ABSTRACT

Objectives To analyse the trends of amenable mortality rates (AMRs) in children over the period 2001–2015.

Design Time trend analysis.

Setting Thirty-four member countries of the Organisation for Economic Co-operation and Development (OECD).

Participants Midyear estimates of the resident population aged ≤ 14 years.

Primary and secondary outcome measures Using data from the WHO Mortality Database and Nolte and McKee's list, AMRs were calculated as the annual number of deaths over the population/100 000 inhabitants. The rates were stratified by age groups (<1 , 1–4, 5–9 and 10–14 years). All data were summarised by presenting the average rates for the years 2001/2005, 2006/2010 and 2011/2015.

Results There was a significant decline in children's AMRs in the <1 year group in all 34 OECD countries from 2001/2005 to 2006/2010 (332.78 to 295.17/100 000; % Δ –11.30%; 95% CI –18.75% to –3.85%) and from 2006/2010 to 2011/2015 (295.17 to 240.22/100 000; % Δ –18.62%; 95% CI –26.53% to –10.70%) and a slow decline in the other age classes. The only cause of death that was significantly reduced was conditions originating in the early neonatal period for the <1 year group. The age-specific distribution of causes of death did not vary significantly over the study period.

Conclusions The low decline in amenable mortality rates for children aged ≥ 1 year, the large variation in amenable mortality rates across countries and the insufficient success in reducing mortality from all causes suggest that the health system should increase its efforts to enhance child survival. Promoting models of comanagement between primary care and subspecialty services, encouraging high-quality healthcare and knowledge, financing universal access to healthcare and adopting best practice guidelines might help reduce amenable child mortality.

INTRODUCTION

The health of children and adolescents is an important goal for every society, both because

Strengths and limitations of this study

- This is the first study to analyse trends in child mortality amenable to healthcare.
- Thirty-four Organisation for Economic Co-operation and Development countries were included in the analyses to provide a thorough depiction of amenable child mortality in high-income economies.
- Mortality was not disaggregated by ethnicity or socioeconomic characteristics.
- Making international comparisons is difficult due to variations in birth registration laws and death certification practices.

they are vulnerable and because diseases can affect their quality of life. Measures for protecting and improving children's and adolescents' health will yield economic and social benefits beyond improved health outcomes. Indeed, young people have the potential to affect the health of future populations as well as global economic development unless timely and effective strategies are put into place.^{1 2}

For the adoption of new strategies and the planning of interventions, information on the leading causes of death is essential. Many studies have analysed the mortality rates and have identified the main causes of death of children in specific countries³ or areas.⁴ Studies have demonstrated that many different factors contribute to child and adolescent mortality,⁵ including biological and psychosocial,⁶ socioeconomic status,^{7 8} environmental and behavioural factors.⁹ In the landscape described, the mortality burden conditioned by the performance of the healthcare system has not been well

investigated. Although there is no indicator that is able to compressively reflect the performance of the healthcare system, a suitable measurement seems to be the concept of amenable mortality.

Amenable mortality is defined as deaths that, in the light of medical knowledge and technology at the time of death, could be prevented by timely access to good quality care. The concept of mortality amenable to healthcare finds its origins in the evolution of the concept of avoidable mortality, developed by Rutstein *et al.*¹⁰, who created a list of conditions that were considered either treatable or preventable through healthcare services given the current medical knowledge and technology. Rutstein was the first to introduce the term amenable mortality, differentiating between causes that are responsive to medical intervention through treatment and secondary/tertiary prevention actions (eg, cervical cancer, hypertensive disease or appendicitis) and causes responsive to actions beyond healthcare services (preventable conditions such as lung cancer and liver cirrhosis).

In recent years, the concept of amenable mortality has been used as a potential indicator of the performance of healthcare systems by several countries. The amenable mortality has been chosen as indicator in the UK National Health Service Outcomes Framework for 2011–2012¹¹ and in *Australian and New Zealand Atlas of Avoidable Mortality 1997–2001*¹² or in *European Community Atlas of ‘Avoidable Death’*.¹³ Amenable mortality indicators have also been used to report on spatial and temporal distributions and variations in health system performance across countries,^{14–20} as well as across subnational entities,^{12 21–25} socioeconomic status, ethnic groups and sex.^{14 24 26 27} Most of these studies did not assess amenable mortality across ages in different populations and did not focus on child and adolescent age classes.

