ABSTRACT

HD 3167 is a bright ($V=8.9$ mag) K0 V star observed by the NASA's *K2* space mission during its Campaign 8. It has been recently found to host two small transiting planets, namely, HD 3167 b, an ultra short period (0.96 d) super-Earth, and HD 3167 c, a mini-Neptune on a relatively long-period orbit (29.85 d). Here we present an intensive radial velocity follow-up of HD 3167 performed with the FIES@NOT, HARPS@ESO-3.6m, and HARPS-N@TNG spectrographs. We revise the system parameters and determine radii, masses, and densities of the two transiting planets by combining the *K2* photometry with our spectroscopic data. With a mass of $5.69 \pm 0.44 M_{\oplus}$, radius of $1.574 \pm 0.054 R_{\oplus}$, and mean density of $8.00^{+1.10}_{-0.98} \text{ g cm}^{-3}$, HD 3167 b joins the small group of ultra-short period planets

known to have a rocky terrestrial composition. HD 3167 c has a mass of $8.33^{+1.79}_{-1.85} M_{\oplus}$ and a radius of $2.740^{+0.106}_{-0.100} R_{\oplus}$, yielding a mean density of $2.21^{+0.56}_{-0.53} \text{ g cm}^{-3}$, indicative of a planet with a composition comprising a solid core surrounded by a thick atmospheric envelope. The rather large pressure scale height ($\sim 350 \text{ km}$) and the brightness of the host star make HD 3167 c an ideal target for atmospheric characterization via transmission spectroscopy across a broad range of wavelengths. We found evidence of additional signals in the radial velocity measurements but the currently available data set does not allow us to draw any firm conclusion on the origin of the observed variation.

1. INTRODUCTION

Back in 1995 the discovery of 51 Peg b demonstrated that gas-giant planets ($R_p \approx 1 R_{\text{Jup}}$) could have orbital periods of a few days and thus exist quite close to their host star (Mayor & Queloz 1995). Space-based transit search missions such as *CoRoT* (Baglin & Fridlund 2006), *Kepler* (Borucki et al. 2010), and *K2* (Howell et al. 2014) have established that these close-in planets can have radii down to Neptune-like (Barragán et al. 2016; David et al. 2016) and even Earth-like values (Queloz et al. 2009; Howard et al. 2009; Pepe et al. 2013). Close-in exoplanets have challenged planet formation theories and play an important role in the architecture of exoplanetary systems (e.g., Winn & Fabrycky 2015; Hatzes 2016).

Based on the occurrence rate of planets and planet candidates discovered by *Kepler* we know that short-period super-Earths ($R_p = 1 - 2 R_{\oplus}$, $M_p = 1 - 10 M_{\oplus}$) and sub-Neptunes ($R_p = 2 - 4 R_{\oplus}$, $M_p = 10 - 40 M_{\oplus}$) are extremely common in our Galaxy. About 26% of solar-like stars in the Milky Way host small planets ($R_p < 4 R_{\oplus}$) with orbital periods shorter than 100 days (see, e.g., Marcy et al. 2014; Burke et al. 2015). These planets are not represented in our Solar System and were therefore completely unknown to us until a few years ago.

Although *Kepler* has provided us with a *bonanza* of such small planets, little is known about their masses, compositions, and internal structures. Mass determinations with a precision that allows us to distinguish between different internal compositions (better than 20%) have been possible only for a few dozen super-Earths and sub-Neptunes. The small radial velocity (RV) variation induced by such planets and the faintness of most *Kepler* host stars ($V > 13 \text{ mag}$) make RV follow-up observations difficult. These observations either place too much demand on telescope time, or they are simply unfeasible with state-of-the-art facilities.

A special class of close-in objects is composed of exoplanets with ultra-short orbital periods ($P_{\text{orb}} < 1 \text{ day}$; Sanchis-Ojeda et al. 2014). These planets are the most favorable cases for transit and RV search programs, as the transit probability is high ($\propto P_{\text{orb}}^{-2/3}$) and the induced RV variation is large ($\propto P_{\text{orb}}^{-1/3}$). Very short orbital pe-

riods are also advantageous because they are (often) much shorter than the rotation period of the star, allowing the correlated noise due to stellar rotation to be more easily distinguished from the planet-induced RV signal (Hatzes et al. 2011). To date about 80 ultra-short period exoplanets have been discovered¹, mainly from transit surveys starting with CoRoT-7b (Léger et al. 2009). Masses, however, have only been determined for two dozen of these objects. About half of these are gas-giant planets with masses between 1 and $10 M_{\text{Jup}}$. The rest are small planets in the super-earth regime with masses between about 5 and $10 M_{\oplus}$.

Using time-series photometric data from the *K2* space mission, Vanderburg et al. (2016) recently announced the discovery of two small transiting planets around the bright ($V=8.9 \text{ mag}$) K0 dwarf star HD 3167. The inner planet, HD 3167 b, has a radius of $R_p=1.6 R_{\oplus}$ and transits the host star every 0.96 days. By our definition, HD 3167 b qualifies as an ultra-short period planet. The outer planet, HD 3167 c, has a radius of $2.9 R_{\oplus}$ and an orbital period of 29.85 days. The brightness of the host star makes the system amenable to follow-up observations such as high-precision RV measurements for planetary mass determination.

As part of the ongoing RV follow-up program of *K2* transiting planets successfully carried out by our consortium KESPRINT (e.g., Sanchis-Ojeda et al. 2015; Grziwa et al. 2016; Van Eylen et al. 2016; Barragán et al. 2017; Fridlund et al. 2017; Guenther et al. 2017; Nowak et al. 2017), we herein present the results of an intensive RV campaign we conducted with the FIES, HARPS, and HARPS-N spectrographs to accurately measure the masses of the two small planets transiting HD 3167. The paper is organized as follows. In § 2 and § 3 we provide a short recap of the *K2* data and describe our high-resolution spectroscopic observations. The properties of the host star are reported in § 4. We present the data modeling in § 5 along with the frequency analysis of our radial velocity time-series. Results, discussions, and summary are given in § 6 and 7.

¹ See exoplanets.org and exoplanet.eu; as of May 2017.

Figure 1. *K2* light curve of HD 3167 from Vanderburg et al. (2016).

2. *K2* PHOTOMETRY

K2 observed HD 3167 during its Campaign 8 for about 80 days – between January and March 2016 – with an integration time of about 29.4 minutes (long cadence mode). For our analysis presented in § 4.3 and 5.3 we used the light curve extracted following the technique described in Vanderburg & Johnson (2014)². We refer the reader to Vanderburg et al. (2016) for a detailed description of both the *K2* data of HD 3167 and the detection of the two transiting planets. For the sake of clarity we reproduce in Fig. 1 the full light curve of HD 3167 presented in Vanderburg et al. (2016).

3. SPECTROSCOPIC FOLLOW-UP

We used the Fibre-fed Échelle Spectrograph (FIES; Frandsen & Lindberg 1999; Telting et al. 2014) mounted at the 2.56m Nordic Optical Telescope (NOT) of Roque de los Muchachos Observatory (La Palma, Spain) to acquire 37 high-resolution spectra ($R \approx 67000$) in 12 different nights between July and September 2016. FIES is mounted inside a heavily insulated building separate from the dome to isolate the spectrograph from sources of thermal and mechanical instability. The temperature inside the building is kept constant within 0.02 °C. Observations of RV standard stars performed by our team since 2011, have shown that long-exposed ThAr spectra taken immediately before and after short-exposed target’s observations ($T_{\text{exp}} \leq 20$ min) allow us to trace the intra-night RV drift of the instrument to within ~ 2 –3 m/s (Gandolfi et al. 2013, 2015), which is comparable with the internal precision of our FIES RV measurements (Table 5). On the other hand, observations of standard stars performed in different nights have shown

that the inter-night stability of the instrument is 2 to 4 times worse.

