35 Abstract

The present study evaluated the effect of different levels of energy restriction on metabolic 36 parameters in obese ponies. Relative weight changes, markers of lipid metabolism, and 37 oxidant/antioxidant balance were monitored. Eighteen obese (body condition score>7) Shetland 38 39 ponies were studied over a 23.5 week trial, divided into 3 periods. First a 4 week adaptation period in which each animal was fed 100% of their maintenance energy requirements needed to maintain 40 stable obese body weight (MERob). Then a 16.5 weeks weight loss period in which ponies were 41 assigned to receive either 100% (control group, CONTROL), 80% (slow weight loss group, SLOW) 42 or 60% (rapid weight loss group, RAPID) of their MERob. During the 3 week end phase period all 43 animals were again fed 100% of their MERob. Relative weight loss was higher in RAPID 44 45 (P<0.001) compared to SLOW. No linear relationship was found as a doubling in caloric restriction was accompanied with a tripling in weight loss. Relative weight gain afterwards in the end phase 46 47 period was higher in RAPID (P<0.001) compared to SLOW and CONTROL. During the weight 48 loss period, triacylglycerol and non-esterified fatty acids levels were highest in RAPID, as were α tocopherol and ferric reducing ability of plasma. After 8 weeks of weight loss, advanced oxidation 49 protein products were higher in RAPID compared to SLOW and CONTROL (P<0.001). In 50 conclusion, the level of energy restriction influences the extent of changes in oxidant/antioxidant 51 balance. Practically, more severe energy restriction regimens may be associated with a greater 52 regain of weight post restriction. 53

54 Introduction

With a prevalence of 19 to 45 %, overweight and obese horses have become a major welfare problem in modern horse management in developed countries^(1,2). Obesity is associated in particular with an increased risk of insulin resistance as well as laminitis⁽³⁻⁵⁾. Whilst preventing animals from becoming obese is the preferred route, given the current scale of this problem, effective safe weight loss protocols are required especially for the laminitic pony where increased physical activity may be contra-indicated⁽⁶⁾. Recently, several equine studies have been published looking at the efficacy of weight loss programmes with and without exercise⁽⁷⁻⁹⁾.

Most recently, the concept of weight loss resistance in the horse has been highlighted with the suggestion that whereas some animals may respond to moderate caloric restriction (food intake restricted to 1.25% as dry matter intake (DMI) of actual body mass (BM)) with appropriate levels of weight loss, others may require more marked levels of reduction (1.00% of BM as daily DMI)⁽⁹⁾. However, it is well known that too severe caloric restriction in obese equidae may lead to hyperlipemia⁽¹⁰⁾. In dogs, the degree of caloric restriction also affected long term body weight change. A higher caloric restriction resulted initially in a greater level of weight loss, but when
returned to a 'normal' diet, the 'rebound' weight gain was higher⁽¹¹⁾. This rebound weight gain was
significantly correlated with the amount of lost body weight and the caloric restriction level⁽¹¹⁾. This
effect was also seen in human patients⁽¹²⁾.

In obese humans, oxidative stress is related to chronic disease (e.g. hypertension, diabetes, 72 metabolic syndrome, polycystic ovarian syndrome, liver disease)⁽¹³⁾. Human obesity increases the 73 level of oxidative stress⁽¹⁴⁾ as indicated by increased lipid peroxidation^(15,16) and decreased systemic 74 antioxidants^(13,16-19). Moreover, the altered oxidant-antioxidant status in obese children was 75 reversible by a dietary restriction-weight loss program^(19,20). Restricted caloric intake reduced 76 oxidative damage to proteins, lipids, and DNA in rodents⁽²¹⁾. It also reduced serum advanced 77 glycation end products formation in healthy and overweight or obese human adults⁽²²⁾. In horses, 78 79 oxidative stress has been associated with several disorders such as recurrent airway obstruction^(23,24), joint disease⁽²⁵⁾, neurological disorders⁽²⁶⁾ and perfusion related disorders⁽²⁷⁾. 80 Laminitis can be classified under this last condition. Equine digital laminea have relatively limited 81 SOD capacity, which can make this tissue more susceptible to damage by reactive oxygen species, 82 such as superoxide anion⁽²⁸⁾. Insulin induced laminitis on the other hand has been associated with 83 the accumulation of advanced glycation end products in the lamellar tissues of horses⁽²⁹⁾. Insulin 84 resistance, together with general obesity, regional accumulations of fat tissue and hyperleptineamia 85 are features of equine metabolic syndrome (EMS)⁽⁴⁾. Higher plasma advanced glycation end product 86 concentrations, more specific pentosidine, were found in ponies exhibiting clinical features of EMS 87 and with a recent history of or current episode of laminitis compared with ponies with no recent 88 history of laminitis⁽³⁰⁾. Lower antioxidant capacity, by means of by means of decreased erythrocyte 89 glutathione peroxidase activities, has also been described in obese horses⁽³¹⁾. 90