According to the WHO, an estimated 6.3 million children under the age of 15 years died in 2017 (117 000 in the Organisation for Economic Co-operation and Development (OECD) region). A total of 5.4 million of these children were under the age of 5 years, and 2.5 million died within the first month of life. More than half of these early child deaths were due to conditions that could be prevented or treated with access to simple, affordable interventions and were, consequently, amenable.²

The purpose of this study was to analyse the trends of amenable child mortality rates in 34 OECD countries from 2001 to 2015 and to evaluate the pattern across age classes.

MATERIALS AND METHODS

This descriptive study was conducted using secondary data from 34 OECD countries during the period from 2001 to 2015. Mexico and Turkey, although members of the OECD, were not included in the analysis because these countries are not listed among high-income economies in the World Development Indicators dataset (gross national income per capita \geq \$12 056 for fiscal year 2019)²⁸

and had limited data availability. The mortality and population data came from the WHO Mortality Database,²⁹ which comprises deaths registered in national vital registration systems, with the underlying causes of death coded according to the International Classification of Diseases; no permission is required from the WHO if data are used for non-commercial purposes. If reference populations were not available in the WHO Mortality Database, the data were extracted from UN data.³⁰ The country-level data availability is presented in online supplementary file 1.

The causes of death amenable to healthcare were selected by means of the list proposed by Nolte and McKee^{14 31} and used in a working paper by the OECD to generate estimates of amenable mortality for 31 countries.¹⁵ This list includes a selected number of conditions that are treatable based on the clinical effectiveness of existing medical interventions. The age limit for amenable deaths is set at 75 years for most conditions, such as cancer and cardiovascular diseases, but the age limit for some diseases (ie, whooping cough, measles, intestinal infections and respiratory diseases other than pneumonia/influenza) is set at 14 (see online supplementary file 2 for Nolte and McKee's full list). The aggregation of the causes of death operated in the WHO Mortality Database prevents the use of the list of amenable deaths currently adopted by Eurostat.³²

For each country, the amenable mortality rates were calculated as the annual number of deaths in the population aged 0–14 years per 100 000 inhabitants. The rates were stratified by the age groups adopted in the WHO Mortality Database (<1, 1–4, 5–9 and 10–14 years) and by the 33 disease categories defined by Gay *et al.*¹⁵ Due to the instability in the estimates of the annual amenable mortality rates, especially for small population countries, all data were summarised by presenting the average rates for the years 2001/2005, 2006/2010 and 2011/2015. The statistical significance of the percentage changes between these time periods was assessed by using the formula suggested by Hildebrandt *et al.*³³ Data interpretation focused on the countries that showed significant percentage changes over the entire study period (ie, both between 2001/2005 and 2006/2010 and between 2006/2010 and 2011/2015). Differences in the ranking of age-specific causes of death between time periods were evaluated with the Friedman test.

All data were analysed using the Stata software package, V.15. The significance level was set at .05.

Ethics statement

This descriptive study involved aggregate data that exist in the public domain, where it is not possible to identify individuals from the information provided. For this reason, this research did not require ethical approval.

Patient and public involvement

Patients and the public were not involved in the design or planning of the study.

RESULTS

All-cause amenable child mortality rates

The results of the trend analyses conducted over the 5-year periods 2001/2005, 2006/2010 and 2011/2015 are presented in [figure 1](#) and in online supplementary file 3. The amenable mortality rate of the OECD population with <1 year dropped significantly from 2001/2005 to 2006/2010 (332.78 to 295.17 per 100 000, % Δ =-11.3%) and from 2006/2010 to 2011/2015 (295.17 to 240.22 per 100 000, % Δ =-18.6%). Contrary to the OECD rate of children aged <1 year, in the population aged \geq 1 year, the overall OECD rate did not decrease significantly. From 2001/2005 to 2006/2010 and from 2006/2010 to 2011/2015, the mortality rates decreased by 13.4% and 13.0%, respectively, in the 1–4 years age group; by 11.9% and 11.3% in the 5–9 years age group; and by 13.5% and 13.1% for the 10–14 years age group. In 2011/2015, the OECD rate was 4.73 per 100 000 for the 1–4 years age group, 2.02 per 100 000 for the 5–9 years age group and 2.16 per 100 000 for the 10–14 years age group.

Cause-specific child mortality rates

When we examined the distribution of cause-specific mortality rates across multiple age groups and study periods, no statistically significant variations in the OECD population were found. The only exception was a significant decrease in deaths in the first year of life for conditions originating in the early neonatal period (2001/2005 to 2006/2010: 266.3 to 239.8 per 100 000, % Δ =-9.9%; 2006/2010 to 2011/2015: 239.8 to 193.8 per 100 000, % Δ =-19.2%) (see online supplementary file 4).