The FIES observations were carried out as part of the OPTICON and NOT observing programs 16A/055, P53-016, and P53-203. We set the exposure time to 15–20 min and acquired long-exposed ($T_{\text{exp}} \approx 35$ sec) ThAr spectra immediately before and after the target observations. We took at least 2 spectra separated by 1–2 hours per night except on one night. The data were reduced using standard routines, which include bias subtraction, flat fielding, order tracing and extraction, and wavelength calibration. Radial velocities were derived via multi-order cross-correlations, using the stellar spectrum with the highest S/N ratio as a template³. The measured RVs are listed in Table 5 along with their $1\text{-}\sigma$ internal uncertainties and the signal-to-noise (S/N) ratio per pixel at 5500 Å.

We also acquired 50 spectra with the HARPS spectrograph ($R \approx 115000$; Mayor et al. 2003) and 32 spectra with the HARPS-N spectrograph ($R \approx 115000$; Cosentino et al. 2012). HARPS and HARPS-N are fiber-fed cross-dispersed echelle spectrographs specifically designed to achieve very high-precision long-term RV stabilities ($< 1 \text{ m s}^{-1}$). They are mounted at the ESO-3.6m telescope of La Silla observatory (Chile) and at the 3.58m Telescopio Nazionale Galileo (TNG) of Roque de los Muchachos Observatory (La Palma, Spain).

The HARPS and HARPS-N observations were performed as part of the ESO observing programs 097.C-0948 and 098.C-0860, and of the TNG/CAT programs A33TAC.15 and CAT16B.61. We used the simultaneous Fabry Perot calibrator and set the exposure times to 15–40 minutes depending on sky conditions and scheduling constraints. We followed the same multi-visit strategy

Method 1	5275 \pm 62	4.51 \pm 0.05	0.03 \pm 0.05	0.9 \pm 0.1	2.4 \pm 0.5	1.7 \pm 0.6
Method 2	5260 \pm 70	4.52 \pm 0.06	0.04 \pm 0.05	0.9 \pm 0.1	2.3 \pm 0.5	1.8 \pm 0.6
Method 3	5247 \pm 121	4.40 \pm 0.20	0.06 \pm 0.09	0.7 \pm 0.1	–	–

adopted for the FIES observations, i.e., we acquired at least 2 spectra per night in most of the observing nights. The data were reduced using the dedicated HARPS and HARPS-N off-line pipelines and radial velocities were extracted by cross-correlating the extracted echelle spectra with a G2 numerical mask. We tested also the K0 and the K5 mask but found neither a significant improvement of the error bars, nor a significant variation of the relative amplitude of the detected RV variation.

The HARPS and HARPS-N radial velocity measurements and their uncertainties are also listed in Table 5, along with the S/N ratio per pixel at 5500 Å, the full-width half maximum (FWHM) and bisector span (BIS) of the cross-correlation function (CCF), and the Ca II H & K chromospheric activity index $\log R'_{\text{HK}}$. Five out of the 50 HARPS spectra are affected by poor sky and seeing conditions. They are not listed in Table 5 and were not used in our analysis.

4. STELLAR PROPERTIES

4.1. Spectroscopic parameters

We combined separately the FIES, HARPS, and HARPS-N data to produce three co-added spectra of higher S/N ratio and determine the spectroscopic parameters of the host star. The stacked FIES, HARPS, and HARPS-N spectra have S/N ratios of 500, 560, and 480 per pixel at 5500 Å, respectively. We derived the spectroscopic parameters using three independent methods as described in the next three paragraphs. Results for each method and spectrum are listed in Table 1.

– *Method 1.* This uses a customized IDL software suite that implements the spectral synthesis program

SPECTRUM⁴ (V2.76; Gray & Corbally 1994) to compute synthetic spectra using ATLAS 9 model atmospheres (Castelli & Kurucz 2004). The code fits spectral features that are sensitive to different photospheric parameters, adopting the calibration equations of Bruntt et al. (2010) and Doyle et al. (2014) to determine the microturbulent (v_{mic}) and macroturbulent (v_{mac}) velocities. It uses the wings of the Balmer lines to obtain a first guess of the effective temperature (T_{eff}), and the Mg I 5167, 5173, 5184 Å, the Ca I 6162, 6439 Å, and the Na I D lines to refine the effective temperature estimate and derive the surface gravity ($\log g_*$). The iron abundance [Fe/H] and projected rotational velocity $v \sin i_*$ are measured by fitting many isolated and unblended iron lines.

– *Method 2.* This uses the spectral analysis package SME (V4.43; Valenti & Piskunov 1996; Valenti & Fischer 2005) along with both ATLAS 12 and MARCS model atmospheres (Kurucz 2013; Gustafsson et al. 2008). SME calculates synthetic spectra and fits them iteratively to the observed high-resolution echelle spectra using a chi-squared minimization procedure. Micro and macro turbulent velocities are estimated using the same calibration equations adopted by the first method. T_{eff} , $\log g_*$, [Fe/H], and $v \sin i_*$ are derived by fitting the same spectral features as in the previous paragraph.

– *Method 3.* This is based on the classical equivalent width (EW) technique applied to about 100 Fe I and 10 Fe II lines. It uses the public version of the line list prepared for the Gaia-ESO Survey (Heiter et

⁴ Publicly available at <http://www.appstate.edu/~grayro/spectrum/spectrum.html>.

al. 2015), which is based on the VALD3 atomic database (Ryabchikova et al. 2011). T_{eff} is obtained by removing trends between the abundance of a given element and the respective excitation potential; $\log g_*$ is derived by assuming the ionization equilibrium condition, i.e., by requiring that for a given species the same abundance (within the uncertainties) is obtained from lines of two ionization states (typically neutral and singly ionized species); v_{mic} and $[\text{Fe}/\text{H}]$ are estimated by minimizing the slope of the relationship between abundance and the logarithm of the reduced EWs. Equivalent widths are measured using the code D00p (Cantat-Gaudin et al. 2014), a wrapper of DAOSPEC (Stetson & Pancino 2008). The photospheric parameters are derived with the code FAMA (Magrini et al. 2013), a wrapper of MOOG (Snedden et al. 2012).

The three techniques provide consistent results, regardless of the used spectrum and/or method. While we have no reason to prefer one method over the other, we adopted the results of *Method 1* applied on the FIES, HARPS, and HARPS-N spectra. The final adopted values for T_{eff} , $\log g_*$, $[\text{Fe}/\text{H}]$, and $v \sin i_*$ are the averaged estimates we obtained using the first method; the corresponding uncertainties are defined as the square root of the individual errors added in quadrature, divided by three. We obtained $T_{\text{eff}} = 5286 \pm 40$ K, $\log g_* = 4.53 \pm 0.03$ (cgs), $[\text{Fe}/\text{H}] = 0.03 \pm 0.03$ dex, and $v \sin i_* = 1.8 \pm 0.4$ km s $^{-1}$ (Table 2). Our results are in fairly good agreement with the spectroscopic parameters derived by Vanderburg et al. (2016).

