higher frequencies.

The MS charts reported in Figure 4b appear smoother than in the previous experiment, with the methanol signal dropping with a knee-shape along the first 5 min and then stabilizing on a closely constant value. The stable methanol conversion testifies the non-deactivating nature of the amorphous carbon dominating the set of spectra (Figure 4a). Both ethylene and propylene show onsets with the same trend but opposite sign, reaching the full productivity at  $\sim 10$  min of TOS. Again, the delay among the methanol drop and the reaching of complete productivity are ascribed to primary size of the SAPO-34 particles [44].

The operando experiment conducted within the Linkam CCR1000 reactor cell points out a similar chemistry with respect to the one performed with the magnetic stirring setup, however occurring with a completely different timescale. The data presented in Figure 4 account for a catalyst which is still fully active, containing a small fraction of deactivating species. The initial formation of condensed aromatic species (PAHs) is clearly observed and their signals intensities increase along the whole TOS here investigated. A slight accumulation of heavy alkenes becomes visible only at late TOS, compatibly with the steady-state conversion observed by MS.

### 3.3 Comparison of the setups

The operando UV-Raman experiments reported in Figure 3 and Figure 4 demonstrate the impact of the choice of the setup on the achieved spectroscopic results. Even if the overall chemistry of the hydrocarbon transformation is consistently similar in both cases, the spatiotemporal advancement of these reactions toward deactivating species is certainly different. With the magnetic stirring reactor cell a rapid transformation of PAHs into heavy alkenes is observed, and the major changes take place along the first 20-30 min, while in the remaining 60-70 min only minor changes occur. In contrast, for the fluidized bed reactor along the same time frame, first the build-up of PAHs is observed, followed by a slow but continuous growth of heavy alkenes. In order to assess the degree of deactivation obtained in the two cases, in Figure 5 the final TOS spectra (90 min) for both the setups are compared with the spectrum of fully deactivated SAPO-34 unloaded from a conventional testing reactor as reported in ref. [8].

Figure 5. UV-Raman spectra of SAPO-34 collected: A) with the magnetic stirring reactor cell, after 90 min of MTH reaction ( $400\text{ }^{\circ}\text{C}$ ,  $2\text{ g}_{\text{MeOH}}\text{ g}_{\text{cat}}^{-1}\text{ h}^{-1}$ ); B) with the Linkam CCR1000 reactor cell, after 90 min of MTH reaction ( $400\text{ }^{\circ}\text{C}$ ,  $2\text{ g}_{\text{MeOH}}\text{ g}_{\text{cat}}^{-1}\text{ h}^{-1}$ ); and C) ex situ on a fully deactivated sample upon 20 h of MTH reaction ( $400\text{ }^{\circ}\text{C}$ ,  $2\text{ g}_{\text{MeOH}}\text{ g}_{\text{cat}}^{-1}\text{ h}^{-1}$ ) in a conventional testing setup (see ref. [8]). The spectra are arbitrary normalized to their most intense signal for the sake of clarity.

The final spectrum collected with the magnetic stirring setup closely resembles the one obtained ex situ on a fully deactivated SAPO-34. This observation is thus compatible with a fully deactivated catalyst, which contrasts with the residual activity observed by MS in the operando experiment. This contradicting behavior can be explained by considering the typical spatiotemporal evolution of the MTH reaction when performed in a fixed bed reactor: the reaction zone and consequently the deactivation occurs first at the top layers and then progressively proceeds toward the bottom of the reactor, in a way often described as a “burning cigar” [19,20,38,39]. Since in the stirring magnet setup the catalyst is loaded as a pellet, it is probed from the top and the sample depth investigated by UV-Raman is limited (below the  $\mu\text{m}$ ). The obtained result can be rationalized as the observation of the top layers of the fixed bed, whose deactivation occurs much faster in comparison to the whole catalyst pellet/bed.

In the case of the Linkam CCR1000 reactor cell, the molecular features found after 90 min of reaction are instead representative of a fully operating catalyst, in agreement with the low amount of alkenes detected spectroscopically and the steady state conversion followed by the MS. This behavior in the fluidized bed can be explained by a locally lower methanol concentration due to back-mixing with products, leading to a much slower deactivation [40]. As a result, the deactivation occurs homogeneously over the whole catalyst bed, and the laser is probing the Raman signal from fluidized catalyst particles of the integral reactor.

The key characteristics of the two reactors and the observable spatiotemporal behavior are highlighted in Table 1.

Table 1. Summary of the key information from the operando UV-Raman/MS experiments conducted with the magnetic stirring and the Linkam CCR1000 reactors.

Setup	Main observed species (Raman)	Methanol conversion (MS)	Temporal framework	Spatial framework
Magnetic stirring	Alkenes	Decreasing	Deactivation stages	Catalytic bed top layers
Linkam CCR1000	Amorphous carbon	Constant	Steady-state conversion	Integral catalytic bed

It is evident that the two setups allow the spectroscopic characterization of very different reaction stages, even though working under the same reaction conditions. The magnetic stirring setup provides access to the last reaction stages (i.e. the proper deactivation), since it probes a specific portion of sample (i.e. the top of the catalytic bed) subject to a faster decrease of the catalytic activity, in agreement the peculiar spatial behavior of the MTH reaction [19,20,38,39]. Conversely, the Linkam CCR1000 reactor allowed probing the steady-state behavior, since the catalytic is bed is integrally sampled (i.e. yielding an averaged spatial information) and thus avoiding a locally faster deactivation as in the case of the magnetic stirring setup.

#### 4 Conclusions

In this work, the operando UV-Raman characterization of SAPO-34 during MTH reaction has been presented. In particular, the role of the setup and spatial location of the spectroscopic probe for the study has been discussed. While possible sample damaging induced by the intense excitation source could be avoided in both setups, the presented results have disclosed the importance of the spatial concentration profiles in a reactor and how these can be observed by spectroscopy. Due to the peculiar spatial deactivation profile of the MTH reaction in a fixed bed reactor, the magnetic stirring setup (mimicking a fixed bed reactor) showed spectroscopic evidences of an advanced degree of deactivation, though the catalyst was found still active by online MS. For the fluidized bed setup, even after the same reaction time, the spectroscopic features and the activity measurements both evidenced a catalyst far from deactivation, as a result of using and probing the integral catalyst bed. Combining the complementary pieces of information coming from the two experiments gave a complete spatiotemporal view of the MTH reaction over SAPO-34.

As a general remark, this work wants to emphasize the importance of the choice of the setup in determining the measurement outcomes in all the cases where spatiotemporal resolution is critical parameter: a careful discussion of the data on the basis of the adopted technique/setup is compulsory, as exemplified in this report.

#### Acknowledgments