In equidae, little is known about the effect of weight reduction programmes on the oxidantantioxidant status. Therefore, the aim of the present study was to test the effect of different levels of energy restriction on weight loss and subsequent rebound weight gain, and oxidant/antioxidant balance. It was hypothesised that greater energy restriction would result in more weight loss, accompanied with an improved oxidant/antioxidant balance (increased antioxidant defence and lowered oxidant markers). A second hypothesis was that a more rapid weight loss would be accompanied by a greater weight gain when the ponies were fed again at maintenance energy levels.

98 Materials and methods

99 Animals and husbandry

Eighteen obese (body condition score, BCS $\geq 7/9$)⁽³²⁾ Shetland geldings, aged 9.3 \pm 3.9 years (Table 100 1) were studied over a 23.5 week period (August to January). Only animals in good health and 101 dental status were recruited. No prior history of clinical lameness and laminitis was reported for the 102 ponies involved in the present study. No evidence of hyperinsulinemia was noticed at the start and 103 104 throughout the study. The aim of the presents study was not to evaluate the effect of weight loss on glucose and insulin dynamics, therefore, no glucose tolerance tests were implemented. Routine foot 105 care, vaccination and anthelmintic treatments were undertaken before and, if necessary, during the 106 study. Ponies were housed individually during feeding times in 9 indoor boxes of 9m² or in 9 stalls 107 with an indoor and outdoor unit with a combined area of 13.83m². During the rest of the day, ponies 108 were group-housed in a large barn (inner part: 285m², outer part: 275.5m²). On the floor of the barn, 109 110 rubber mats were placed as bedding material. Water was freely available at all times. The study design was approved by the Ethical Committee of the Faculty of Veterinary Medicine, Ghent 111 University (EC2011/098). All ponies remained healthy and no clinical abnormalities were seen. 112

113 Study design

For a month before the start of the adaptation period, the ponies were given *ad libitum* access to the same low energy hay (Table 2) as would be used during the trial. The ponies also received the same vitamin, protein and mineral supplement (Spillers Gro'N Win®, MARS Horsecare) (Table 3) as fed during the trial. The trial itself was divided into 3 periods: an adaptation period of 4 weeks, a weight loss period of 16.5 weeks, and an end phase period of 3 weeks (Table 3).

During the adaption period, the maintenance energy requirements to maintain stable obese body 119 weight (MERob) were determined for each pony individually. Initially, the low energy hay was fed 120 to provide 121% of maintenance net energy requirements as described by Van Weyenberg et al.⁽³³⁾, 121 based on their actual obese body weight (BW). Ponies also received the protein/vitamin/mineral 122 123 balancer at approximately 1.32 g/kg ideal BW/day. This amount of balancer is similar to 12.5% of their maintenance digestible energy requirements for (estimated) ideal body weight (according to 124 NRC recommendations)⁽³⁴⁾ and corrects for all possible vitamin and protein insufficiencies from the 125 hay diet. During the adaption period, BW was measured 3 times a week and based on these 126 measurements, changes in the amount of hay fed were made to maintain a stable obese body weight. 127 At the end of the last week of the adaption period individual MERob (100% iMERob) could be 128 129 determined for each animal.