4.2. Stellar mass, radius, and age

We followed the same method adopted by Vanderburg et al. (2016) and derived the mass, radius, and age of HD 3167 using PARAM, an on-line interface for Bayesian estimation of stellar parameters⁵. Briefly, PARAM interpolates the apparent visual magnitude, parallax, effective temperature and iron abundance onto PARSEC model isochrones (Bressan et al. 2012), adopting the initial mass function from Chabrier (2001). We used our spectroscopic parameters (§ 4.1) along with the V-band magnitude listed in the EPIC input catalog ($V = 8.941 \pm 0.015$ mag) and the Hipparcos' parallax (21.82 ± 1.05 mas, van Leeuwen 2007)⁶. Following the method outlined in Gandolfi et al. (2008) and using the broad-band photometry available in the EPIC input catalog, we found that the interstellar reddening is indeed consistent with zero ($A_V = 0.02 \pm 0.03$ mag), as expected given the short distance to the star (45.8 ± 2.2 pc). We

set the interstellar absorption to zero and did not correct the apparent visual magnitude.

HD 3167 has a mass of $M_* = 0.877 \pm 0.024 M_\odot$ and a radius $R_* = 0.835 \pm 0.026 R_\odot$, implying a surface gravity of $\log g_* = 4.51 \pm 0.03$ (cgs), in agreement with the spectroscopically derived value (§ 4.1). The isochrones constrain the age of the star to be 5 ± 4 Gyr.

4.3. Stellar activity and rotation period

The average Ca II H & K activity index $\log R'_{\text{HK}}$, as measured from the HARPS and HARPS-N spectra, is -5.03 ± 0.01 and -5.06 ± 0.02 dex, respectively, indicative of a low chromospheric activity level⁷. We checked if the extrinsic absorption, either from the interstellar medium (ISM) or from material local to the system, biases the measured values of $\log R'_{\text{HK}}$ (Fossati et al. 2013, 2015). The far-ultraviolet (FUV) stellar emission, which originates in the chromosphere and transition region, provides instead an unbiased measure of the stellar activity (Fossati et al. 2015). We measured the excess of the chromospheric FUV emission – directly proportional to stellar activity – by estimating the difference between the measured GALEX FUV flux and the photospheric flux derived from a MARCS model with the same photospheric parameters as the star (Gustafsson et al. 2008) rescaled to fit the observed optical (Johnson and Tycho) and infrared (2MASS and WISE) photometry of HD 3167. The fit accounts for the interstellar extinction reported in § 4.2. We obtained an excess emission in the GALEX FUV band of about $260 \text{ erg cm}^{-2} \text{ s}^{-1}$, indicative of a low level of stellar activity (Shkolnik et al. 2014), in agreement with the $\log R'_{\text{HK}}$ value. This provides evidence that the Ca II activity index $\log R'_{\text{HK}}$ is very likely not biased by extrinsic absorption.

The light curve of HD 3167 displays a 0.08 % flux drop occurring during the first half of the *K2* observations and lasting for about 35-40 days (Fig. 1). If the variation were due to an active region moving in and out of sight as the star rotates around its axis, then the rotation period of the star should be at least twice as long, i.e., 70-80 days. Such a long rotation period seems to be unlikely for a K-type dwarf and is inconsistent with our $v \sin i_*$ measurement and stellar radius determination (see below). Figure 2 shows the distribution of the rotation period of 3591 late G- and early K-type dwarfs as measured by McQuillan et al. (2014) using *Kepler* light curves. We selected only *Kepler* stars with photospheric parameters similar to those of HD 3167, i.e., objects with $5170 \leq T_{\text{eff}} \leq 5370$ K and $\log g_* \geq 4.40$

⁵ Available at <http://stev.oapd.inaf.it/cgi-bin/param>.

⁶ *Gaia*'s first data release does not report the parallax of HD 3167.

⁷ As comparison, the activity index of the Sun varies between -5.0 and -4.8 dex.

Figure 2. Rotation period distribution of *Kepler* field stars with $5170 \leq T_{\text{eff}} \leq 5370$ K and $\log g_{\star} \geq 4.3$ (cgs), as extracted from the work of McQuillan et al. (2014).

(cgs). None of the “HD 3167’s *Kepler* twins” has a rotation period longer than 70 days. Moreover, only 9 objects have a rotational period exceeding 50 days. As both the K2 light curves of HD 3167 – as extracted by Luger et al. (2016) and Aigrain et al. (2016) – display the same feature, we conclude that the observed 0.08 % flux drop is very likely an instrumental artifact caused by the spacecraft pointing jitter.

Figure 3 shows the Lomb-Scargle (LS) periodogram (Lomb 1976; Scargle 1982) of the K2 light curve of HD 3167 following the subtraction of the best fitting transit models of planet b and c (§ 5). Besides a very strong peak at ~ 75 days due to the flux drop described in the previous paragraph, there are 2 additional significant peaks at 14 and 23.5 days with a Scargle’s false alarm probability (FAP) lower than 0.1 %. Since the period ratio is close to 0.5, we interpreted the former as the first harmonic of the latter. With an amplitude of about 0.04 %, the 23.5-day signal is clearly visible in the first half of the K2 time series data, whereas is barely visible in the second half of the photometric data (Fig. 1). As a sanity check, we split the light curve into two chunks of ~ 40 days and calculated the LS periodogram of each chunk. The 23.5-day signal is detected also in the second half of the light curve but with a lower significance. This is likely due to the 80 % higher noise level of the second half of the K2 data with respect to the first half, as pointed out by Vanderburg et al. (2016).

We interpreted the 23.5-day signal as the rotation period of the star and attributed the peak at 14 days to the presence of active regions located at opposite stellar longitudes. We measured a rotation period and uncertainty of $P_{\text{rot}} = 23.52 \pm 2.87$ days defined as the position and full width at half maximum of the corresponding peak in the LS periodogram. If the rotation period of the star were instead 14 days, the magnetic activity of the star would very likely be stronger than what measured from the $\log R'_{\text{HK}}$ activity index (Suárez Mascareño et

Figure 3. Lomb-Scargle periodogram of the K2 light curve of HD 3167. The horizontal dashed line marks the 0.1% FAP as defined in Scargle (1982).

Table 2. Stellar parameters.

Parameter	Value
Effective Temperature T_{eff} (K)	5286 ± 40
Surface gravity ^(a) $\log g_{\star}$ (cgs)	4.53 ± 0.03
Surface gravity ^(b) $\log g_{\star}$ (cgs)	4.51 ± 0.03
Iron abundance [Fe/H] (dex)	0.03 ± 0.03
Projected rot. velocity $v \sin i_{\star}$ (km s^{-1})	1.8 ± 0.4
Interstellar extinction A_{v} (mag)	0.02 ± 0.03
Stellar mass M_{\star} (M_{\odot})	0.877 ± 0.024
Stellar mass R_{\star} (M_{\odot})	0.835 ± 0.026
Age (Gyr)	5 ± 4
Rotation period P_{rot} (day)	23.52 ± 2.87
Distance ^(c) (pc)	45.8 ± 2.2

^aFrom spectroscopy.

^cHipparcos’ distance from van Leeuwen (2007).

al. 2015). It is also worth noting that the distribution of the rotational periods of HD 3167’s *Kepler* twins is peaked between 20 and 25 days (Fig. 2).

The spectroscopically derived projected rotational velocity of the star $v \sin i_{\star} = 1.8 \pm 0.4 \text{ km s}^{-1}$, combined with the stellar radius $R_{\star} = 0.835 \pm 0.026 R_{\odot}$, implies an upper limit on the rotation period of 23.5 ± 5.3 days, in agreement with the period derived from the K2 light curve, further corroborating our results. This also suggests that the star is seen nearly equator-on and that the transiting multi-planet system around HD 3167 might be aligned along the line-of-sight.

