Abstract

We analyse the long-term effects of experiencing bullying victimisation in junior high school, using rich data on a large cohort of English adolescents. The data contain self-reports of five types of bullying and their frequency, for three waves, when the pupils were aged 13 to 16 years. We assess the effects of bullying victimisation on short- and long-term outcomes, including educational achievements, earnings, and mental ill-health at age 25 years using a variety of estimation strategies - least squares, matching, and inverse probability weighting. We also consider attenuation associated with relying on self-reports. The detailed longitudinal data, linked to administrative data, allows us to control for many of the determinants of child outcomes that have been explored in previous literature, together with comprehensive sensitivity analyses, to assess the potential role of unobserved variables. The pattern of results strongly suggests that there are quantitatively important long run effects on victims – stronger than correlation analysis would otherwise suggest. In particular, we find that both type of bullying and its intensity matters for long run outcomes such as obtaining a degree, income, and mental health.

Acknowledgements: We are grateful to our respective institutions for providing support to facilitate our collaboration. Gorman and Walker were supported by the UK Economic and Social Research Council funded project ES/R003629/1 on the effects of schooling on long-term outcomes. Harmon and Staneva's contribution was supported by the Australian Research Council through a Discovery Program Grant (DP140102491), and the Centre of Excellence for Children and Families over the Life Course (CE140100027). None of the above played any direct role in the research. We are grateful to comments from seminar and conference participants at the Society of Labour Economics 2019 conference, the Royal Economics Society 2019 conference, Temple U, CUNY, Sydney U, Kentucky, VU Wellington; and particularly to Alexander Mas at Princeton, Ken Troske at U Kentucky, and Miguel Sarzosa at Purdue for their comments, support and advice. The data was provided via the secure server at the UK DataService and is available to other researchers subject to registration and training. The authors are happy to assist other researchers by providing their code and advice to facilitate replication and extensions to the work.

1. Introduction

Being bullied at school is thought to be a widespread phenomenon that harms many children.^{1,2} However, there is relatively little quantitative research into the wider and longer-term effects of having been bullied as an adolescent, and little research has explored the implications of the heterogeneous nature of bullying.³ This paper aims to quantify the impacts of the variety of bullying on a range of important life outcomes. We analyse a range of schooling outcomes, including: high-stakes qualifications at the end of compulsory schooling, at age 16, that track pupils into academic or vocation curricula to age 18 and into university. We also analyse wider outcomes at age 25 years: the effects on income; unemployment; and a mental (ill) health index. In addition to a binary definition of the bullying, we pursue wider definitions: we use factor analysis to create a summary variable capturing the variation in the type and frequency⁴ of bullying, and we construct a multi-valued categorical treatment which allows the effects to differ by type and intensity.

We use statistical methods which rely on a selection on observed variables assumption paired with a comprehensive range of sensitivity analyses and falsification tests. In particular, we use least squares to adjust for observable factors, as well as matching and weighting methods to reduce the effects of functional form assumptions - employing propensity score matching (PSM) where we consider a single discrete treatment, and inverse probability weighted regression analysis (IPWRA) where we consider multiple treatments. The IPWRA analysis facilitates the estimation of the effects of different types and intensities.

A limitation of our work is that our estimates could be affected by bias due to selection on unobservables. On the other hand, we have data on many of the determinants of bullying identified in the previous literature, and we build a case for depending on a selection-on-observables assumption. Nonetheless, our estimated coefficients on bullying are not necessarily causal and we recognise that bias from unobserved variables remains a concern. Importantly, we implement tests which explore the

¹ Throughout we refer to victimisation through bullying at school simply as bullying. Bullying in this paper is wholly school based – we do not consider, for example, workplace or domestic sources of bullying.

² The 2017 edition of the Annual Bullying Survey, a large on-line non-random ‘snowball’ survey of young people in secondary schools and colleges across the UK, records 54% of all respondents had been bullied at some point in their lives. According to this survey, one-third of all victims experience social anxiety, one-third experience depression, and a quarter of the victims had suicidal thoughts.

³ A recent comprehensive review of the psychology literature can be found in Ren and Voelkel (2017), and a succinct review of the education literature that focusses on England can be found in Brown (2018). OECD (2017) also provides international evidence.

⁴ Olweus (1997) emphasizes the requirement that it is only repetitive actions that count as bullying.

potential role of selection on unobservables, and our application shows that it would take large, likely implausible, levels of selection bias to drive our results to zero. Thus, we feel able to offer this work in the spirit of shining a light on an important but difficult issue, where we currently know very little about the magnitude of the effects. Being able to estimate bounds on the causal effect may show us that bullying is sufficiently important to want to take policy action. Moreover, knowing about sources of heterogeneity might tell us how and what should be the highest priorities. Thus, we report a mosaic of results for a variety of outcomes, including long term outcomes, reflecting the range of possible definitions of the treatments, estimation methods, and control variables. Together, the results suggest that there are important long-run effects of bullying victimisation.

2. Existing bullying literature

Victims of frequent bullying have reported a range of psychological, psychosomatic and behavioral problems – including anxiety and depression, low self-esteem, mental health problems, sleeping difficulties, sadness, and frequent pain. Reviews of the work on bullying in the education and psychological literature can be found, for example, in Sharp (1995), Ladd et al. (2017), Bond *et al* (2001), Due *et al* (2005), Arseneault *et al* (2010), Ford et al., (2017), Woods and Wolke (2004).

There is little economics research on bullying. The seminal work is Brown and Taylor (2008) who use the UK National Child Development Study (NCDS) cohort of children born in a particular week in 1958. The strength of this early contribution to the economics literature on bullying is that it uses a high quality and large cohort study that follows children through school and long into the labour market. The weakness is that it includes many variables that seem likely to be bad controls.

There are few studies that address the issue of causality. Eriksen et al. (2014) use Danish data that, like our own analysis, combines administrative registers with a detailed survey, but considers only educational outcomes at age 16 based on tests in language and mathematics skills. Eriksen et al. (2014) attempt to estimate the causal effect of elementary school bullying on these age 16 outcomes through an identification strategy based on classroom peer effects. That is, they assume that the proportion of class children whose parents had criminal backgrounds affects other children only through a bullying channel. They report an OLS estimate of earlier bullying of -0.14 of a standard deviation of the grade point average (GPA) at 9th grade. But their IV results, are almost an order of magnitude larger, not smaller as a conventional selection story might suggest. Moreover, it seems likely that having children from extremely challenging backgrounds in the classroom would have an