In the following weight loss period, ponies were divided into 3 groups stratified for balanceddistribution according to age and BCS. Age was taken into account as plasma protein glycation,

more specific pentosidine, increase in horses during aging⁽³⁵⁾. The control group (CONTROL)
received 100% of their iMERob during this entire period. The 'slow' weight loss group (SLOW)
was offered 80% of their iMERob. The 'rapid' weight loss group (RAPID) was restricted to 60% of
their iMERob.

During the end phase period, all animals were again fed 100% of their original iMERob determinedat the end of the adaptation period for another 3 weeks.

Throughout the study, daily hay rations were equally divided between 2 meals (09:00 am and 03:00 pm) and offered from small holed haylage nets in order to maximise the time spent foraging. The
balancer was only offered during the morning feeding.

141 *Determination of body mass*

During the adaptation period and the end phase period, ponies were weighed (\pm 0.1 kg) 3 times a week between 08.00 and 09.00 am. During the weight loss period, ponies were weighed between 08.00 and 09.00 am on the first day of each week. All measurements were carried out on a calibrated scale (error \pm 0.01kg) (Bascules Robbe, serial number 137, Torhout, Belgium).

146 Blood sampling

Blood sampling was undertaken in the early morning prior to feeding. During the weight loss 147 period, blood samples were drawn every week on Monday into Vacuette® tubes (Z Serum Clot 148 Activator, 4 ml) in order to monitor triacylglycerol (TAG) and non-esterified fatty acids (NEFA). In 149 weeks 1, 5, 9, 13, 17, 21.5, and 24.5, blood samples were also taken for the analysis of glucose 150 (Vacuette® tube, FX Sodium Fluoride/Potassium oxalate, 2 ml), and insulin, ferric reducing ability 151 of plasma (FRAP), thiobarbituric reactive substances (TBARS), superoxide dismutase (SOD), α-152 153 tocopherol, and leptin (Vacuette® tube, Z Serum Clot Activator, 9 ml). Every 8 weeks, heparin plasma (Vacuette® tube, LH Lithium Heparin, 9 ml) was collected for subsequent analysis of 154 protein, advanced glycation end products (pentosidine and carboxymethyllysine), and advanced 155 oxidation protein products (AOPPs). The blood samples were stored at 4°C until centrifugation at 156 3000 x g for 10 minutes. Subsequently, plasma and serum samples were stored at -20°C until 157 analysis. 158

159 Plasma glucose and insulin concentrations

Fasting plasma glucose concentration was measured by enzymatic colorimetric assay method (REF
3L82-21 and 3L82-41) using an Abbott Architect C16000 autoanalyzer (Abbott Diagnostic

162 Laboratories, Chicago, IL, USA) with the hexokinase-G6PDH method^(36,37).

- 163 Serum insulin concentrations were measured immunoradiometrically^(33,37) (insulin IRMA Ref 5251,
- 164 Diasource Europe S.A., Nivelles, Belgium). An implementation validation procedure has previously
- 165 briefly been described by Bruynsteen et al.⁽³⁷⁾.
- 166 *Markers of lipid metabolism*

Serum TAG was measured enzymatically (REF 7D74 304706/R02) using an Abbott Architect
C16000 autoanalyzer (Abbott Diagnostic Laboratories, Chicago, IL, USA). Serum NEFA
concentrations were measured by the Randox NEFA kit (REF FA 115, Randox Laboratories
Limited, United Kingdom) modified for use in the Daytona System.

171 *Markers of antioxidant status*

172 Analysis of FRAP was determined by spectrophotometrical analysis (Monarch Chemistry System, Instrumentation Laboratories, Zaventem, Belgium) as described by Benzie and Strain⁽³⁸⁾ and 173 previously validated in horses by Balogh et al.⁽³⁹⁾. In this assay, antioxidant activity was measured 174 in terms of reduction of ferric tripyridyl triazine complex to the ferrous form at low pH, which was 175 monitored by measuring the change in absorption at 593 nm. Results are reported as the 176 concentration of Fe²⁺ measured per L of serum after reaction (µmol/l). The SOD concentration was 177 measured with a commercially available assay kit (REF 19160 SOD determination kit, Sigma-178 Aldrich) which is based on the colorimetric reaction between water-soluble tetrazolium salt (WST) 179 and superoxide anion. Absorbance was read at 450 nm with the Victor 3 Plate reader (Perkin 180 Elmer). Measurement of α -tocopherol was performed by reversed phase HPLC and 181 spectrophotometrical UV detection. The RT-HPLC analytical column was a Prontosil 120-3-C18 182 (particle size 3 µm and length 100 mm; Thermo Fisher Scientific Inc., West Palm Beach, Florida, 183 USA) and UV detection was determined at an absorbance of 295 nm (UV2000, Thermo Fisher 184 Scientific). 185