5. DATA ANALYSIS

5.1. Periodogram analysis of the radial velocities

We first performed a frequency analysis of the RV measurements in order to look for possible periodic signals in the data and assess if, in the absence of the K2 transit photometry, we would have been able to detect the presence of HD 3167 b and c. For this purpose we used only the HARPS and HARPS-N measurements because of the higher quality and superb long-term stability of the two instruments.

We first analyzed the two data sets separately to account for the velocity offset between the two spectrographs. Although HARPS and HARPS-N are very similar, a small offset ($<10 \text{ m s}^{-1}$) is expected given, e.g., the different detector, optics, wavelength coverage of the two instruments. The generalized Lomb-Scargle (GLS; [Zechmeister & Kürster 2009](#)) periodograms of the HARPS and HARPS-N RVs show a significant peak at the orbital period of HD 3167 b, with a false alarm probability⁸ (FAP) of about 10^{-5} and 10^{-7} , respectively (top and middle panel of Figure 4). We conclude that the signal of the inner planet HD 3167 b is clearly present in both data sets. The GLS periodogram of the HARPS data displays a significant peak at ~ 32 days ($\text{FAP}=10^{-4}$), which is close to the orbital period of HD 3167 c (29.85 days). However, the outer transiting planet remains undetected in the HARPS-N data, owing to the uneven sampling of the orbital phase of the outer transiting planet with this instrument (Fig. 9).

On three occasions⁹ we observed HD 3167 nearly simultaneously (within 10 minutes) with HARPS and HARPS-N. We used these measurements to measure the offsets of the RV, FWHM, BIS and $\log R'_{\text{HK}}$ between the two data sets and calculate the periodograms of the combined data. We found $\Delta \text{RV}_{(\text{HS}-\text{HN})} = 8.0 \pm 0.5 \text{ m s}^{-1}$, $\Delta \text{FWHM}_{(\text{HS}-\text{HN})} = 0.068 \pm 0.006 \text{ km s}^{-1}$, $\Delta \text{BIS}_{(\text{HS}-\text{HN})} = 0.009 \pm 0.003 \text{ km s}^{-1}$, and $\Delta \log R'_{\text{HK}}_{(\text{HS}-\text{HN})} = -0.030 \pm 0.005$. We stress that these offsets have only been used to perform the periodogram analysis of the joint data.

As expected, the GLS periodogram of the joint data set (bottom panel of Fig. 4) shows a very significant peak at the orbital period of the inner planet HD 3167 b ($\text{FAP}=10^{-10}$) and a moderately significant peak at the orbital period of HD 3167 c.

It's worth noting that the three periodograms show also the presence of a significant peak at 23.8 days (0.042 c/d), which is close to the rotation period of the star. We stress, however, that this peak corresponds to

Figure 4. GLS periodograms of the HARPS (top panel), HARPS-N (middle panel), and HARPS+HARPS-N (bottom panel) RV measurements. The vertical dashed lines mark the orbital periods of HD 3167 b (0.96 d) and HD 3167 c (29.85 d).

the 1-day alias of the orbital period of HD 3167 b. The periodogram of the RV residuals – as obtained following the subtraction of the signals of the two planets – show no peaks at 0.042 c/d (Fig. 6).

5.2. Orbital solution of HD 3167 b

We performed a Keplerian fit of the FIES, HARPS, and HARPS-N RV data following the floating chunk offset (FCO) method described in [Hatzes et al. \(2011\)](#). The FCO method exploits the reasonable assumption that,

⁸ The FAPs reported in this subsection have been calculated using Eq. 24 of [Zechmeister & Kürster \(2009\)](#) and should be regarded as preliminary estimates. Deriving reliable FAPs through a bootstrap analysis – as presented in § 5.4 – goes beyond the scope of this subsection.

⁹ Epochs 2457611, 2457646, and 2457692.

for ultra-short period planets, RV measurements taken on a single night mainly reflect the orbital motion of the planet rather than other, longer period phenomena such as stellar rotation, magnetic activity, and additional planets. If we can sample a sufficient time segment of the Keplerian curve, then these nightly “chunks” can be shifted until the best fit to the orbital motion is found. This method was successfully used to determine the mass of the ultra-short period planets CoRoT-7b (Hatzes et al. 2011) and Kepler-78b (Hatzes 2014).

The ultra-short period planet HD 3167 b is well suited for application of the FCO method. This technique is particularly effective at filtering out the RV jitter due to activity. The star has an estimated rotation period of about 23.5 days (§ 4.3), which is longer than the orbital period of HD 3167 b. Although HD 3167 is a relatively inactive star, the FCO method helps in filtering out even a small amount of activity. HD 3167 c has an orbital period of about 29.95 days, which results in a change of less than 0.01 in phase within the nightly visibility window of the target (~ 5 -6 hours). The RV of the star due to the outer transiting planet does not change significantly during an observing night. Moreover, each of the three data sets has its own zero-point offset, which is naturally taken into account by the method. Finally, the FCO technique also removes – or at least greatly minimizes – any long term systematic errors, such as the night-to-night RV drifts of FIES (§ 3).

We modeled the FIES, HARPS and HARPS-N RV measurements with our code `pyaneti` (Barragán et al. 2016), a MCMC-based software suite that explores the parameter space using the ensemble sampler with the affine invariance algorithm (Goodman & Weare 2010). Following Hatzes et al. (2011), we divided the RVs into three subsets of nightly measurements – one per instrument – and analyzed only those radial velocities for which multiple measurements were acquired on the same night, leading to a total of 12, 15, and 11 chunks of nightly FIES, HARPS, and HARPS-N RVs, respectively. The best fitting orbital solution of HD 3167 b was found keeping period and transit ephemeris fixed to the values derived by our joint analysis described in § 5.3, but allowing the RV semi-amplitude variation K_b and the 38 nightly offsets to vary. We also fitted for $\sqrt{e_b} \sin \omega_{*,b}$ and $\sqrt{e_b} \cos \omega_{*,b}$, where e_b is the eccentricity and $\omega_{*,b}$ is the argument of periastron of the star (Ford 2006). We adopted uniform uninformative priors within a wide range for each parameter and ran 500 independent Markov chains. The burn-in phase was performed with 25000 iterations using a thin factor of 50, leading to a posterior distribution of 250000 independent data points for each fitted parameter. The final estimates and their $1-\sigma$ uncertainties were taken as the median and the 68 % of the credible interval of the pos-

Figure 5. *Upper panel:* FIES (triangles), HARPS (circles), and HARPS-N (squares) RV measurements and circular orbital solution of HD 3167 b (solid line) derived using the FCO method. Different colors represent measurements for different observing nights. *Lower panel:* Residuals to the circular model.

terior distributions.

We obtained a best fitting non-zero eccentricity of $e_b = 0.112 \pm 0.024$. We also fitted the RV data assuming a circular orbit ($\sqrt{e_b} \sin \omega_{*,b} = \sqrt{e_b} \cos \omega_{*,b} = 0$). Figure 5 displays our FIES, HARPS, and HARPS-N measurements along with the best fitting circular (thick line) and eccentric model (dashed line). Different symbols refers to different instrument, whereas different colors represent different nights. We note that the best fitting eccentric solution might be driven by the uneven distribution of data points along the RV curve (Fig. 5). In order to assess the significance of our result we created 10^5 sets of synthetic RVs that sample the best fitting circular solution at the epochs of our real observations. We added Gaussian noise at the same level of our measurements and fitted the simulated data allowing for an eccentric solution. We found that there is a $\sim 7\%$ probability that the best fitting eccentric solution could have arisen by chance if the orbit were actually circular. As this is above the 5% significance level suggested by Lucy & Sweeney (1971), we decided to conservatively assume a circular model. We found a radial velocity semi-amplitude variation of $K_b = 3.82 \pm 0.42 \text{ m s}^{-1}$ which translates into a mass of $M_b = 5.40 \pm 0.60 M_\oplus$ for HD 3167 b. We note that the eccentric solution provides a planetary mass that is consistent within $1-\sigma$ with the result from the circular model.