impact on other children in a variety of ways, apart from through a bullying channel.⁵ A second paper that considers the endogeneity issue, is Sarzosa and Urzua (2020). This uses a South Korea longitudinal survey of 14-18 years olds with matched administrative education data to identify the effects of being bullied at age 15 on mental and physical health, and risky behaviors measured at age of 18. The authors estimate a structural model that assumes that the outcomes and treatment equations are independent from each other once they control for observable characteristics and latent skills. Their bullying definition refers to pupils being severely teased, threatened, collectively harassed, severely beaten, or robbed but is ultimately a single binary variable. Sarzosa and Urzua (2020) show that non-cognitive skills significantly reduce the likelihood of being a victim of bullying and reduce its impact on outcomes. The authors estimate that victims have significantly higher incidence of self-reported depression, sickness, mental health issues and stress. For example, being bullied at 15 increases sickness and mental health issues by 0.75 and 0.5 of a standard deviation, respectively, at age 18. More recently, Rees, et. al (2020) assess the effects of bullying victimization on the mental health of 14-to-18 year olds in the United States of America (US), exploiting state-level variation in anti-bullying laws (ABLs) which aim to reduce bullying in schools. Using a difference-in-difference strategy, the authors find that bullying victimisation increased the probability of depression and suicidal behaviours among young women, with the effects being most pronounced among non-white, and lesbian, gay, bisexual, or questioning, youth. The effect sizes are large; ABL adoption is associated with a 13-16 percent reduction in suicides among young women aged 14-to-18 years. These findings suggest that school bullying is extremely detrimental to the mental health of young people in the US context - especially those in marginalised groups.

3. Data and Specification

We use a large representative cohort study of English children, born in 1989/90, who have been followed from age 13/14 to age 25 years, at which point educational attainment has largely been completed and labour market outcomes are recorded.⁶ The data is known as *Next Steps*, previously as the Longitudinal Study of Young People in England, LSYPE (University College London, 2017a, 2017b).⁷ LSYPE covers family, education, and labour market variables, and covers sensitive issues,

⁵ For example, Carrell and Hoekstra (2010) show that troubled children have a direct negative spillover effect and significantly decrease the reading and math test scores of their peers.

⁶ The details of the educational context in England is provided in the Web Appendix.

⁷ The Wave 8 survey sought consent from LSYPE participants to allow further administrative data matched to LSYPE. We intend to return to this issue if such a longer-term follow-up of the LSYPE cohort becomes successful. We will also pursue further and later outcomes that will be included in Wave 9 at age 31 which will be available in 2022.

such as risky behaviours and personal relationships. LSYPE selected observations to be representative of the English population, but specific groups were oversampled - in particular, youths from low socioeconomic backgrounds and minorities (see Department of Education, 2010). Sampling weights are included in the dataset and more details can be found in Centre for Longitudinal Studies (2018) and Anders (2012).

The survey started in 2004 when the young people were at the age of 13/14 (in school year 9). In the first wave, around 15,000 young people were interviewed across more than 700 schools. The survey followed these individuals for seven years (age 14-21) and then re-interviewed them in Wave 8 at age 25. Non-response in the first wave was approximately 25%, and thereafter there was approximately 10% in each subsequent wave. There was then a four-year break until wave 8 (age 25) – when a lot of new household formation occurs, which contributed to a further drop. There does not seem to have been any substantial attrition as children completed compulsory schooling or when the survey moved to mixed collection methods.⁸ The survey data are matched to an administrative register known as the National Pupil Database (NPD), which includes the LSYPE sample of that 1990 birth cohort and the detailed histories of educational attainment of all pupils in the cohort.

3.1 Outcomes

We study the impact of bullying on the following outcomes - most of which we think of as being long-term ones, but also include the most important proximate high-stakes educational outcomes:⁹

- Having 5+ passes, including Maths and English, in junior high exit examinations - which is the most important criterion for a post-16 academic track (“5+ GCSE”)
- Having at least one Advanced-level qualification (or vocational equivalent) which contributes to university admission (“Any A-levels”)
- Points sum of the best 3 A-level (or equivalent) points, based on the best three subjects¹⁰ (“Best 3 A-level points”)
- Receiving a university degree (“University degree”)
- Natural log of weekly income (“Ln Income”)
- Not in employment, defined as not being an employee or self-employed, and so includes not in the labour force (“Not employed”)

⁸ While it is not possible to completely rule out the possibility of bias due to attrition, because it relates to unobserved selection, we do conduct analyses with and without the survey weights provided. This work does not materially differ from the results presented here. Further details are available on request.

⁹ There are several other long-term outcomes in LSYPE that might be interesting to explore but this would diversify into areas that are less central to the interests of economists. Nonetheless, this would make a worthwhile extension to this work.

¹⁰ Points (which are assigned based on the grades achieved) from the best three A-level or equivalent qualifications are commonly used as the basis of admission by most UK HEIs. See: <https://www.ucas.com/sites/default/files/2015-uk-qualifications.pdf>.

- General Health Questionnaire, measuring mental ill-health from 0 to 12, where 0 represents perfect health and 12 represents maximum distress (“*Mental health*”).

3.2 *Bullying Data*

Our bullying data is unusually comprehensive because it consists of five types, seven frequencies (including none) and was collected over three waves of data corresponding to the lifecycle peak in victimisation. This data provides the flexibility to define a large number of possible treatments. The data asks pupils (and the main parent) whether the child was a victim of bullying in the last year. In particular, in each of the first three waves subjects were asked whether they had experienced any of the following five forms of bullying last year:

- Upset by name-calling, including text or email¹¹
- Excluded from a group of friends
- Made to hand over money or possessions
- Threatened with violence
- Experienced actual violence

In addition to type of bullying, the data contains information on frequency: “every day”; “a few times a week”; “once or twice a week”; “once every two weeks”; “once a month”; and “less often than this”. However, estimating large numbers of treatments defined by interactions between types, frequencies, and waves using a dataset with a relatively small sample is unlikely to yield precise estimates. We therefore examine appropriate ways of creating summary measures that seem acceptable to the data. In preliminary OLS estimation, available on request, we use nested testing to aggregate types and intensities to achieve a statistically acceptable specification that would be sufficiently parsimonious to allow estimation using a number of methods. The first definition of a treatment is a binary variable equal to one if a child has experienced any bullying across the three waves, and zero otherwise. The majority of the existing quantitative literature uses just one variable to define bullying, and this treatment provides a baseline specification that is comparable with previous studies. Second, we define a richer summary measure, using factor analysis, which combines information on type and frequency of bullying over the three waves. This imposes no structure on the data but allows us to explore the effects using a variable that captures the complexity of the victimisation. The rationale behind these variables is as follows. Rather than impose constraints on the raw data to generate more

¹¹ The data predates the much greater penetration of social media channels. LSYPE2, 10 years after this cohort even then records that only 10% of such behaviour is mediated through social media.

parsimonious specifications, we first take a data-driven approach using exploratory factor analysis.¹² We conduct the factor analysis on the frequency of bullying variables, which are distinct by type and wave. We find evidence of just one common factor which we interpret as a measure of cumulative bullying intensity.¹³ This score is standardized to have a mean of zero and a standard deviation of one, which allows us to interpret subsequent results in terms of a standard deviation of the bullying intensity. This approach extracts the variation available by type, frequency and wave in a pragmatic, but data-driven, way.