186 *Markers of oxidant status*

The TBARS concentration was measured spectrophotometrically (Monarch Chemistry System, 187 Instrumentation Laboratories, Zaventem, Belgium) as described by Lin et al.⁽⁴⁰⁾ and reported as 188 concentration of malondialdehyde (MDA) measured per ml of serum after reaction (nmol/ml). 189 Plasma protein content (protein) was determined using the BCA protein assay kit according to the 190 manufacturer's instruction (Pierce® BCA Protein Assay Kit, Pierce Biotechnology). Pentosidine 191 (PENT) was determined with high performance liquid chromatography (HPLC) detection according 192 to Valle et al.⁽³⁰⁾ with slight modifications. Chromatography was performed using a Waters system 193 (Waters S.P.A., Milan, Italy) equipped with a Bio-Tek SFM25 fluorimeter detector (Kontron 194

Instruments, Milan, Italy). Briefly, protein content, after delipidation with hexane and precipitation 195 with trichloroacetic acid, was hydrolyzed with 6 mol/l hydrochloric acid for 18 h at 110 °C in 196 borosilicate screw-capped tubes, dried in a Speed-Vac concentrator and then reconstituted in 197 HPLC-grade water containing 0.01 mol/l heptafluorobutyric acid (HFBA), filtered through a 0.45-198 199 µm pore diameter Ultrafree MC (Millipore, Milano, Italia) and injected into a Aeris peptide 3.6u XB-C18 Reverse-Phase column (25 cm \times 0.46 cm, 3.6 μ m) with a curvilinear gradient program of 200 20%-40% phase B (methanol) in 30 min, while solvent A was H₂O. Both water and methanol 201 contained 0.01 mol/l HFBA. The PENT peaks were monitored using a fluorescent detector at λ_{ex} 202 335 nm and λ_{em} 385 nm wavelengths. A PENT synthetic standard (prepared as described by 203 Grandhee and Monnier, 1991)⁽⁴¹⁾ was injected at the start of each run to determine the PENT 204 concentration in the sample by peak area comparison. The amount of PENT was expressed as pmol 205 per mg of plasma protein content. Inter and intra-assay CV was 4.8 and 5.4% respectively. 206 207 Carboxymethyllysine (CML) was evaluated by ELISA methods (EIAab, Wuhan, China) according 208 to the manufacturer's instructions. The detection range of CML ELISA kit was 0.78-58 ng/ml, so the plasma samples were diluted 1:50. Absorbance was read at 450 nm. Results were expressed as 209 pg/mg protein. Inter and intra-assay CV was 10.7 and 9.8% respectively. Determination of AOPP 210 was based on spectrophotometric detection according to Witko-Sarsat (1996)⁽⁴²⁾. The AOPP levels 211 were measured by spectrophotometry on a microplate reader and were calibrated with chloramine-T 212 (CT) solutions, which in presence of potassium iodide absorb at λ 340 nm. In test wells, 200 µl of 213 HSA preparation (diluted 1/10 in PBS) was placed on a 96-well microtiter plate, and 20 µl of acetic 214 acid was added. In standard wells, 10 µl of 1.16 M potassium iodide was added to 200 µl of CT 215 solution (0–100 μ M) followed by 20 μ l of acetic acid. The absorbance of the reaction mixture was 216 217 immediately read at 340 nm against a blank containing 200 µl of PBS, 10 µl of potassium iodide, 218 and 20 µl of acetic acid. The AOPP concentrations were expressed as µmol/l of CT equivalents. The inter and intra-assay CV was 7.2 and 6.9% respectively. 219

220 Serum leptin concentrations

Leptin was measured using a multispecies RIA kit (Millipore, St. Charles, Missouri, USA) validated for the use in horses⁽⁴³⁾. The antibody used was guinea pig anti-human leptin. In absence of a purified leptin preparation, results are reported as human equivalents of immunoreactive leptin (ir-leptin).