5.3. Transit and RV joint analysis

We performed a joint modeling of the *K2* and RV measurements with `pyaneti`. The photometric data includes 6 and 15 hours of *K2* data-points centered around each transit of HD 3167 b and c. We detrended the seg-

ments using the program `exotrending`¹⁰. Briefly, we fitted a second order polynomial to the out-of-transit data and removed outliers using a 3-sigma-clipping algorithm applied to the residuals of the preliminary best fitting transit models derived using the formalism of [Mandel & Agol \(2002\)](#) coupled to a non-linear least square fitting procedure. As for the RV data sets, we used only the HARPS and HARPS-N measurements because of the long-term instability of the FIES spectrograph (§3).

We modeled the RV data with two Keplerian signals and fitted the transit light curves using the [Mandel & Agol \(2002\)](#)’s model with a quadratic limb darkening law. To account for the *K2* long cadence data, we integrated the transit models over 10 steps. We adopted the same Gaussian likelihood as defined in [Barragán et al. \(2016\)](#). For each planet i we fitted for the orbital period P_i , time of first transit $T_{0,i}$, scaled semi-major axis a_i/R_* , impact parameter b_i , planet-to-star radius ratio R_i/R_* , and RV semi-amplitude variation K_i . We assumed a circular orbit for the inner planet and fitted for $\sqrt{e_c} \sin \omega_{*,c}$ and $\sqrt{e_c} \cos \omega_{*,c}$ for the outer planet.

The 30-minute integration time of *K2* smears out the shape of planetary transits increasing the degeneracy between the scaled semi-major axis a/R_* and the impact parameter b ([Csizmadia et al. 2011](#)). We therefore set Gaussian priors for the stellar mass and radius using the values derived in §4.2 and constrained a_i/R_* of both planets from their orbital periods through Kepler’s third law.

We explored the parameter space with 500 independent chains created from random priors for each parameter, as listed in the second column of Table 3. The convergence of the MCMC chains was checked with the Gelman-Rubin statistic. Once all chains converged, we ran 25000 more iterations with a thin factor of 50. This led to a posterior distribution of 250000 independent points for each fitted parameter.

The two-planet model provides a poor fit to the HARPS and HARPS-N measurements with a RV χ^2 of 597 and $\chi^2/\text{dof} = 8.7$, suggesting that additional signals might be present in the data, as discussed in the next section.

5.4. Frequency analysis of the RV residuals

After fitting the two transiting planets, we inspected the RV residuals to look for additional signals in the Doppler data. The upper panel of Fig. 6 shows the GLS periodogram of the RV residuals (thick black line). There are 3 significant peaks at $f_1=0.094$ c/d ($P_1=10.7$ d), $f_2=0.119$ c/d ($P_2=8.4$ d), and $f_3=0.167$ c/d ($P_3=6.0$ d). We assessed their FAP

Figure 6. *Top panel:* GLS periodograms of the HARPS and HARPS-N RV residuals. The vertical dashed blue lines mark the frequencies $f_1=0.094$ c/d, $f_2=0.119$ c/d, and $f_3=0.167$ c/d whose FAP is less than 10^{-4} , as derived using a bootstrap randomization procedure. *Middle-panel:* Discrete Fourier transform of the HARPS and HARPS-N RV residuals. The dotted red line marks the window function shifted to the right by $f_1=0.094$ c/d and mirrored to the left of this frequency. *Lower panel:* Window function. The red arrows mark the two peaks presented in the main text.

following the Monte Carlo bootstrap method described in [Kürster et al. \(1997\)](#). We computed the GLS periodograms of 10^4 fake data sets obtained by randomly shuffling the RV measurements, keeping the observation time-stamps fixed. The FAP is defined as the fraction of those periodograms whose highest power exceeds the power spectrum of the original observed data at any frequency. We found no false positives out of our 10^4 trials, implying that f_1 , f_2 , f_3 have a FAP lower than 10^{-4} .

As a sanity check, we employed the program `Period04` ([Lenz & Breger 2004](#)) to calculate the discrete Fourier transform (DFT) of the RV residuals. We used the pre-whitening technique (see, e.g., [Hatzes et al. 2010](#)) to subsequently identify significant peaks in the power spectrum and remove the corresponding signal from the data. Briefly, we performed a least squares sine-fit to the amplitude and phase at the first dominant frequency found by the DFT and subtracted the fit from the time series. We then reiterated the process to identify and subtract the next dominant Fourier component. The iteration was stopped once we reached the level of the noise. We regarded as significant only those signals whose amplitudes are more than 4 times the Fourier noise level ([Breger et al. 1993](#)). The Fourier fit of the RV residuals was obtained with only two dominant fre-

¹⁰ Available at <https://github.com/oscaribv/exotrending>.

quencies, namely, $f_1=0.094$ c/d and $f_3=0.167$ c/d, with an amplitude of 1.4 and 1.1 m s^{-1} , respectively.

The periodogram of the sampling pattern - the so-called “window function” - shows two peaks at 0.025 c/d (40 d) and 0.039 c/d (25 d). They are highlighted by two red arrows in the lower panel of Fig. 6. We note that the beat frequency between $f_1=0.094$ c/d and $f_2=0.119$ c/d is equal to 0.025 c/d, which corresponds to one of the two frequencies seen in the window function. This led us to suspect that f_1 and f_2 are aliases of one another and share the same physical origin. We verified this hypothesis using again the pre-whitening technique. We performed a least-squares sine-fit to the amplitude and phase at either f_1 or f_2 , subtracted the best fit from the RV time series, and recalculated the GLS periodogram of the new residuals. Regardless of which of the two signals is fitted and subtracted first, by removing one of the two we also remove the other, as expected from alias peaks, confirming our hypothesis. We note that the subtraction of the signal at either f_1 or f_2 does not remove $f_3=0.167$ c/d, which remains significant in the GLS periodogram of the new residuals.

The middle panel of Fig. 6 shows the DFT of the RV residuals (thick black line), along with the window function shifted to the right by $f_1=0.094$ c/d and mirrored to the left of this frequency (red dotted line). It is evident that f_2 , along with most of the side lobes seen to the right and left of f_1 , is an alias of the latter related to the observing window. We conclude that f_1 is very likely the actual periodicity. We also note that f_3 is not an alias of f_1 , as there is no peak detected in the “shifted” window function at this frequency, corroborating our pre-whitening analysis.

To further assess which of the two signals is the actual periodicity, we performed a least-squares multi-sine fit to the amplitude and phase at the frequency couples f_1 , f_3 , and f_2 , f_3 . We then created synthetic RVs residuals using the best fitting parameters, added white noise, sampled the simulated data at the epochs of our real observations, and calculated the GLS periodograms. We found that “fake” data sets obtained from the couple f_1 , f_3 reproduce better the observed periodogram than the couple f_2 , f_3 . This further supports the fact that the RV residuals contain only two significant signals at $f_1=0.094$ c/d ($P_1=10.7$ d) and $f_3=0.167$ c/d ($P_3=6.0$ d).