Finally, we define a multi-valued categorical variable to capture potential heterogeneity in treatment effects. This variable aims to allow different effects by type and intensity of bullying. We first reduce the number of treatments by collapsing the number of types to two, by combining the three types that relate to violence (actual violence, threatened violence, and demanding money or belongings under duress) and collapsing the two non-violent types (name calling and social exclusion) into one. This is largely a practical matter to preserve cell sizes. We justify this aggregation on the grounds that that some types, e.g., extortion, have a very low incidence so the data would be unlikely to have the power to detect small effects on outcomes, and the variables in these grouping are naturally correlated: extortion usually occurs because of violence, or some implied threat. While the frequency variable is originally reported on a six-point scale from “every day” to “less than once per month”, we impose cardinal interpretations by assigning the number of school days corresponding to each level, ranging from zero to 200 school days.¹⁴ Therefore, after collapsing into two bullying types, we create two continuous variables by summing the total instances of violent and non-violent bullying instances across the three waves. For example, because for each type there are a maximum of 200 instances in each wave, the maximum number of non-violent instances across the three waves would be 1200. This restriction does not focus on heterogeneous effects in the timing of bullying, but rather measures the *cumulative* effect of being bullied. To capture heterogeneity in the pattern of bullying, we create a multi-valued treatment variable summarising the violent and non-violent frequency variables. This variable takes on nine values indicating each combination of: violent, non-violent, no or little bullying,

¹² Factor analysis is commonly used when using data sets with large numbers of observed variables that are thought to reflect a smaller number of underlying latent variables.

¹³ These are found using standard procedures according to which only factors with eigenvalues greater than or equal to one should be retained. See Fiorini and Keane (2014) for a similar application. The first factor explains 73% of the variance. We tried oblique rotation techniques to allow the factors to be correlated but the rotation did not affect the estimates.

¹⁴ Assuming 200 school days in a year, we make the following imputations: “every day” = 200 instances per annum; “a few times a week” = 100 ; “once or twice a week” = 60 instances; “once every two weeks” = 20 instances; “once a month” = 10, and “less often than this” = 2.

moderate bullying and high bullying. No or little bullying is defined as a frequency of zero days, or the lowest frequency of two days. This means this lowest category is 0 to 4 days for non-violent bullying (2 days multiplied by 2 types) and 0-6 days for violent (maximum of 2 days multiplied by 3 types). High bullying is defined as being in the top quartile of the bullying frequency distribution: experiencing 100 days or more of bullying in a school year. Moderate bullying is the remaining group. Thus, we focus on three definitions of bullying – a *binary variable* indicating whether the pupil has been bullied, of any type or frequency, at any point over the three waves of data (and a corresponding variable based on the parent reports); a *continuous variable* constructed via a factor analysis of the frequency of each bullying type in each wave (and a corresponding variable based on the parent reports); and a *multi-valued discrete treatment* for each combination of violent or non-violent bullying type, and none, moderate or high cumulative frequency of occurrence over three waves. Table 1 summarises the nature of this variable.

3.3 Summary statistics:

The most general sample for analysis is restricted to individuals who participated in Wave 8, to yield long term outcomes, and also participated in Wave 1 and have complete data on the most basic set of covariates we use (N=7,569). As we add further covariates and consider outcomes from various sources in our linked administrative data, the sample reduces. Testing for differences in key characteristics across the different estimation samples does not reveal significant differences (available on request). LSYPE contains survey weights, to adjust for the complex survey design (a function of ethnicity, area deprivation and school type, among other factors) and survey drop-out (modelled as a function of observed characteristics in the data). We may wish to use the weights if we suspect they may be correlated with our treatment effects, i.e. that the survey design or survey drop-out may bias our results. In the main analyses, we do not use the weights. However, where we can we have also fitted the models with the survey weights, yielding negligible differences in our parameters estimates (available on request), such that we feel confident using the weights would not alter our findings more generally. However, we do adjust the standard errors for clustering by school.

Summary statistics for the outcomes and the control variables are provided in Table 2. These statistics are unweighted and should not be interpreted as population-representative estimates. Some 45% of children are male; 69% self-report white as their ethnicity, 6% of all children report that English is not their first language; the KS2 and KS3 scores are average points scores from the National Pupil Database (NPD), and are recorded at age 10 and 13 respectively; and 16% of children live with just one of their biological parents. Parents were asked if their child was in their first ranked secondary school—which we include because a child might be more likely to be bullied and have lower

achievement, irrespective of bullying, if the child has not been able to gain admission to her most favoured school. 82% are placed in their first-choice school.

The Index of Deprivation included in the analysis is the IDACI (income deprivation affecting children index), a subset of the Index of Multiple Deprivation, measuring the proportion of children aged 0 to 15 living in income deprived families, defined including people out of work, and people with low income (Department for Communities and Local Government, 2015). Locus of control captures individual beliefs about whether life events are mostly internally or externally determined (Rotter, 1966). People with an external locus of control believe that they lack control on what happens in life. On the other hand, individuals with internal locus of control generally believe that life events are mostly caused by their own decisions and behaviours. We measure locus of control using responses to six questions and we use factor analysis to create a continuous index of locus of control. LSYPE includes four questions on working attitudes (see the web appendix Table WA5 for details) and we use factor analysis to create an index of work ethic from these. The parental education variables reflect the rapid expansion that had occurred in HE provision in the late 80's and early 90's so that 37% of the children have gained a HE degree compared to 25% for their mothers - the interviewed "main parent" is the parent most involved in the child's schooling, and is almost exclusively the mother. We have a wide variety of outcomes. The proportion attaining 5+ GCSE passes, 69%, comes from the NPD data and is matched into the LSYPE data. Whether the individual took any A-levels (or equivalent "level 3" qualifications), 51% in Table 2; and the sum of the points of the best three subjects taken (excluding General Studies – a very broad subject that is sometimes taken as a fourth A-level subject) using the grade to points conversion scale prevalent at the time, is taken from wave 7. Income is recorded for the individual in wave 8 of LSYPE. Unemployed is defined to include all those not in the labour force (i.e. not self-employed or an employee). Mental (ill) health is measured using the General Health Questionnaire (GHQ), which is a count of up to 12 conditions, so a higher score indicates poorer health.

