ABSTRACT

Background: Almost all of the epidural hemangiomas reported are cavernous hemangiomas. Purely extradural spinal capillary hemangiomas are very rare. Capillary hemangiomas are hamartomatous malformations that result from proliferations of vascular endothelial cells. Only ten cases have been reported in the English literature, treated with surgical excision. Case description: A case of a dorsal extradural spinal capillary hemangioma is described. A total surgical removal has been performed after spinal angiography and embolization. Complete surgical removal should always be the goal in these lesions. Embolization did not show to reduce bleeding during the surgical procedure in this case.

Introduction

Vascular lesions of the spine are uncommon pathologies, mostly challenging to treat especially for surgeons. Among them, purely extradural hemangiomas are unusual. Generally, most exclusively epidural hemangiomas reported are cavernous hemangiomas.¹⁻⁴ Hasan et al. reported that cavernous hemangiomas were found in 11% of spines on autopsy.⁵ Conversely, purely extradural spinal capillary hemangiomas are very rare. Capillary hemangiomas are ubiquitous hamartomatous malformations that result from proliferations of vascular endothelial cells.⁶ Only ten cases have been reported in the English literature,⁷ and among them only a case has occurred in childhood.⁸

In this report we described a case of a dorsal extradural spinal capillary hemangioma and reviewed the literature. This work has been reported in line with the SCARE criteria.⁹

Case presentation

This is a case of a 52-years-old woman. In her past history she referred psoriasis and removal of a benign breast tumor. During the last 5 years a subtle misdiagnosed onset of a paretic-spastic gate occurred, until the situation progressively significantly impaired her quality of life. Then a Magnetic Resonance Imaging (MRI) of the cervico-dorso-lumbar spine showed an epidural lesion at the level of D6-D9 with extension into the left
D7 foramen (Figure 1). Significantly flow voids was seen on T2, indicating the probably highly vascular origin of the lesion. The lesion enhanced intensely. Spinal cord was severely dislocated anteriorly, with iperintense cord signal as a sign of mielopathy.

On neurological examination, she had bilateral lower limbs weakness ranging from 3/5 proximally to 4/-5 distally. She had hypoestesia of light touch from D7 level, but not of temperature. 68 Her gait was wide based. She complained urinary incontinence and dorsalgia. Babinski sign was observed bilaterally. Clonus was observed at left. Her reflexes were exaggerated at lower limbs. She was not able to walk autonomously.

The patient underwent a CT scan that showed that there was no bone involvement of vertebrae. The case was discussed between neurosurgeons and neuroradiologists. Because of the high suspect of a vascular origin of the lesion, the patient underwent a spinal angiography. The target was to better understand the nature of the lesion and, if possible, to investigate the possibility of a preliminary treatment before surgical procedure. The catheterism showed the presence of an abounding pathological circulation feeded by the left D6 intercostal artery. The branch involved in the supply of the lesion was occluded with polyvinyl alcohol particles, obtaining a complete radiological devascularization (Figure 2). The following day the patient underwent surgical procedure. A D6-D9 laminotomy with ultrasonic aspirator and following laminoplasty was performed (Figure 3(A)). The lesion appeared as a reddish epidural mass that was resected en bloc. It was soft and hemorrhagic despite the embolization (Figure 3(B)).

Postoperatively she rapidly improved and was able to walk autonomously after two weeks. Twelve months after rehabilitation she referred no more dorsalgia and improvement of sphincteric control. Only residual hypoesthesia remained. Histopathology analysis revealed the final diagnosis: capillary hemangioma (Figure 4(A) and (B)).