225 Statistical analysis

The statistical analysis was based on a linear mixed model with pony as random effect and treatment, time and their interaction as categorical fixed effects. A separate analysis was done for the weight loss period and the end phase period. Because there was a large spread in initial body weight at the start of the weight loss period (100 - 243.3kg), changes in body weight were expressed as relative difference (% change) with the baseline value (i.e., week 5 for weight loss period and week 21.5 for end phase period) were used as response variable. Absolute values were used for the other measured parameters. After the overall analysis, the three treatment groups were compared pairwise at each time point using Bonferroni's adjustment technique for multiple comparisons. The global significance level was equal to 5%.

235 **Results**

236 Feed intake

Daily hay intake throughout the study is described in table 3. All ponies ate all of the balancer throughout the entire study. The average DMI at the end of the adaptation period in the CONTROL, SLOW, and RAPID group respectively was 1.86 ± 0.18 , 1.96 ± 0.15 , and 1.95 ± 0.27 % of the obese BW at the end of the adaptation period. The DMI intake during the weight loss period in CONTROL, SLOW, and RAPID was 1.86 ± 0.18 , 1.57 ± 0.12 , and $1.17\% \pm 0.16$ of the BW at the end of the adaptation period. During the end phase period, ponies received the same DMI as in the adaptation period. Energy intake is described in table 3.

244 *Relative weight changes*

During the entire weight loss period (w5-21), CONTROL lost an average of $0.42 \pm 0.45\%$, SLOW 3.59 ± 0.63%, and RAPID 10.81 ± 0.77% of their initial body weight (Figure 1). A more rapid weight loss was seen in the group with the highest energy restriction (RAPID, P<0.001), but the relationship between caloric restriction and percentage weight loss was not proportional as a doubling in caloric restriction (20% compared to 40%) was accompanied with a tripling in weight loss (3.59 compared to 10.81%).

At the end of the end phase period, CONTROL, SLOW, and RAPID had respectively regained 1.11 \pm 1.64, 1.41 \pm 1.04, and 3.40 \pm 0.94% of their BW at the start of the end phase period (w21.5). During the end phase period, a treatment effect was found between CONTROL and RAPID (P<0.001), and SLOW and RAPID (P<0.001) meaning that RAPID gained significantly more weight during the send phase period than SLOW and CONTROL.

256 Plasma glucose and insulin concentrations

Throughout the weight loss period, glucose values changed over time independently of treatment (P<0.001) (data not shown). No significant effects were found for insulin during the weight loss period and/or end phase period.

260 Markers of lipid metabolism

Higher and more rapid maximum TAG values were reached in RAPID (P=0.001) during the first part of the weight loss period (Figure 2). At the end of the end phase period, TAG values were decreased more rapidly in RAPID compared to SLOW and CONTROL (P<0.001).

- The NEFA concentrations changed during the weight loss period (P<0.001), with higher values in RAPID compared to SLOW and CONTROL (P=0.021). At the end of the end phase period, the NEFA concentrations were decreased in RAPID, whereas in CONTROL and SLOW values
- respectively increased and remained stable (P=0.014) (data not shown).

268 Antioxidant status

269 The FRAP concentrations changed during the weight loss period (P<0.001), with the highest values

in RAPID (P<0.001) (Figure 3). Comparing the end of the end phase period with the beginning,

FRAP concentrations increased in SLOW and CONTROL, while they remained constant in RAPID
(P<0.001).

During the weight loss period, SOD values changed (P=0.036) with lower values in RAPID after 8
weeks of weight loss (P=0.003). The SOD concentrations increased in the 3 groups during the end
phase period (P=0.003) (data not shown).

276 The α -tocopherol values changed over time during the weight loss period with an increase in 277 RAPID compared to more stable values in SLOW and slightly decreasing values in CONTROL 278 (P=0.004) (Figure 4). Rapidly decreasing values were noticed in CONTROL and RAPID during the 279 end phase period, whereas α -tocopherol values only slightly decreased in SLOW (P<0.001).