Table 3 reports means and standard deviations of key variables by bullying status: whether a child has *never* been bullied, has been bullied in only wave of data, or has been bullied across *multiple* waves of data. Boys are slightly more likely to report being bullied than girls. White families are overrepresented among the repeated bullying category compared with other ethnicities. Children in sole parent families are statistically significantly more likely to suffer multiple instances of bullying compared with pupils in

two-parent families. There appears to be little difference in the propensity to be bullied by measures of socio-economic status, such as the area-based deprivation index (IDACI), or parental education level. This makes sense because a key determinant of being bullied is being *different* from those around you, rather than the levels of any particular variable (see Ttofi. and Farrington (2011). In contrast, there are substantive differences in outcomes by bullying status, especially mental health, unemployment, and income.

In Web Appendix Table WA1 we explore whether the bullying pattern a pupil experiences is associated with a higher likelihood of dropping out of the survey by Wave 8, which shows that in fact those who are bullied across multiple waves are slightly more likely to remain until the final Wave. This is in line with the patterns of observable bullying selection in Table 3, in that children from White, and more educated households, are more likely to report being bullied, but with no difference by prior attainment - a pattern which does not align with common patterns of survey drop-out, which typically run in the opposite direction.

Figures 1 and 2 give a sense of the distributions of bullying frequency by type of bullying and wave (among those who report both). Figures 1a and 1b shows the extensive margin of victimisation experience by type - that is, the proportion of girls and boys reporting each type of bullying in each wave. Victimization falls across waves for each type, consistent with the existing literature. It is also clear that name-calling and social exclusion are more prevalent for girls and violence more prevalent for boys.

Figures 2a and 2b show the intensive margin of victimisation by type and wave—that is, the average numbers of days the youths report experiencing each type of bullying in each wave. Again, victimisation falls over waves and, boys tend to experience more instances, especially of violent types. Exploration of serial correlation in bullying across waves suggested that this was high, for all three main types. For this reason, we feel justified in thinking that frequencies for each type could be aggregated across waves. That is, it may not matter than a bullying instance occurred in Wave 1 or another wave; rather it appears to be the case that it is only the cumulative bullying experienced that matters, not its distribution by age.

Figure 3 compares the child and parent reports of experiencing bullying. Typically, the child reports show a higher prevalence of bullying. The reports from both child and parents follow a similar downward trend over the three waves reflecting the decrease in bullying as children mature. It is useful to have a second report of bullying, even though both are subjective, since it allows for a useful sense check on the importance of measurement error on the estimates of the effects on outcomes. We show

the outcomes associated with each type and frequency of bullying in the web appendix, Figure WA3. We group the days of bullying instances into the three levels defined earlier (None, Low, High), and show, for each intensity group cell, the means for each of our outcomes. These figures show the expected pattern, that increasing bullying intensity is associated with worsening outcomes. This pattern is especially pronounced for unemployment and mental ill-health.

The graphs also foreshadow non-linearities in the effects of bullying: moving from moderate to high bullying is associated with a larger drop in outcomes, compared with moving from no bullying to moderate bullying. This is an issue we return to in our modelling. Finally, the graphs show important differences in the incidence of different types of bullying by gender, but this is not something that we pursue due the reduced estimation efficiency in the gender sub-samples.

4. Estimation

We explore a range of empirical methods based on various assumptions. We first consider OLS estimates, as a benchmark, then propensity score matching (PSM), and finally multiple treatment effects with inverse-probability-weighted regression (IPWRA).

4.1 OLS analysis

We begin by estimating the following simple linear relationship using OLS:

$$Y_{ih} = \mathbf{B}'_{ih}\boldsymbol{\beta} + \mathbf{X}'_{ih}\boldsymbol{\gamma} + \epsilon_h + \omega_{ih} \quad (1)$$

where Y_{ih} represents one of the several outcomes, observed at age 16, 18 or 25 years depending on the outcome in question, for individual i who attended high school h ; \mathbf{B}_{ih} , represents the bullying variable which may be a scalar or a vector, for student i attending high school h ; ¹⁵ \mathbf{X}_{ih} is a vector of child characteristics (e.g. ethnicity, month of birth, etc), school characteristics (e.g. school type), and family characteristics (e.g. maternal education and marital status), and ϵ_h is a school fixed effect while ω_{ih} captures unobservables that vary across i and across h . The inclusion of the school fixed effects allows us to account for unobserved time-invariant school characteristics, which may affect bullying and pupils' outcomes at the same time—for example, the disciplinary regime at the school. Using school fixed effects in many of our models allows us to capture the idea that it is the *relative* characteristics of pupils, compared with one's proximate peers, which are important for determining whether a child is bullied.

¹⁵ The dependent variables are only observed once, so although having bullying data for three waves we do not include a subscript since we accepted the restriction that the corresponding $\boldsymbol{\beta}$ s did not differ significantly.

In this specification the coefficients on our \mathbf{B}_{it} indicators, β , are the parameters of interest. While the OLS estimator adjusts for observable factors, the resulting estimates do not necessarily warrant a causal interpretation. The plausibility of the conditional independence assumption required for a causal interpretation depends on the relationship between the outcomes and the covariates \mathbf{X}_i . As such, it has become common to explore the stability of the parameters of interest by varying the set of control variables \mathbf{X}_i . In particular, \mathbf{X}_i might include pre-treatment controls - specifically, KS2 scores that might reflect pre-treatment bullying in primary school. We use two sets of covariates, each including school fixed effects. The first is a parsimonious specification that includes only those variables that seem plausibly exogenous: gender, ethnicity, month of birth, Government Office Region (GOR), and English being a second language (ESL). The second specification is an intermediate one which also includes a set of controls which we think of as being predetermined in Wave 1 of the data (age 14): local area deprivation, parental information including age, education, health, income and marital status, test scores at age 10 (KS2), and whether the school was the parent's first choice school. We would be concerned that any further extension beyond this specification would run a risk of including "bad controls" which would generate biased coefficients.

We implement a number of falsification, or placebo, tests. We assess the effects of the binary bullying variable on variables which should *not* be impacted by bullying if we have adequately controlled for selection into being bullied, i.e., they are either determined *before* bullying occurred, or are measured afterward but there is no reason to believe that they should be affected by bullying. Therefore, we expect to not see any significant effects of bullying in this analysis, unless our observed effects of bullying are driven, to some extent, by confounding. Finding appropriate predetermined variables in our data is difficult, but we identify the following candidates: the share of pupils in the school gaining 5+ GCSEs in 2001 (the first wave in the estimation sample is 2004); the Key Stage 2 scores of pupils attending the school in 2001; the deviation of the pupil's average height measured at age 25 from their high school peers; and whether the pupil took either the Math or Science Extension Test at primary school. The rationale for the deviation from average height of peers is to pick up children who may have been relatively small at school, and therefore more likely to be bullied due to their physical attributes. We do not observe pupils' heights while they are at school, only at age 25 years, so we need to make the strong assumption that relative height has stayed constant. But if we have adequately controlled for the determinants of being bullied, we should not see an 'effect' of bullying on relative height at age 25 years. Finally, taking the Math or Science Extension tests could represent a proxy for being an intellectual or social outlier, as measured prior to high school.