What are the sources of the two signals at 6.0 and 10.7 days detected in the RV residuals? Are they due to activity, additional planets, or both? We note that the two periods are close to the first and third harmonic of the rotational period of the star ($P_{\text{rot}} = 23.52 \pm 2.87$ days). This might lead us to suspect that magnetic activity coupled with stellar rotation is the source of the two additional signals. Active regions separated by ~ 90 and ~ 180 degrees in longitude could account for the two pe-

riodicities. To further investigate this hypothesis, we calculated the GLS periodograms of the activity indicators - namely, the full width at half-maximum (FWHM) and bisector span (BIS) of the cross-correlation profile, and the Ca II H & K activity index ($\log R'_{\text{HK}}$) - but found no significant peak. We stress, however, that this cannot be used to exclude that activity is the source of the observed RV variation. Given the amplitude of the two signals (1.2 and 1.4 m s^{-1}) and low projected rotational velocity of the star ($1.8 \pm 0.4 \text{ km s}^{-1}$), the suppression of granular blueshift in magnetized regions of the photosphere of HD 3167 is expected to be the source of the observed “jitter”. Based on observations of the Sun as a star, Haywood et al. (2016) recently found that the traditional activity indicators perform poorly in tracing the RV jitter of slowly rotating stars with low level of magnetic activity, such as in the case of HD 3167.

We further investigated the nature of the additional signals detected in the RV residuals using the stacked Bayesian generalized Lomb-Scargle (BGLS) periodogram proposed by Mortier & Collier Cameron (2017). This tool exploits the BGLS algorithm described in Mortier et al. (2015), which in turn is a Bayesian version of the GLS periodogram of Zechmeister & Kürster (2009). As described in Mortier & Collier Cameron (2017), the stacked BGLS periodogram relies on the assumption that the power (or probability) of a coherent RV signal - such as that produced by a *bona fide* orbiting planet - is expected to increase by adding more data points. On the contrary, the RV signal produced by stellar activity is usually incoherent, since its amplitude, phase, period vary with time, due to the evolution of active regions, differential rotation, and magnetic cycle. Its significance can thus increase or decrease as more RV measurements are added to the data set. The tool calculates the BGLS periodogram for n out of N RVs (where $n \leq N$), adds the next point, recalculates the BGLS periodogram, and iterate the process till the last available measurement.

Figure 7 shows the BGLS periodogram (upper panel) and the stacked BGLS periodogram (lower panel) of the HARPS and HARPS-N RV residuals. As expected, the two dominant peaks at 6.0 and 10.7 days are clearly visible along with their aliases related to the observing window. We note that both signals do not seem to show a steadily increasing power (or probability) as we would expect from signals arising from presence of planets. Is this enough to claim that the two periodic signals are due to activity? Following Johnson et al. (2016), we created a data set of synthetic RV residuals containing two sinusoidal signals at the same period, phase, and amplitude as the observed data. We added Gaussian noise and sampled the simulated RVs at the time stamps of our observations.

Figure 7. Stacked BGLS periodogram of the HARPS and HARPS-N RV residuals.

The BGLS periodogram and stacked BGLS periodogram of the synthetic data are shown in Fig. 8. As is evident from a visual inspection, Fig. 7 and 8 share roughly the same peaks and a similar pattern. None of the two simulated *coherent* signals shows a steadily increasing power. Given the data, this simulation proves that our sampling of two truly coherent signals at 6.0 and 10.7 days can mimic the trend expected from activity-induced RV variation in the stacked BGLS periodogram.

We conclude that, although we found evidence that there are two additional signals with periods of 6.0 and 10.7 days in the HARPS and HARPS-N measurements, the sampling of our observations, as well as the limited number of RVs and their noise level do not allow us to assess whether the two signals are due to activity, or are rather induced by two additional orbiting planets. We thus include the two signals in our analysis but warn the reader that more observations are needed to unveil their true nature.

6. RESULTS

We used the code `pyaneti` to perform the final joint modeling of the *K2* and RV measurements. We fitted the transit and RV curves of HD 3167 b and c following the guidelines presented in § 5.3, and incorporated the modeling of the two additional RV signals at 6.0 and 10.7 days using two sinusoidal curves. We set uniform priors for the periods of the two additional signals – using a 2-day range centered around the values found by the frequency analysis presented in § 5.4 – and adopted uninformative priors over a wide range for the corre-

Figure 8. Stacked BGLS periodogram of the simulated RV residuals.

sponding phases and amplitudes. To account for additional instrumental noise not accounted by the nominal RV error bars and/or imperfect treatment of the various sources of RV variations (e.g., stellar activity and/or additional planets), we added jitter terms to the equation of the likelihood for the HARPS and HARPS-N RV data following the method described in Dumusque et al. (2014).

We report our results in Table 4. The parameter estimates and their error bars were taken to be the median and the 68 % credible interval of the final posterior probability distribution of each parameter. Fig. 9 shows the *K2* transit light curves and best fitting transit models, as well as the HARPS and HARPS-N RVs and best fitting Keplerian models of HD 3167 b and c. The RV fits to the two additional signals at 6.0 and 10.7 days are shown in Fig. 10.

The mass of HD 3167 b is in very good agreement with the value we derived using the FCO method corroborating our analysis (cfr. § 5.2). Similarly, the RV offset between HARPS and HARPS-N ($\Delta RV_{(\text{HS}-\text{HN})} = 8.3 \pm 0.2 \text{ m s}^{-1}$) agrees with the value presented in § 5.1 ($\Delta RV_{(\text{HS}-\text{HN})} = 8.0 \pm 0.5 \text{ m s}^{-1}$). Finally, our values of the planetary radii agree within less than 1- σ with those found by Vanderburg et al. (2016).

Does the inclusion of the 6.0 and 10.7-day signals bias the mass determinations of HD 3167 b and HD 3167 c? A two-planet model fit that included only planet b and c gives RV semi-amplitude variations of $K_b = 3.74 \pm 0.39 \text{ m s}^{-1}$ and $K_c = 2.29 \pm 0.45 \text{ m s}^{-1}$, respectively. By adding only the 10.7-day signal we get $K_b = 4.06 \pm 0.37 \text{ m s}^{-1}$ and $K_c = 2.04 \pm 0.43 \text{ m s}^{-1}$. By

Figure 9. Transit light curves and RV curves of HD 3167 b (upper panels) and HD 3167 c (lower panels). The best fitting transit and Keplerian models are overplotted with thick black lines. The *K2* data points are shown with red circles (left panels). The HARPS and HARPS-N RV measurements are plotted with red circles and blue diamonds, respectively, along with their nominal uncertainties (right panels).

adding both the 10.7-day and the 6.0-day signal we obtain $K_b = 4.02 \pm 0.31 \text{ m s}^{-1}$ and $K_c = 1.88^{+0.40}_{-0.42} \text{ m s}^{-1}$, proving that the RV semi-amplitude variations – and thus the determination of the planetary masses of HD 3167 b and HD 3167 c – are not significantly affected by the inclusion of the two additional signals.

7. DISCUSSION AND SUMMARY

The ultra-short period planet HD 3167 b has a mass of $M_b = 5.69 \pm 0.44 M_\oplus$ and a radius of $R_b = 1.574 \pm 0.054 R_\oplus$, yielding a mean density of $\rho_b = 8.00^{+1.10}_{-0.98} \text{ g cm}^{-3}$. Figure 11 displays the position of HD 3167 b on the mass-radius diagram compared to the sub-sample of small transiting planets ($R \leq 4 R_\oplus$) whose masses and radii have been derived with a precision better than 20 %. Theoretical models from Zeng et al. (2016) are overplotted using different lines and colors. The precision of our mass determination (14 %) allows us to conclude that HD 3167 b is a rocky terrestrial planet with a composition consisting of $\sim 50\%$ silicate and $\sim 50\%$ iron.