Globally, for the years 2001/2005, 2006/2010 and 2011/2015, there were no significant differences in the age-specific percentage distribution of causes of death (<1 year: Friedman test (p)=0.955 (0.372); 1–4 years: 0.864 (0.607); 5–9 years: 0.470 (0.740); 10–14 years: 1.773 (0.398)). As shown in [table 1](#), the three leading causes of death by age groups over the 15 year study period were the following: conditions originating in the early neonatal period, congenital cardiovascular anomalies and pneumonia for children aged <1 year and congenital cardiovascular anomalies, leukaemia and respiratory diseases (excluding pneumonia/influenza) for all other age groups.

Country-specific amenable child mortality rates

As shown in [figure 1](#) and online supplementary file 3, the amenable mortality rate for the population aged <1 year dropped significantly over the entire study period in 15 countries (USA, Israel, Japan, South Korea, Czechia, Estonia, Germany, Italy, Latvia, Hungary, Poland, Spain, Austria, UK and Australia). In addition to the decrease in conditions originating in the early neonatal period, other causes contributed to a significant reduction in mortality for some of these countries: septicaemia, pneumonia and nephritis/nephrosis in the USA, septicaemia in Poland and congenital cardiovascular anomalies in Japan and Spain. See online supplementary file 4 for

country-specific and cause-specific mortality rates in the <1 year population.

Although the overall OECD rate did not decrease significantly in the population aged \geq 1 year, some country-specific data exhibited significant trends ([figure 1](#)). However, no country showed a significant linear decline in mortality over the entire study period for all age groups ([figure 1](#)).

DISCUSSION

In this time trend analysis, we found a significant decline in amenable child mortality rates for the <1 year age group in the 34 OECD countries between 2001/2005 and 2011/2015 and a slow decline in the other age groups. These results confirm the trend shown by previous studies conducted on six OECD countries that had been selected to provide a variety of forms of healthcare delivery between 1956 and 1980²¹ and highlight that policies to reduce amenable mortality rates are still needed, even in settings where the quality of medical services and resources is high.

These results are driven by the fact that the only significantly reduced cause of death was conditions originating in the early neonatal period in the <1 year group. Surprisingly, the decline was not more pronounced among countries with higher mortality in 2001/2005, indicating that continued gains in child survival occurred both in low-mortality and high-mortality countries. The most representative countries are Japan, which showed an improvement in its performance despite starting from low values in 2001/2005, and Hungary and the USA, which showed high amenable mortality rates in 2001/2005.

The results concerning country-specific amenable child mortality rates showed that the reductions in the age-specific rates were not evenly distributed across OECD countries. There was not a single cause for which the age-specific mortality rates declined in the countries studied, and the success in reducing mortality rates was not consistent for all causes. These achievements corroborate another of our results, highlighting that the causal distribution of the age-specific mortality rates did not vary over the period examined and that, namely, the conditions originating in the early neonatal period, congenital cardiovascular anomalies, pneumonia, leukaemia and all respiratory diseases (excluding pneumonia/influenza) were consistently top ranked. Because these are the main causes related to chronic disorders and pathologies that require acute care delivered quickly, our results suggest that the models of care for children should be revised. Sidebotham⁵ has argued that child diseases might broadly be divided into chronic (eg, leukaemia) and acute diseases (eg, pneumonia) and that a single model cannot be proposed but each needs a different, although interconnected, health system solution.

Wolfe³⁴ highlights that the presence of children with chronic disorders requires substantial changes from a hospital-centric model to a model in which primary care

OECD, Organisation for Economic Co-operation and Development.

and secondary care providers and public health services work closely together. Models of comanagement are essential to promote ongoing communication and coordination between primary care and subspecialty services. It would be inefficient for subspecialists to provide primary care, and ineffective for primary care providers to attempt to stay abreast of the latest therapies for chronic diseases. Because the majority of chronic illness care is performed within the primary care setting and because primary care physicians spend a considerable amount of time treating chronic illness, primary care should play a central role in the overall coordination and continuity of people's care providing greater access to specialists and more timely follow-up care after emergency room visits.³⁵ The few studies evaluating this new approach to work showed an improvement in child survival,^{36–38} and thus traced a possible path to improve amenable mortality from chronic diseases.