In a second approach to exploring the potential role of unobservable, we use the test proposed by Oster (2019) that indicates the level of selection on unobserved variables, as a proportion of the level of selection on observed variables, that would be required to drive the treatment effect to zero – captured by her parameter δ ¹⁶. Results from this test are reported in Section 6 below, and they provide evidence supporting the credibility of our main estimates.

4.2 PSM analysis

We complement least squares estimation with propensity score matching (PSM). Matching offers a number of advantages compared with OLS: increased similarity (balance) in the distribution of covariates between the treated and control group; explicit consideration of the degree of overlap; and a reduced reliance on a linear functional form. The primary approach we use is kernel propensity score matching. We complement this with a number of alternative estimation methods, to ensure our results are not an artefact of one particular approach: nearest neighbour (NN) propensity score matching, and multivariate distance matching on the Mahalanobis distance (MDM). In Web Appendix Figures WA1 and WA2 we also report a histogram showing the resulting overlap between treated and controls, together with a plot summarising the balance statistics.

To evaluate the sensitivity of the matching estimates to confounding, we employ the sensitivity analysis developed in (Nannicini, 2007; Ichino *et. al.*, 2008). This sensitivity analysis simulates the effects of a potential binary confounder on the average treatment effect on the treated (ATT). This method is similar in concept to many other sensitivity analyses in the statistics and econometrics literature who also assess the sensitivity to unobserved confounding (for example, Oster 2019). One advantage of this specific approach is that it does not require a parametric outcome model, making it suitable to use in a matching context. The idea is that we may suspect that the conditional independence assumption may not hold, given the covariates we observe. However, we might think that conditional on an omitted variable, denoted U , the assumption would plausibly hold. Matching on U , in addition to the vector \mathbf{X} , would allow us to obtain a consistent estimate of the ATT. By specifying the joint distribution of U , the binary treatment, denoted B , and the outcome, denoted Y , we can compute the “unbiased” ATT, which accounts for the confounding effects of U . We can compare this to our

¹⁶ The assumptions underpinning the calculation of δ can be varied. In particular, the researcher can vary the assumed value of R^2 -max, the R -squared from a hypothetical regression of the outcome on treatment and both observed and unobserved controls. The default option is to set this as 1, which may not be plausible in situations where it is inconceivable that one might be able to explain all the variation in the outcome. A rule of thumb proposed in Oster (2019) is to set R -max equal to 1.3 times the R -squared from a regression of the outcome on the treatment and observed control variables (denoted \bar{R}). The suggested cut-off to define an ‘acceptable’ level of selection is an estimate of δ (calculated using R -max = 1.3* \bar{R}) that exceeds 1. This was the level that was found to be consistent with that observed in a sample of papers using RCTs in Oster (2019). Therefore, we report δ based on this level of R -max.

original, which does not adjust for U , to assess the difference made by accounting for the unobserved covariate.

To operationalise the method, one needs to specify the distribution of a hypothesised U , in relation to B and Y . Equation 2 highlights the maintained simplifying assumption that U is binary and independent of \mathbf{X} .

$$p_{ij} \equiv pr(U = 1 | B = i, Y = j) = pr(U = 1 | B = i, Y = j, \mathbf{X}) \quad (2)$$

After specifying p_{ij} , the relevant value of U is assigned to each observation, depending on which category of i, j they are in, and U is included in the calculation of the ATT as an additional covariate. For a given set of parameters, the matching procedure is performed multiple times with varying draws of U , and the estimate of the ATT is the average over the estimates in each simulation. The standard errors are calculated using Rubin's rules for computing standard errors across multiple datasets.

The first way we operationalise this is to pick U such that the unbiased effect would be driven to zero, and then assess the substantive plausibility of such a confounder. A second way to operationalise this is to specify U to mimic the distribution of some observed confounder which may represent a more plausible scenario.¹⁷ We choose three such variables to explore this: the “sole parent family” variable; the “English second language” variable; and a binary variable, which we call “outlier”, that indicates being in either the top or the bottom decile of the Key Stage 2 distribution in their school (i.e., compared with being in the middle of the distribution as the base category). We choose these variables as it seems plausible that they may possibly affect both the probability of being bullied and the outcomes. We then assess the extent to which these hypothetical confounders would reduce the estimated treatment effect.

To assess the economic plausibility the hypothetical confounder U , when specified to reduce the treatment effect to zero, we report both two types of odds ratios: the *selection effect* and the *outcome effect* (Nannicini, 2007; Ichino *et. al.*, 2008). The *selection effect* quantifies the degree to which the posited unobserved covariate increases selection into being bullied: specifically, the odds of being bullied associated the binary confounder taking the value one, divided by the odds of being bullied associated the binary confounder taking the value zero. The *outcome effect* quantifies the degree to which the posited unobserved covariate increases the average outcome: specifically, the odds of a

¹⁷ We use the user-written Stata program `sensatt` to implement these procedures.

binary outcome associated with having the confounder taking the value one, divided by the odds of a binary outcome associated with having the confounder taking the value zero. The idea is that if an unobservable must have implausibly large selection and outcome effects to materially change our results then this would provide evidence supporting the robustness of our results. Results from these tests are presented below, as appropriate, and generally confirm that it would take implausible levels of selection on unobservables to invalidate the main findings.

4.3 *Treatment effects with IPWRA analysis*

The OLS and PSM analysis so far has employed a simple binary treatment. To improve on this, we also consider a continuous treatment constructed using factor analysis on the frequency of each type of bullying in each wave. Beyond this data reduction approach we consider multiple treatments defined by the varying intensities and types of bullying. We also examine the role of different types of bullying using inverse probability weighted regression adjustment (IPWRA) treatment effects estimation based on Imbens and Wooldridge (2009) and its implementation in Cattaneo et al. (2010).¹⁸ We use IPWRA to explore the effects of a multi-valued treatment taking nine values: each combination of no bullying, low bullying and high bullying frequency, for two types of bullying (violent and non-violent).

Specifically, the probability of “treatment” (in this context, having a certain combination of violent/non-violent and low/high frequency bullying) is estimated using a multinomial logit specification. The inverses of these predicted probabilities are used as weights in a second-stage regression-adjustment (Wooldridge, 2007; Wooldridge, 2010; and Imbens and Wooldridge, 2009). The IPWRA estimator has the so-called “double robustness property” (Wooldridge, 2007 and 2010) in that only one of the two equations in the model must be correctly specified to consistently estimate the parameters of interest. Nonetheless, estimation by IPWRA relies on the conditional-independence assumption in order to identify the effect of bullying on long term outcomes. If we have enough information on the observable differences between youths with and without the treatments, we can heavily weight treated observations that have similar observables to untreated individuals and obtain unbiased estimates of the causal relationship between bullying and long-term outcomes (Mendolia and Walker, 2015).