280 Oxidant status

During the weight loss and end phase period, TBARS values changed over time independently of treatment (P<0.001 and P=0.042 respectively) (data not shown).

Throughout the weight loss period, AOPP values changed differently over time between the 3 treatment groups, with an increase in RAPID in the first part compared to stable or decreasing values in SLOW and CONTROL respectively (P=0.015) (figure 5). 286 No significant effects were found for PENT and CML.

287 Serum leptin concentration

Serum leptin concentrations changed during the weight loss period (P=0.002) and between the treatments (P=0.001) with the lowest values in RAPID (Figure 6). At the end of the end phase period, most rapidly decreasing leptin values were found in CONTROL compared to RAPID and SLOW (P<0.001).

292 **Discussion**

To the authors' knowledge, this is the first study describing the effect of different levels of energy 293 restriction on weight loss and oxidative stress in ponies/equidae. In the present study, the higher 294 calorie restriction (RAPID) was associated with the greatest weight loss, as has also been described 295 previously in dogs⁽¹¹⁾. A doubling of the percentage of caloric restriction was associated with a 296 tripling in percentage of weight loss (3.59% in SLOW compared to 10.81% in RAPID). The highest 297 energy restricted group (RAPID), however, also showed the greatest weight gain when they 298 received again their 100% iMERob, a similar finding to that described in dogs⁽¹¹⁾ and humans⁽¹²⁾. 299 Increased metabolic efficiency, as has been described in obesity-prone rats after weight loss⁽⁴⁴⁾, 300 could be a possible explanation, although specific parameters (thyroid hormones, metabolic rate, 301 individual total and resting expenditure) to confirm this were not measured in the present study. In 302 obesity-prone rats, metabolic efficiency remained elevated and contributed to a lower energy 303 expenditure, a greater energy imbalance, and a high rate of weight regain early in relapse⁽⁴⁴⁾. 304 MacLean and colleagues⁽⁴⁴⁾ estimated that adjustments in appetite and resting energy expenditure 305 significantly contributed to the energy imbalance when rats were given free access to a low-fat diet. 306

Mean weekly weight loss in RAPID corresponded to 0.68%, which is comparable to the losses 307 described in the weight loss trial of Dugdale and co-workers⁽⁸⁾ who observed weekly weight losses 308 of 0.7% by feeding 1% of actual BW as DMI daily in obese pony mares. In that same study, BW 309 decreased by 4.3% during the first week of the weight loss period, which was attributed to 310 decreased gut fill and possibly depletion of glycogen reserves associated with the transition from ad 311 *libitum* food intake (positive energy balance) to restricted food intake (negative energy balance). 312 This phenomenon was not seen in the present study where BW loss of RAPID in the first week only 313 314 reached 0.87%. This could possibly be attributed to the feeding strategy in the adaptation period in this study, in which the ponies were fed at their maintenance energy requirements to maintain stable 315 316 obese body weight instead of *ad libitum* food intake in the trial of Dugdale and co-workers⁽⁸⁾.

Leptin levels at the end of the weight loss period were lower compared to the start of the weight loss period, which is in accordance with findings in other weight loss studies in ponies^(33,45). In the present study, refeeding the animals to 100% iMERob resulted in further lowering of the leptin levels in the energy restricted groups, a rather unexpected finding as higher leptin levels would be expected because of the higher energy intake and subsequent satiety effect of this hormone⁽⁴⁶⁾. No clear explanation could be found for this.

When the horse's body is in a state of negative energy balance, it changes to a more catabolic state. 323 In an attempt to maintain normoglycemia, there is a shift toward use of fatty acids as primary 324 energy source⁽¹⁰⁾. Given the higher predisposition of hyperlipemia in Shetland ponies with obesity 325 as a fortifying factor^(47,48), this was obviously a potential concern. However, a previous study with 326 Shetland pony geldings with even more severe (but introduced very gradually) caloric restriction at 327 35% of maintenance energy requirements had reported no adverse health effects⁽³³⁾. In the present 328 study, statistically higher serum TAG and NEFA levels were found in SLOW and RAPID 329 compared to CONTROL, with the highest levels in RAPID. Triglyceride concentrations, however, 330 never exceeded the upper limit of the normal range (< 500 mg/dl)⁽¹⁰⁾ and none of the ponies showed 331 any adverse clinical signs. During the first weeks of the weight loss period, accumulation of TAG in 332 333 the serum was positively associated with the extent of the weight loss. After 4 weeks of caloric restriction, even though weight loss was still occurring, TAG concentrations gradually returned to 334 335 baseline levels.