HD 3167 b adds to the sample of low-mass, close-in

planets with a RV-determined mass and a bulk density suggestive of a mostly rocky composition. Planets belonging to this sample have a restricted Jeans escape parameter $\Lambda \lesssim 20$ (Table 3). This parameter, defined as

$$\Lambda = \frac{GM_{\text{pl}}m_{\text{H}}}{k_{\text{B}}T_{\text{eq}}R_{\text{pl}}}, \quad (1)$$

has been introduced by Fossati et al. (2017) who found that the hydrogen-dominated atmospheres of exoplanets with $\Lambda \lesssim 20$ lie in the “boil-off” regime (Owen & Wu 2016; Cubillos et al. 2017), where the escape is driven by the atmospheric thermal energy and low planetary gravity. Fossati et al. (2017) also found that the atmosphere of hot ($T_{\text{eq}} \gtrsim 1000 \text{ K}$), low-mass ($M_p \lesssim 5 M_\oplus$) planets with $\Lambda \lesssim 20$ shrinks to smaller radii so that their atmosphere evolves out of the “boil-off” regime in less than about 500 Myr.

Because of the very large escape rates after the dispersal of the proto-planetary disc, planets such as HD 3167 b have lost quickly (within a few hundreds Myr) their primary hydrogen-dominated atmosphere, as supported, e.g., by the non-detection of a hydrogen exosphere around the ultra-short period planet 55 Cnc e

Figure 10. Radial velocity curves of the two signals at 10.7 days (upper panel) and 6.0 days (lower panel) and best-fitting models. The HARPS and HARPS-N RV measurements are plotted with red circles and blue diamonds, respectively, along with their nominal uncertainties.

(Ehrenreich et al. 2012). We remark that this fast escape is not driven by the high-energy stellar flux, but by the high temperature of the lower atmosphere and low planetary gravity. This implies that these planets subsequently developed a secondary, possibly CO₂-dominated, atmosphere while the host star was still young and hence active. This led to the fast escape – this time instead driven by the high-energy stellar flux – also of the secondary atmosphere (Kulikov et al. 2006; Tian 2009), leaving behind the strongly irradiated rocky surface. It is therefore foreseeable that the high surface temperature led then to the formation of magma oceans on the day side (Miguel et al. 2011; Demory et al. 2016), which out-gases and sputters minerals, forming a tenuous atmosphere not too dissimilar from that of Mercury (e.g. Pfleger et al. 2015). Over time lighter elements escape from the atmosphere, leaving behind a possibly extended exosphere composed mostly by heavy refractory elements that could be detected in transit at ultraviolet and optical wavelengths. This picture would be reinforced if the orbit of HD 3167 b had a non-zero eccentricity, as this would lead to tidal heating and thus

Table 3. Low-mass ($M \lesssim 8.4 M_{\oplus}$) planets with RV-determined masses, $\Lambda \lesssim 20$, and bulk densities suggestive of a mostly rocky composition (mean density $\rho_p > 4 \text{ g cm}^{-3}$). Except for HD 3167 b, all values are taken from Cubillos et al. (2017).

Planet	Λ	ρ_p g cm^{-3}
55 Cnc e	15.6	5.14
CoRoT-7 b	15.6	7.97
GJ 1132 b	18.4	5.79
HD 219134 b	20.6	5.94
Kepler-10 b	8.9	6.31
Kepler-78 b	5.5	6.43
Kepler-93 b	18.1	6.82
Kepler-97 b	12.3	5.93
HD 3167 b	15.6	8.00

to a more extended magma ocean. The detection of the exosphere would then enable for the first time the study of the mineralogy of a rocky planet orbiting a star other than the Sun.

With a mass of $M_c = 8.33^{+1.79}_{-1.85} M_{\oplus}$ and a radius of $R_c = 2.740^{+0.106}_{-0.100} R_{\oplus}$ the outer planet HD 3167 c has a mean density of $\rho_b = 2.21^{+0.56}_{-0.53} \text{ g cm}^{-3}$, which is consistent with a composition comprising a solid core surrounded by a thick atmosphere. HD 3167 c joins the small group of low-density mini-Neptunes with precise mass and radius determinations (Fig. 11).

HD 3167 c is expected to have a completely different nature with respect to the inner planet b. Despite the lack of mass measurements, Vanderburg et al. (2016) noticed that HD 3167 c may be a primary target for transmission spectroscopy. The rather large pressure scale height of about 350 km and the brightness of the host star ($V=8.9$ mag) make HD 3167 c an ideal target for transmission spectroscopy observations across a wide range of wavelengths, from the far-ultraviolet to the infrared. One can expect the planet to have a rather large hydrogen-rich cloud made of gas escaping from the planetary upper atmosphere under the effect of the high-energy stellar radiation, similarly to GJ 436 b (Kulow et al. 2014; Ehrenreich et al. 2015). This cloud would be detectable at Ly α during primary transit. Such observations would then provide us with crucial information about the properties of the upper planetary atmosphere and its environment (e.g., stellar wind density and velocity). Observations at longer wavelengths would instead give us the opportunity to study the lower atmosphere and infer its chemical composition and physical properties. HD 3167 c appears to be one of the best candidates to investigate the atmosphere of a low-mass planet.

Figure 11. Mass-radius diagram for well-characterized (5- σ precision level or better) super-Earths and Neptunes. From bottom to top, the solid curves are theoretical models (Zeng et al. 2016) for planets with a composition of 100% iron (brown), 50% silicate and 50% iron (dashed red), 100% silicate (beige), 50% silicate and 50% water (dashed blue), water (light blue). HD 3167 b & HD 3167 c are highlighted with different symbols and colors.

We found evidence for two additional signals with periods of 6.0 and 10.7 days in the HARPS and HARPS-N data. The respective RV semi-amplitude variations are $1.34^{+0.27}_{-0.28} \text{ m s}^{-1}$ and $1.26 \pm 0.25 \text{ m s}^{-1}$. If the signals were caused by two additional orbiting planets, their minimum masses would be $4.24^{+0.87}_{-0.89} M_{\oplus}$ and $3.28 \pm 0.65 M_{\oplus}$, respectively. According to the forecasting model of Chen & Kipping (2017), the two putative planets would have radii of ~ 1.9 and $1.5 R_{\oplus}$, implying that *K2* would have likely detected their transits if the two planets were transiting HD 3167. We searched the light curve for additional transit signals using the DST code of Cabrera et al. (2012), but found none. The null detection of the transits of the two putative additional planets requires that their orbits are inclined by at least 2-3 degrees relative to the orbits of planet b and c. Although a dynamical N-body simulation carried out with *mercury6* (Chambers 1999) shows that such a compact planetary system would be stable for at least 10^7 years, we stress again that our current data set does not allow us to assess whether the two signals are due planets and/or

activity. Additional RV observations are needed to unveil the real nature of the two signals.