5. Results

¹⁸ These effects are estimated using the *teffects ipwra* routine in Stata 15 (STATA Corp, 2017).

We first present headline results for our two simplest cases: where bullying is a discrete variable corresponding to reporting “any” bullying; and a continuous variable derived from factor analysis. We then report results where we disaggregate to explore the effects of multiple treatments – violent vs non-violent forms and different intensities.

5.1 *Headline estimates*

Table 4 shows the OLS results for the “Any bullying” measure, which is typically used in the literature.¹⁹ We report results for boys and girls pooled, with a gender control included (the web appendix Table WA3 provides estimates by gender). OLS results are reported in Table 4 for effects on having 5+ GCSE passes, taking A-levels, and A-level score (which is a primary determinant of university admission); the intermediate outcome of having a university degree by age 25; and long run outcomes at age 25 (log income, being unemployed, and the mental health score). Model 1 includes as covariates: gender, ethnicity, birth month, region (GOR), and English being a second language, along with school fixed effects. Adjusting for these basic controls, we find large detrimental effects of experiencing bullying. The probability of gaining 5+ GCSE passes is reduced by 6.3 percentage points (10% from a mean of 0.69). The probability of staying at school to take a A-levels is reduced by 4.6 percentage points (9.0% reduction from a mean of .51), and the A-level points from those qualifications are reduced by about 5 points (5% of a standard deviation). Turning to longer run outcomes, income at age 25 years is reduced by 2.3% (£7 per week of the sample mean). The probability of being unemployed increases by 3.5 percentage points (35% from a mean of 0.10). Perhaps most strikingly, the GHQ mental ill-health index increases by 0.97, a large effect size of about one third of a SD. Evidently, being subject to any bullying, *within* schools, controlling for basic covariates, is strongly associated with worsened outcomes.

However, these effects may be driven, to some extent, by confounding. Model 2 aims to address this by adding a rich set of relevant controls that are associated with both being bullied and child outcomes. For the GCSE outcome, A-level participation, income at age 25 years, and university degree, adding these relevant controls reduces the effect sizes by about half, and they remain statistically significant (aside from the degree case). For example, the probability of gaining 5+ GCSEs is now 4% lower (and reduced to 2.4 percentage points in Model 2); the probability of staying on in

¹⁹ A not insubstantial group who report being bullied respond to the frequency question, for at least one of the bullying types, with “it varies” (n=885/7,569). While this group are counted as being bullied (bullying=1) in the discrete definition used to generate the Table 4 OLS results and the Table 7 PSM results, for the analyses which utilise the frequency data (the factor analyses and the IPWRA analyses), the “it varies” frequency report is set to missing. We take a conservative approach of using complete-case analysis, rather than endeavoring to impute the potential values of the “it varies” frequency.

school to take A-levels is around -2.5% (reduced by 2 percentage points compared to Model 1); the points gained from those qualifications is reduced by about -6 points (6% of a SD) in Model 2; the probability of having a university degree is now reduced to a 1 percentage point fall (although not significantly so); and the effect on income at 25 is now reduced by 1% (a £3 per week reduction from the sample mean); and, finally, the GHQ mental ill-health index larger at 0.91, a robustly large effect size of 29% of an SD. However, there may still remain some selection on unobservables, which we explore by reporting the δ parameter proposed in Oster (2019). The estimates of the δ parameter are consistent with an ‘acceptable’ level of selection according to the rule-of-thumb suggested in Oster (2019). The only exception (for Model 2 results) is log income, which has a *negative* δ associated with it.²⁰ Table 4 also presents the bounds on β that are derived from imposing the reasonable (but conservative) assumption that selection on unobservables is equally as important as selection on observables, and sign of the selection effect runs in the same direction for both observables and unobservables ($\delta=1$).

Table 5 shows the same analysis for the case where bullying is recorded as a continuous variable, based on a factor analysis exercise. There is a very similar pattern of results to Table 4, although the coefficients are not comparable because Table 5 is based on a continuous measure of bullying while Table 4 is a simple dummy variable. Model 2 generally has smaller coefficients than model 1 in both tables, as we might expect. The Oster’s δ , as to be expected, generally falls as we move from model 1 to model 2. Yet, in most cases, the results in both tables suggest that, even in model 2, the estimates are unlikely to be zero under reasonable assumptions about possible confounders.

The Oster bounds in Table 5 reflect this conclusion, as the intervals bounded by the treatment effect (assuming no selection on unobservables) and the bias-adjusted treatment effect (assuming equal, positive, proportional selection on observables and unobservables) do not contain zero.

5.2 *Robustness checks*

Table 6 presents results from several falsification tests and show OLS estimates of the association of being bullied with four outcomes: historical information on school performance, and two individual level outcomes - absolute deviation from average peer height, and whether the

²⁰ A negative value of delta is generated when the correlations between observables and the treatment, and between unobservables and treatment, have opposing signs.

individual took KS2 Maths and Science extension tests²¹. Observing an effect on these outcomes would suggest that we are conflating the bullying effects on long run outcomes with omitted variable bias. Conditioning on the variables listed in Model 2, we do not observe any significant effects on these outcomes. This provides further support for the credibility of our results and for thinking that Model 2 successfully controls for the key determinants of bullying outcomes.

Aside from the issues associated with identification, the estimates could also be driven by the functional form imposed in the OLS estimation. Therefore, we also investigate propensity score matching. In Table 7, the propensity score findings show a similar pattern to those in Model 1 of Table 4, suggesting that the Table 4 results are not driven by the functional form of the OLS model.

The first row of estimates in Table 8 is copied from the first column of Table 7's PSM estimates. We first consider, in the second row, the plausibility of a binary confounder that would drive our treatment effects to zero. Taking the first outcome in Table 8 as an example, gaining 5+ GCSE passes, we see there would need to be large outcome and selection effects to make this effect completely disappear. The binary confounder U would need to *increase* the odds of being bullied by a factor of at least 4.3 and *decrease* the odds of gaining 5+ GCSE passes by a factor of 0.2. While this may be plausible, looking across the outcomes it seems that the longer run effects are most robust to selection (and so would require the most extreme confounding to reduce the treatment effect to zero). For instance, for mental health, the binary confounder U would need to *increase* the odds of being bullied by a factor of at least 16.3 and *decrease* the odds of being in the top quartile of the GHQ distribution by a factor of 23.6. This type of extreme confounder seems an unlikely scenario. To assess more realistic potential confounders, we evaluate the effects of simulated variables that mimic the distribution of relevant observed variables in our data, in relation to the treatment and outcome. The next three rows in Table 8 assess the effects of adding each of our selected simulated variables to be potential confounders in our data: being in a sole parent family; having English as a second language; and being in the top decile or bottom decile of the Key Stage 2 distribution on the child's school. These variables were chosen as being likely to reflect perceived or actual differences from one's classmates, which would both shape the propensity of being bullied and be likely to have direct effects on the outcome.