Together with the increase in percentage weight loss, and TAG and NEFA concentration in the 336 blood, an increase in plasma antioxidant capacity (as indicated by α -tocopherol and FRAP) was 337 seen during the first 4 to 8 weeks of the study. The increase in α -tocopherol (as part of the vitamin 338 E) could also be related to the fact that this liposoluble vitamin is released from the fat deposit as 339 this is one of the major storage sites of vitamin $E^{(43)}$. By the end of the weight loss period, these 340 values had returned to baseline levels, suggesting perhaps that the stimulus for increased antioxidant 341 demand had been resolved (lowered blood TAG and NEFA concentrations). The pro-oxidant 342 marker TBARS was lower at the end of the weight loss period compared to the start, indicating that, 343 as in humans⁽¹³⁾, dietary interventions resulting in even limited weight loss may help the 344 oxidant/antioxidant equilibrium. The parameter TBARS has been broadly used for the measurement 345 of lipid peroxidation, as it is one of the better predictors of oxidative damage⁽⁵⁰⁾. However, its use 346 has been criticised due to low specificity⁽⁵⁰⁾ and sensitivity⁽⁵¹⁾. In order to have a good 347 understanding of the oxidant/antioxidant status, multiple measures of oxidative damage should be 348 evaluated^(27,50). Therefore, in the present study, oxidative damage to proteins was also evaluated. In 349

humans, lipids as well as carbohydrates are important contributors to chemical modification of 350 proteins, leading to lipoxidation products⁽⁵²⁾. Chemical modification of amino acids in proteins 351 during lipid peroxidation results in the formation of lipoxidation products like AOPP. The higher 352 increase in AOPP in RAPID after 8 weeks of weight loss compared to SLOW could therefore be 353 354 related to the higher TAG and NEFA values in RAPID, which are prone to oxidation. No significant effects were found for CML and PENT, which could be due to the tight glycemic control in the 355 ponies and the fact that TAG and NEFA levels were not high enough to form these glycoxidation 356 and lipoxidation markers⁽⁵³⁾. 357

358 In conclusion, different levels of energy restriction will influence the extent of any weight loss, although there was no apparent linear relationship between the extent of energy restriction and 359 percentage of weight loss. A doubling in percentage of energy restriction was associated with a 360 tripling in % of weight loss. Following the weight loss period, the more extensive weight loss was 361 associated with more rapid and greater weight regain when ponies were fed again at 100% of their 362 MERob. Based on the results of the present study, it can be recommended in practice that if the 363 obese equids are fed a more severe calorie restricted diet in order to achieve weight loss within a 364 reasonable time period, it is even more important that once the animal's ideal weight is reached, 365 366 monitoring continues in order to avoid rapid weight gain rebound effect.

Finally, energy restriction and consequently weight loss can affect the oxidant/antioxidant balance, although significant effects were only seen in this study with the highest level of calorie restriction. However, these rather small effects are thought not to be of any biological significance and further research into the effect of weight loss on the oxidant/antioxidant balance is warranted.

371 Acknowledgements

The authors gratefully acknowledge Ségolène Leveillé Nizerolle, An Cools, Kristel Rochus, Hannelore Van de Velde, Sanne Ott, Annelies De Spiegeleer, Galena Quist-Rybachuk, Christel Moons, Adronie Verbrugghe and Ruben Decaluwé for helping with the feeding practices and blood sampling of the ponies, and Sarah Van Beirs, Laura Statius, Steven Galle, and Ellen Van de Maele for their excellent care of the ponies. The authors also wish to thank Herman De Rycke, Roberta Borghi, Nicola Traverso, Daniel Vermeulen, and Inge Vaessen for the analyses.