Sidebotham and Mackenbach judge as determinants of amenable mortality in acute diseases the universal access to healthcare and the presence of professionals with appropriate training.^{5 18} The relevance of access may at least partially explain our results in some countries. For example, in Chile, where the mortality rate of pneumonia was consistently high for the <1 year group, the healthcare system replicates class inequalities. Studies have identified and tracked several important inequalities in the burden of infant mortality for infectious diseases by socioeconomic level in Chile, showing that this gap is discriminatory because disadvantaged households underuse healthcare services (due to social or economic exclusion).^{39 40} In Slovakia, where also the mortality rate of pneumonia was high for the <1 year group, social health insurance system formally covers all residents and has a benefit package that all insurance companies must provide for their insured. In theory, the insurance system is thus designed to provide everybody with the same

benefit package, regardless of their health status, ability to pay or place of residence. In practice, coverage varies across the country, mainly because the supply of human resources (especially specialists and general practitioners (GPs)) is not adequate in all regions and districts, and sometimes providers are simply not available.⁴¹

The access to healthcare professionals with adequate training looks at the models of first contact between patients and clinicians and on their expertise. Although an international debate is open on the best pattern of paediatric primary care among a paediatrician-based system, a combined system or a system based on GPs/family doctors,⁴² some authors highlight the importance of primary care paediatricians, especially because primary care paediatricians who look after children are likely to have more professional training and competencies than GPs, who often, receiving an insufficient or not existing or non-mandatory training, do not have capabilities to diagnose and treat a child in effective times.^{34 43 44}

Supported by the specialised literature, the availability of high-quality healthcare and knowledge and the use of best practice guidelines are also determinants of amenable mortality.^{5 18} These determinants provide one possible explanation for our results, in particular for the reduction in mortality by conditions originating in the early neonatal period. Several lines of evidence support the hypothesis that neonatal intensive care has resulted in decreased mortality. Marked declines in neonatal and infant mortality rates are coincident with the introduction and progressive development of neonatal intensive care^{45 46} and with specific neonatal intensive therapeutic improvements.^{47–50} The second line of evidence regarding the effect of neonatal intensive care on infant mortality is the observation that low birthweight infants born in hospitals with tertiary-level neonatal intensive care units have lower mortality rates than infants born in hospitals without such units.^{51 52} Finally, a third line of evidence

referring to improving high-risk obstetric care has been associated with decreases in neonatal mortality.^{46 53}

Variations in child mortality exist even in countries where high-quality healthcare is available. Part of this variation may be due to a failure in implementing treatment protocols or evidence-based best practices tailored with the local conditions. This suggestion may provide some explanation of the mortality decrease in some countries, such as Hungary and Japan, which have supported the introduction of evidence-based protocols on routine newborn care and have trained nursery staff members on the protocols.^{54 55}

Our study has the same limitations as all studies that use secondary data. It is undeniable that international variations in birth registration laws and practices and the process of death certification have the potential to bias the international comparisons of child mortality. Additionally, international comparisons of mortality rates are confounded by the various ways in which countries classify preterm infants near the threshold of viability.⁵⁶⁻⁵⁸ Considering these issues, our study only evaluates the trend of amenable mortality rates, and a comparison analysis was not performed. Also, although much of the literature assessing the contribution of healthcare to health focuses on mortality data, data on children may be of limited value because the number of deaths is small, making interpretation difficult. However, we believe that the small numbers were mitigated by the fact that our study analysed the rates and trajectories of multiple countries over a 15-year time period. Another limitation is that our analysis did not account for mortality disparities within countries that were attributable to ethnicity, race, socioeconomic status or geographic residence, since our data sources did not include this information. Evidence from the USA, for example, showed higher levels of amenable mortality among people disadvantaged in terms of race or socioeconomic status.^{59 60} Considering that the perinatal mortality of the USA has a prevailing effect on premature births and that striking racial disparities persist, with African-Americans exhibiting higher rates of preterm delivery than any other major racial/ethnic group,⁶¹ potentially large variations within populations may be concealed. Lastly, our study is based on the definition of amenable death in its original sense of mortality responsive to medical intervention through treatment, although several countries, such as UK, Canada and Australia, have broadened definitions for their avoidable mortality indicators to include deaths from conditions avoidable through primary prevention. This broadened definition suggests that the models of care for children should be revised and that policies must be adopted in order to prevent specific causes of death before the point of reaching the healthcare system. These policies include population health interventions such as the obligation of physical activity during adolescence in schools or the taxation of tobacco and sugar-sweetened beverages.

Some preliminary conclusions can be drawn from this study. Over the 15-year period from 2001 to 2015,

the amenable mortality rate in <1 year olds progressively declined in most OECD countries. Second, OECD countries had success in reducing mortality from conditions originating in the early neonatal period. Lastly, the low decline in amenable mortality rates for children aged ≥ 1 year, the high variation in amenable mortality rates across countries and the insufficient success in reducing mortality from all causes suggest that the health system should increase its efforts to improve health outcomes for children.