²¹ The extension paper was introduced in 2001/2 to measure and stretch the most mathematically able 11 year olds (scoring over 90% in the main test). It was subsequently dropped, but was later reintroduced.

Beginning with effects of the simulated unobserved confounder mimicking the distribution of the sole parent family variable, this would reduce the effect on the GCSE variable by only about 3% i.e. (comparing row 1 with the equivalent row in column 1 of Table 8, -0.071 to 0.069). Adding the simulated variable to the A-level outcomes determinants the bullying estimates is reduced by only 4% and in the ln(income) equation by about 6%, but it has negligible effects on the other treatment effects. The simulated unobserved confounder mimicking the distribution of ESL again has little impact on the estimated treatment effects, aside from reducing the effect of on mental health by 1%.

Finally, we also examine the simulated unobserved confounder that mimics the distribution of being in the tails of the prior ability distribution. This would reduce the effect on the GCSE variable by about 1.4% and has negligible effects on the other treatment effects. Our conclusion from this analysis is that, overall, scenarios emulating realistic levels of confounding could reduce our treatment effects by between 0%-6%, depending on which outcomes is considered. Therefore, it seems unlikely that our results could be entirely, or even predominantly, driven by selection. The type of confounding required for this to be likely to happen appears to be substantively implausible.

5.3 *Multiple treatments*

Finally, we explore the role of type and frequency together using treatment IPWRA estimation of multiple treatments. The aim is to show the merit of viewing bullying as a multi-valued treatment problem. Figure 4 summarises the estimates (available in Web Appendix Table WA5) for the four long run outcomes: (a) university degree, (b) income, (c) unemployed, (d) mental health. The dots are point estimates, while the vertical lines represent 95% confidence intervals. Our results, for each outcome variable, are grouped into three groups, where we look at the effect of increasing violence for a given level of non-violent bullying (grouped by the dashed lines). Thus, in Figure 4a we see that with, no violent bullying, increasing the intensity of violent bullying decreases the probably of having a degree. Similarly, in Figure 4d we find that there is (almost) a monotonically increasing adverse effect of violent bullying at any level of non-violent bullying; **and**, looking across groups, we see that as the **non-violent** bullying level rises this (almost) monotonic pattern of increasing effect of violent bullying across the groups of non-violent levels increases successively.

While most of these individual interacted treatment effects are not individually statistically significant from zero, the pattern of these results suggests that the interaction of more bullying of one type conditional on the level of another type is generally to have an adverse effect on outcomes. The estimates for the short-term outcomes are presented in Figure 5. We again visualise the estimates as interactions of more serious bullying and divide these into three groups of successively higher levels

of severity. Even with this minimal extension that considers just two types of bullying at three levels of intensity (none, low, high), we find systematic effects of both type and frequency using IPWRA. Especially for the longer run outcomes, it appears that much of the effects is driven through the most intense forms of bullying - high intensity, and violent. Other types and frequencies also have effects, especially for mental health where any combination of violent (V) and non-violent (NV) bullying, whether at high or low intensity, have statistically significant adverse effects – raising the mental ill-health count by between 0.5 and 1.5 where the mean is 2.3. The effects on income are large and negative (-4%) only for the relatively small proportion of the population who experience high intensity bullying and either high or low NV bullying. The results in Figure 5 suggest that these effects on income in Figure 4 may stem, in part, from negative impacts of bullying combinations on the probability of attaining 5+ GCSEs or any A level. These results strongly reject the idea that a single treatment is sufficient to capture the complex effects of bullying.

6. Conclusion

This paper investigates the effects of bullying in secondary school on later academic and labour market outcomes. We do this by exploiting a rich conditioning set of observables, and using a range of estimation methods: OLS, matching and weighting. The data come from a large high-quality cohort study in England, LSYPE, linked with administrative data on education records. Our empirical findings show that school bullying has negative consequences for short-term academic outcomes and persists to have adverse *long-term* effects—the strongest effects are on mental health, but we also find effects on unemployment and income measured at 25 years. We also find some evidence that type and intensity of bullying matters. For example, for the gold standard academic progression criterion of having 5+ GCSEs at age 16, the results suggests that it is not a higher degree of violent bullying alone that matters, it is the combination of **both** violent **and** non-violent bullying that matters. Similarly, in the case of mental (ill) health, it is again the **combination** of violent and non-violent bullying that generates much of the effect. The effect of low (medium, high) intensity non-violent bulling is a 0.6 (0.7, 0.9) of an SD increase in mental ill health, but add low (medium, high) intensity violent crime and the combined treatment effects is 0.7 (0.9, 1.4) of an SD.

We conduct a comprehensive battery of sensitivity tests to explore our main identifying and estimation assumptions. The results of this indicate that it is unlikely that our effects are entirely driven by selection on unobserved variables. A cautious interpretation of the results is that any of our effect sizes could potentially be reduced, but not eliminated, by unobserved selection. Even in this scenario, the estimate effects remain large enough to be of substantive importance. The most robust effects are on mental ill-health and unemployment. Being bullied exerts long run adverse effects of children's life

outcomes. Based on our analyses, we feel confident that this finding is not an artefact of a particular estimation or identification assumption. If we take the mental health effects alone the costs associated with such an increase would be important enough to justify greater effort in reducing bullying. This conclusion is in line with existing literature, which consistently finds large detrimental effects of school bullying on mental health, across various identification strategies and measures of mental health (Sarzoza and Urzua, 2015; Rees et. al, 2020). Thus, the results have relevance for policy. Our results further suggest that low levels of non-violent bullying have modest effects, but higher intensity bullying has much larger effects. These findings suggest that the long run consequences of bullying should not be underestimated, and perhaps policy should be targeted more heavily on the extreme cases of violent and persistent cases.

There are several important ways that this research might, data permitting, be extended to broaden the reach of policy relevance. First, we do not analyse cyber-bullying. The children in the LSYPE data used here do not report explicitly on cyber-bullying. However, child and main parent reports of cyber-bullying are reported in LSYPE2 that was collected for a cohort ten years later than LSYPE, when smartphone use had become more prevalent among young people²². Secondly, it would be useful to explore workplace bullying and its effects. The age 25 follow up does contain contemporaneous bullying information and it shows a high correlation with bullying at age 14 to 16, however the data from the planned further follow-up subsequent to age 25 year are not yet available. Thirdly, we focus here on economic outcomes, and the work could be extended to a wider range of social outcomes.

Finally, the analysis relies on a selection on observables assumption. Although we explore the potential role of selection on unobservables via a battery of sensitivity analyses, which provides reassuring results, it would be useful to have confirmation from treatment effects based on exogenous variation and more objective measures of bullying. Such an analysis is not yet possible in our context because of data limitations and the lack of a suitable study design. We offer our results in the spirit of highlighting an important but difficult issue, for which we currently know relatively little about the magnitude and persistence of the consequences for young people.