Financial support

This study was part of the postgraduate study of the first author and funded by the Institute for Promotion of Innovation through Science and Technology in Flanders (IWT, grant number 101572). This study was also funded by the 2011 WALTHAM-Buckeye Equine Research Grant.
Prof. Pat Harris, who is affiliated with WALTHAM, was involved in the study design and
manuscript drafting.

384 Conflict of Interest

385 None.

386 Authorship

L.B. was responsible for the study design, study performance, data analysis and manuscript drafting. M.H. and G.P.J.J., supervisor and co-supervisor of L.B. respectively, contributed to the development of the study design, data analysis and manuscript drafting. P.A.H. contributed to the study design and manuscript drafting. L.D. was responsible for data analysis and manuscript drafting. E.V. was responsible for advanced glycation end products analysis and manuscript drafting. P O. was responsible for advanced glycation end products analysis. K.V. collaborated in the study performance and contributed to the manuscript drafting.

530	TABLES
531	Table 1: Phenotypic summary of each study group at the beginning of the weight loss period. Data
532	describing age (years), body weight (kg), % overweight based on estimated ideal body weight and

body conditions score (BCS) are presented. Data are provided as means \pm SE.

Group	Age (years)		BW ((kg)	% overweig on estimate BW	BCS (2	BCS (1-9)		
	mean	SE	mean	SE	mean	SE	mean	SE	
CONTROL	9.7	1.9	140.8	39.8	26.4	3.6	8.3	0.3	
SLOW	9.0	1.5	170.3	38.0	28.0	4.0	8.2	0.3	
RAPID	9.3	1.7	154.1	25.6	27.4	6.4	8.3	0.3	

Table 2: Analysed (hay) and labelled (supplement) nutrient composition of the hay and supplement

Nutrient	Hay	Supplement	
Dry matter	885	888.1	g/kg
Crude protein	89.3	320	g/kg
Crude ash	63.3	150	g/kg
Crude fibre	371.8	50	g/kg
Crude fat	14.7	NI	g/kg
Starch	12.4	50	g/kg
alpha-tocopherol	17.5	1500	mg/kg
DE	8.1	13.5	MJ/kg

536 (Spillers Gro'n Win®, MARS Horsecare) on dry matter basis.

537 NI, not indicated on label; DE, digestible energy

Table 3: Energy intake during adaptation period, weight loss period, and end phase period. Individual maintenance requirements to maintain stable obese body weight were determined during the adaptation period. During the weight loss period, ponies were divided into 3 treatment groups (n=6), were they received 100% of individual maintenance requirements to maintain stable obese body weight (control group, CONTROL), 80% of individual maintenance requirements to maintain stable obese body weight (slow weight loss group, SLOW) or 60% of individual maintenance requirements to maintain stable obese body weight (rapid weight loss group, RAPID). Energy intake was calculated as digestible energy (DE). Daily dry matter intake (DMI) as % of body weight (BW) is also given in the table.

Adaptation period and end phase period						Weight loss period				
Group	Energy intake (% of iMERob)	Energy intake (MJ/kg BW)		% of offered hay consumed		Energy intake (% of iMERob)	Energy intake (MJ/kg BW)		% of offered hay consumed	
	Mean	Mean	SE	Mean	SE	Mean	Mean	SE	Mean	SE
CONTROL	100%	0.17	0.01	97.50	1.45	100%	0.17	0.01	99.63	0.31
SLOW	100%	0.17	0.01	99.84	0.21	80%	0.14	0.00	99.21	1.42
RAPID	100%	0.17	0.01	99.98	0.06	60%	0.10	0.01	98.80	1.7

iMERob, individual maintenance energy requirements to maintain stable obese body weight; CONTROL, control group; SLOW, slow weight loss
 group; RAPID, rapid weight loss group.

547

Figure 1: Body weight change (%) during the weight loss period and end phase period as a proportion of the value at week 5 (beginning of weight loss period) in the control group (CONTOL, \circ), slow weight loss group (SLOW, \bullet) and rapid weight loss group (RAPID, Δ). Data are given as means \pm SEM. Abbreviations: CONTROL, control group; SLOW, slow weight loss group; RAPID, rapid weight loss group.