**Discussion**

Capillary hemangiomas are composed of vascular endothelial cells and belonged to a group of hamartomatous lesions classified according to the predominant type of vascular channel observed histologically: capillary, cavernous, arterio-venous or venous.8

Among them, most exclusively epidural hemangiomas described in literature were cavernous hemangiomas.1,3 Histologically, cavernous malformations showed a large number of sinusoidal channels spread in collagenous tissue.3 On the contrary, capillary hemangiomas are composed of thin and irregular capillary sized vessels in a low attenuating fibrosis and lobular architecture.10,11 Moreover, they showed low mitotic activity, positive reactions for CD31 and CD34, negative reactions for S100 and epithelial membrane antigen.1

In the literature, only ten cases of purely epidural capillary hemangioma have been reported (Table 1). Among them, there is only a case presented in childhood. The others occurred in adults over the age of 40. Of these capillary hemangiomas, seven were in the thoracic region and two in the lumbar region.

Generally, central nervous system cavernous hemangiomas can show sign of hemorrages of various ages.8 Epidural hemangiomas, on the contrary, present usually with compressive myelopathy or radicular pain – depending on the localization – and back pain. There are some reports showing hemorragic presentations of cavernous epidural hemangiomas,3 but in none of the cases of capillary hemangiomas described there was sign of previous hemorrhage. In our case, actually, the patient clinically presented with progressive paraparesis, sphincteric incontinence and dorsalgia due to mechanical compression, misdiagnosed for 5 years.

The most important diagnostic exam is without any doubt the MRI, although radiologic aspects are non-specific. These lesions are generally well-circumscribed and a dumbbell shape can be observed, though this could be also an imaging pattern of tumors like meningiomas and neuromas.8
If surgeon has not an acute compression to deal with, an angiography is recommended. In this case, actually, because of the long duration of neurological history, the patient underwent a medullary angiography. After consultation with neuroradiologists, the lesion was embolized trying to avoid an exceeding bleeding during the following surgical procedure. The lesion was completely removed en bloc. There are no reports describing pre-operative embolization in extradural capillary hemangiomas. Despite the treatment, bleeding during surgery was remarkable and embolization did not bring any advantage. Thus some considerations could be made: a radiological embolization of the feeder, or its early surgical cauterization, as for artero-venous malformations of brain and spine does not necessarily results in a devascularization because of compensatory collateral circulation. Moreover, it could potentially worsen the compression in the spinal canal. Finally, it is a procedure that carries its own potential risks and morbidity.

A laminoplasty was performed: the cervical canal was opened with a bilateral laminotomy by using a ultrasonic dissector. Laminoplasty was preferred in order to obtain a clear exposure of the spinal canal, to better protect the spinal cord after the excision and to allow a following stabilization with screws if necessary. The treatment of choice for capillary hemangiomas is a complete surgical removal, as total resection is the cure of this benign lesion, although it could be difficult to achieve in its frequent foraminal extension. Some authors recommend that surgery should be performed even in the absence of neurological symptoms if there is a cord compression on MRI, or at least a close follow-up.7

**Conclusion**

Capillary Hemangiomas are very rare in their purely extradural localization. Neurological symptoms are due to mechanical compression. MRI is the imaging tool of choice. Medullary angiography can usually confirm the vascular origin of the lesion. Embolization did not show to reduce bleeding during the surgical procedure in the case described. Complete surgical removal should be the goal.

**Ethics statement:**

The patient has consented the submission of this case report to the journal.

**Conflict of interest statement:**

The corresponding author certifies that there is no actual or potential conflict of interest in relation to this article.

**Figure legends**

Figure 1. MRI appearance of an epidural capillary hemangioma: hypointense on T1-weighted, hyperintense on T2 weighted and enhancement with gadolinium.

Figure 2. Angiogram of the lesion, before (left) and after (right) the embolization with radiological disappearance of its vascular pattern. Nevertheless bleeding during surgery was remarkable.

Figure 3. (A) Laminoplasty after hemangioma removal. (B) The lesion resected en bloc.
Figure 4. (A) Low power (100×) image showing the lobular architecture with numerous capillary sized vessels in the monotonous hypocellular fibrous stroma. (B) Medium power (200×) image showing the single layer of benign flattened endothelial cells.