²² Only 10% of pupils reported being sent offensive or hurtful texts, emails, or online posts.

Notes: Robust standard errors, clustered by school, in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. School fixed effects are included in all specifications. β = coefficient on bullying; $se(\beta)$ robust standard error of β ; δ (calculated using $R-max=1.3*\bar{R}$, as explained in STATA’s `psacalc` routine) indicates how much selection on unobservables would be required to drive the β to zero, measured proportional to selection on observed variables. Results by gender are reported in Web Appendix Table WA4. We lose precision and generally the boy/girl differences are not significant with the exception of the effect on university degree which is found to be strongly negative for boys and zero for girls.

Table 5: *OLS estimates of the effects of ‘bullying factor’ with Oster diagnostics*

c) Best 3 A-level points

f) Mental health at 25

B: Educational context

Compulsory schooling in England starts at age four to five: children are expected to be attending full-time schooling at the age of five and are admitted each September to a “Primary” school before they reach that age. At age 11 (Year Six) there is usually a transition to “secondary” school for a further five years of study, although in a few areas there is an intermediate stage of schooling provided by “middle schools” that cover 11 to 13. The end of compulsory schooling is now somewhat blurred with children being expected to continue in school (usually in secondary schools from 16 to 18 often in the same location/campus as earlier schooling occurred, but sometimes in a “Sixth Form” college that admits children from nearby secondary schools for further study). Further Education colleges offer an alternative post-18 route of mainly vocational training up to age 18; and all those in work from age 16 are expected to combine this with at least 20 hours of training per week that may be based in a FE college or in the workplace. There is often an element of selection by ability, based on earlier attainment, in admission to the academic track in post-16 schools and sixth form colleges.

There is a common curriculum across almost all English schools which is organized into ‘Key Stages’ with KS1 being up to age seven, KS2 being from ages eight to 10, KS3 being ages 11-13, KS4 being ages 14-16, and KS5 being 17-19. There are low stakes tests at the end of each of KS1-3. At the end of KS4, students take the high-stakes General Certificate of Secondary Education examinations (GCSEs). Students are usually examined in between five and ten subjects, and usually needed to attain passing grades (A, B, C) in at least five, including Mathematics and English, in order to be tracked into further academic study in senior high school. After their GCSEs, students may decide to pursue further studies from age 16 to 18, typically in just three or four subjects for study at Advanced (A) level, depending on their academic preferences and intentions toward higher education. Higher Education (HE) admission is driven largely by results in A-level examinations, taken at the end of KS5, that are graded A to E and grades are often converted into a cardinal scale by assigning points to grades to facilitate aggregation to a single metric.

The overwhelming majority of children attend publicly-funded secondary schools which admit children based on parental preferences and ration places at the margin, usually according to school proximity to home, if capacity constraints bind. These include “community” schools that are managed by their Local Education Authorities, although funding is provided under complex arrangements that involve central and local governments—and these arrangements are currently evolving into a national funding formula which allows for high need schools. Approximately 6% of high school children attend private schools, which usually have charitable status and operate on a not-for-profit basis – a small minority of which are faith schools. The majority are non-residential, but some provide “boarding” places. They can admit by ability and can charge fees and may provide bursaries. Home schooling is rare in England (current estimates suggest less than 0.5%), whilst a small proportion of secondary school children (less than 5%) attend academically selective publicly-funded (Grammar) schooling (a reduction from around 20% of much earlier cohorts). There are also publicly-funded schools that use can religious background as an admission requirement and have a degree of autonomy from local government control. Finally, there are an increasing number

other publicly-funded schools, known as Free Schools and Academies. They also have a degree of autonomy from local government, are funded largely from central government, and operate on a non-profit basis.²³

In the UK, the policy approach to bullying has not been prescriptive. A range of resources are made available for the school leadership, allowing the school to choose the most appropriate as opposed to the more formal processes seen in other countries. Among the successful practices in the UK, the authors listed: proactive peer support (peer listening and buddy schemes, peer mediators trained in restorative approaches, and peer “playgrounders”); Head Teacher/School Principal ‘open door’ policy for parents and children; positive play sessions, safe-haven designated spaces; home visits; reactive and restorative strategies. The Department of Education (DfE) has, from 2014, required schools to implement an effective anti-bullying strategy by adopting anti-bullying policies with clear definitions and procedures that are communicated to the whole school community

In addition to investigating educational achievement at school, we also consider the effects on longer term outcomes – at HE and in work. HE is usually pursued from age 18 at over 150 Higher Education Institutions (HEIs), some very small and specialised, which are collectively referred to as universities. Higher education participation rates are over 40% of the cohort and this has grown dramatically in the last three decades. Course fees have been dramatically increased (and public funding almost eliminated) as austerity measures since 2010 but there is now a comprehensive, sophisticated, and highly subsidized, student loan program that supports access, especially for low parental income students. Take-up of these loans is high and repayments are income contingent with any balance after 30 years being written off. As a result, demand for university is relatively inelastic to the posted price, and there is little evidence that fees have resulted in any fall in participation - neither overall, nor for low SES students. Dropping-out is relatively scarce (around 8% across the sector). Although England is geographically small, and so proximity to a university is much easier than in most other countries, the majority of students move away from their parental homes to study HE, and most of those that do will form (or join) households elsewhere when they graduate and start work. Finally, with respect to HE attainment, HEIs in England, (and Wales and Northern Ireland) offer undergraduate courses that are typically 3 years duration, studied mostly on a full-time basis and mostly straight from senior high school. Courses are usually specialized where a single narrow major is often pursued exclusively. Unlike the US, UK undergraduate professional courses such as law, medicine, and management are available across many HEIs.

²³ Free Schools and Academies often belong to chains of similarly branded schools and are effectively new entrants to the sector. Many former community schools have converted to Academy status. Many have a faith focus to them. Academy status was originally given to failing secondary schools, in an attempt to turn them around, but this status has been increasingly given to successful secondary schools who are often then required to assist in the management and operations of nearby weaker schools.

C: LSYPE data

Table WA6 Questions used to constrict non-cognitive skills

Locus of control:

- I can pretty much decide what happens in my life
- If someone is not a success in life, it is usually his fault
- How well you get in this world is mostly a matter of luck
- Even if I do well at school, I will have a hard time
- People like me do not have much of a chance
- If you work hard at something, you will usually succeed

Possible answers: Strongly agree, Agree, Disagree, Strongly disagree

Work ethic:

- Doing well at school means a lot to me
- At school, I work as hard as I can
- Working hard at school now will help me to get on later in life
- If you work hard at something, you will usually succeed

Possible answers: Strongly agree, Agree, Disagree, Strongly disagree