We are extremely grateful to the NOT, ESO, TNG staff members for their unique and superb support during the observations. We thank Xavier Bonfils, François Bouchy, Martin Kürster, Jorge Melendez, and Nuno Santos who kindly agreed to exchange HARPS time with us. D.G. would like to acknowledge the inspiring discussions with Conny Konnopke, Nuccio Lanza, Paul Robertson, Rodrigo Diaz, Elisa Delgado Mena, and Aldo Bonomo. D.G. gratefully acknowledges the financial support of the *Programma Giovani Ricercatori – Rita Levi Montalcini – Rientro dei Cervelli* (2012) awarded by the Italian Ministry of Education, Universities and Research (MIUR). M.F. and C.M.P. acknowledge generous support from the Swedish National Space Board. L.F. acknowledges the Austrian Forschungsförderungsgesellschaft FFG project “TAPAS4CHEOPS” P853993. Sz.C. thanks the Hungarian OTKA Grant K113117. H.J.D. and D.N. acknowledge support by grant ESP2015-65712-C5-4-R of

the Spanish Secretary of State for R& D&I (MINECO). This research was supported by the Ministerio de Economía y Competitividad under project FIS2012-31079. J.I.G.H and A.S.M. acknowledge financial support from the Spanish Ministry project MINECO AYA2014-56359-P, and J.I.G.H. also from the Spanish MINECO under the 2013 Ramón y Cajal program MINECO RYC-2013-14875. The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2013-2016) under grant agreement No. 312430 (OPTICON). Based on observations obtained *a)* with the Nordic Optical Telescope (NOT), operated on the island of La Palma jointly by Denmark, Finland, Iceland, Norway, and Sweden, in the Spanish Observatorio del Roque de los Muchachos (ORM) of the

Instituto de Astrofísica de Canarias (IAC); *b)* with the Italian Telescopio Nazionale Galileo (TNG) also operated at the ORM (IAC) on the island of La Palma by the INAF - Fundación Galileo Galilei; *c)* the 3.6m ESO telescope at La Silla Observatory under programs ID 097.C-0948 and 098.C-0860. This paper includes data collected by the *Kepler* mission. Funding for the *Kepler* mission is provided by the NASA Science Mission directorate.

Facilities: Kepler (K2), NOT (FIES), ESO-3.6m (HARPS), TNG (HARPS-N)

Software: IDL, SPECTRUM, SME, FAMA, DDOp, PARAM, pyaneti, exotrending, GLS, Period04, BGLS, DST, mercury6.

Table 4. System parameters.

Parameter	Prior ^a	Value
Model Parameters for HD 3167 b		
Orbital period P_{orb} (day)	$\mathcal{U}[0.9596, 0.9598]$	0.959632 ± 0.000015
Transit epoch T_0 (BJD _{TDB} - 2 450 000)	$\mathcal{U}[7394.3675, 7394.3763]$	$7394.37442^{+0.00060}_{-0.00055}$
Scaled semi-major axis a/R_*	$\mathcal{N}[4.74, 0.18]$	$4.516^{+0.076}_{-0.085}$
Scaled planet radius R_p/R_*	$\mathcal{U}[0, 0.5]$	0.01728 ± 0.00025
Impact parameter, b	$\mathcal{U}[0, 1]$	$0.11^{+0.11}_{-0.08}$
Radial velocity semi-amplitude variation K (m s ⁻¹)	$\mathcal{U}[0, 100]$	4.02 ± 0.31
$\sqrt{e} \sin \omega$	$\mathcal{F}[0]$	0
$\sqrt{e} \cos \omega$	$\mathcal{F}[0]$	0
Derived Parameters for HD 3167 b		
Planet mass M_p (M_{\oplus})	...	5.69 ± 0.44
Planet radius R_p (R_{\oplus})	...	1.574 ± 0.054
Mean density ρ_b (g cm ⁻³)	...	$8.00^{+1.10}_{-0.98}$
Eccentricity e	...	0 (fixed)
Semi-major axis of the planetary orbit a (AU)	...	0.01752 ± 0.00063
Orbit inclination i_p (°)	...	$88.6^{+1.0}_{-1.4}$
Transit duration τ_{14} (hours)	...	1.65 ± 0.03
Equilibrium temperature ^(b) T_{eq} (K)	...	1759 ± 20
Model Parameters for HD 3167 c		
Orbital period P_{orb} (day)	$\mathcal{U}[29.8508, 29.8532]$	$29.84622^{+0.00098}_{-0.00091}$
Transit epoch T_0 (BJD _{TDB} - 2 450 000)	$\mathcal{U}[7394.9763, 7394.9787]$	7394.97831 ± 0.00085
Scaled semi-major axis a/R_*	$\mathcal{N}[46.3, 1.4]$	46.5 ± 1.5
Scaled planet radius R_p/R_*	$\mathcal{U}[0, 0.5]$	$0.03006^{+0.00065}_{-0.00055}$
Impact parameter, b	$\mathcal{U}[0, 1]$	$0.30^{+0.11}_{-0.18}$
Radial velocity semi-amplitude variation K (m s ⁻¹)	$\mathcal{U}[0, 100]$	$1.88^{+0.40}_{-0.42}$
$\sqrt{e} \sin \omega$	$\mathcal{U}[-1, 1]$	$0.00^{+0.17}_{-0.24}$
$\sqrt{e} \cos \omega$	$\mathcal{U}[-1, 1]$	$0.06^{+0.16}_{-0.17}$
Derived Parameters for HD 3167 c		
Planet mass M_p (M_{\oplus})	...	$8.33^{+1.79}_{-1.85}$
Planet radius R_p (R_{\oplus})	...	$2.740^{+0.106}_{-0.100}$
Mean density ρ_c (g cm ⁻³)	...	$2.21^{+0.56}_{-0.53}$
Eccentricity e	...	$0.05^{+0.07}_{-0.04}$
Argument of periastron w_*	...	178^{+134}_{-136}
Semi-major axis of the planetary orbit a (AU)	...	0.1806 ± 0.0080
Orbit inclination i_p (°)	...	89.6 ± 0.2
Transit duration τ_{14} (hours)	...	$4.81^{+0.17}_{-0.09}$
Equilibrium temperature ^(b) T_{eq} (K)	...	548 ± 10
Signal with period of 10.7 days		
Period P_{orb} (days)	$\mathcal{U}[9.4, 12.0]$	$10.77^{+0.15}_{-0.13}$
Radial velocity semi-amplitude variation K (m s ⁻¹)	$\mathcal{U}[0, 100]$	$1.34^{+0.27}_{-0.28}$
Signal with period of 6.0 days		
Period P_{orb} (days)	$\mathcal{U}[5.4, 6.5]$	$5.967^{+0.038}_{-0.035}$
Radial velocity semi-amplitude variation K (m s ⁻¹)	$\mathcal{U}[0, 100]$	1.26 ± 0.25
Other Parameters		
Systemic velocity γ_{HARPS} (km s ⁻¹)	$\mathcal{U}[19.4183, 19.6317]$	19.52311 ± 0.00029
Systemic velocity $\gamma_{\text{HARPS-N}}$ (km s ⁻¹)	$\mathcal{U}[19.4086, 19.6197]$	19.51471 ± 0.00036
RV jitter term σ_{HARPS} (m s ⁻¹)	$\mathcal{U}[0, 10]$	$1.44^{+0.24}_{-0.21}$
RV jitter term $\sigma_{\text{HARPS-N}}$ (m s ⁻¹)	$\mathcal{U}[0, 10]$	$0.95^{+0.24}_{-0.20}$
Parameterized limb-darkening coefficient q_1	$\mathcal{U}[0, 1]$	$0.34^{+0.26}_{-0.15}$
Parameterized limb-darkening coefficient q_2	$\mathcal{U}[0, 1]$	$0.47^{+0.29}_{-0.22}$
Linear limb-darkening coefficient u_1	...	$0.54^{+0.15}_{-0.17}$
Quadratic limb-darkening coefficient u_2	...	$0.04^{+0.35}_{-0.27}$

^a $\mathcal{U}[a, b]$ refers to uniform priors between a and b , $\mathcal{N}[a, b]$ to Gaussian priors with mean a and standard deviation b , and $\mathcal{F}[a]$ to a fixed a value.^b Assuming zero albedo.
