Abstracts

20th WCLC

September 7–10, 2019 | Barcelona, Spain

MEMBERSHIP OFFER

We're more than 7,500 strong! Won't you join us?

Take advantage of this great value now!

JOIN THE IASLC TODAY!

New Members Only

WCLC Special Offer – Join during the WCLC and get two years for the price of one. Your membership starts immediately and doesn't end until December 31, 2021.

WCLC NEW Regular Member:
US $250.00

WCLC NEW Developing Country Member:
US $50.00

WCLC NEW Allied Professional Member:
US $50.00

WCLC NEW Fellow/Resident/Trainee Member: Free

WCLC NEW Patient/Survivor/Caregiver Member: Free

Here are just some of the benefits you'll receive when you become an IASLC member:

- Member access to the *Journal of Thoracic Oncology*
- Discounts to the IASLC World Conference on Lung Cancer and other scientific meetings
- Opportunity to make an impact by participating on IASLC member committees
- Access to the IASLC member directory

To learn more about levels of membership and benefits, visit: www.iaslc.org/membership.

NSCLC Lunch Symposium at the IASLC 2019 World Conference on Lung Cancer

MEDICAL CROSSFIRE®

Leveraging the Lung Cancer Team in Stage III NSCLC With Immuno-Oncology Strategies

Sunday, 8 September 2019
Registration and Lunch: 11:30 – 12:00
Program: 12:00 – 13:30

Conference Main Entrance:
Fira de Barcelona – Gran Via
Hall 8 – North Access
Foc, 37
08038 Barcelona

Program Location:
Hall 6
Barcelona (2005)

Chair

Naiyer A. Rizvi, MD
Professor of Medicine
Director, Thoracic Oncology
Co-Director, Cancer Immunotherapy Program
Price Chair, Clinical Translational Research
Columbia University Medical Center
New York, New York, USA

Faculty

Keith M. Kerr, FRCPath
Aberdeen University Medical School
Scotland, United Kingdom

Suresh Senan, MRCP, FRCR, PhD
Amsterdam University Medical Center
Amsterdam, Netherlands

Prof. Dr. Rolf Stahel
University Hospital Zurich
Zurich, Switzerland

Agenda Topics:

- Assessing Treatment Standards for Patients With Unresectable Stage III NSCLC
- **Medical Crossfire®** #1: Applying the Data to Patients With Stage III NSCLC
- **Medical Crossfire®** #2: Practical Concepts and Best Practices With Novel Immunotherapies for Management of Immune-Related Adverse Events
- **Medical Crossfire®** #3: Future Applications for Immunotherapy in Stage I-III NSCLC

Overview:

Medical Crossfire®: Leveraging the Lung Cancer Team in Stage III NSCLC With Immuno-Oncology Strategies will feature expert perspectives on the application of immunotherapy as a component of treatment with curative intent in patients with non–small cell lung cancer (NSCLC). This program will feature a multidisciplinary faculty, including world-renowned experts in medical oncology, radiation oncology, and surgery. Current standards of care in patients with unresectable stage III NSCLC will be addressed, including the role of biomarkers and management of immune-related adverse events. Potential future roles for immunotherapy in stage I-III NSCLC will also be discussed, including incorporation into combined modality regimens and perioperative immunotherapy in patients with resectable disease. Throughout the program, expert **Medical Crossfire®** discussion panels will illustrate how experts address challenges in the implementation of immunotherapy for patients with locally advanced NSCLC. Be sure to join us for this exciting opportunity to improve your practice.

Accreditation/Credit Designation

The **Medical Crossfire®: Leveraging the Lung Cancer Team in Stage III NSCLC with Immuno-Oncology Strategies**, Barcelona, Spain, 08/09/2019-08/09/2019 has been accredited by the European Accreditation Council for Continuing Medical Education (EACCME®) with 2 European CME credits (ECMEC®s). Each medical specialist should claim only those hours of credit that he/she actually spent in the educational activity.

Through an agreement between the Union Européenne des Médecins Spécialistes and the American Medical Association, physicians may convert EACCME® credits to an equivalent number of *AMA PRA Category 1 Credits™*. Information on the process to convert EACCME® credit to AMA credit can be found at www.ama-assn.org/education/earn-credit-participation-international-activities.

Live educational activities, occurring outside of Canada, recognised by the UEMS-EACCME® for ECMEC®s are deemed to be Accredited Group Learning Activities (Section 1) as defined by the Maintenance of Certification Program of the Royal College of Physicians and Surgeons of Canada.

View the supporter statement at **gotoper.com/go/WL19Sup**

This program was approved by the IASLC 2019 World Conference on Lung Cancer Program Committee as an independent activity held in conjunction with the IASLC 2019 World Conference on Lung Cancer. This program is not sponsored or endorsed by IASLC and is not part of the official IASLC accredited program.

PL01 NEW QUESTIONS WITH IMAGINATIVE ANSWERS
SUNDAY, SEPTEMBER 8 08:15–09:45

PL01.01 TUMOR-AGNOSTIC BIOLOGICALLY DRIVEN TREATMENTS: AN ENDLESS DREAM?

R. Doebele

University of Colorado, Aurora/United States of America

The identification of several oncogenes in non-small cell lung cancer (NSCLC) along with the development of cognate, targeted tyrosine kinase inhibitors (TKIs) has revolutionized the treatment approach for patients with this disease. Several oncogene targets have been successfully deployed in other malignancies, including melanoma (BRAF), GIST (KIT), CML (BCR-ABL) and other malignancies. However, until recently, the conventional wisdom has said that targeted therapies will not have similar efficacy for the same class of oncogenes across different tumor histologies. This point of view was likely largely grounded in two perceptions: 1) certain oncogenes are heavily associated with certain tumor histologies (e.g., BCR-ABL in CML or EGFR in NSCLC) and 2) based on the differential activity of BRAF/MEK inhibition in melanoma compared to colorectal cancers (CRC) harboring BRAF V600E mutations. Since then, BRAF +/- MEK inhibition has demonstrated remarkable response rates in NSCLC, anaplastic thyroid cancer, and hairy cell leukemia suggesting that CRC may be the exception rather than the rule. In 2012, we identified the first NTRK1 fusion in NSCLC,1 and while prior reports of NTRK gene fusions existed, 2 there were no therapies developed for this oncogene. Preclinical *in vitro* and in vivo models suggested that ATP-competitive inhibitors had activity irrespective of NTRK1/2/3 gene (TRKA/B/C kinases) and also irrespective of tumor histology.3 Clinical trial data with the two lead TRK inhibitors, larotrectinib4 and entrectinib, 5 confirmed both of these preclinical findings of activity in NTRK1/2/3 across tumor histologies, validating the concept of tumor (or tissue) agnostic therapeutic strategies in cancer. Similar to NTRK gene fusions, ALK, ROS1 and RET gene fusions have not only been identified in NSCLC, but also in other tumor histologies. Clinical data suggest similar opportunities for these oncogene targets. For examples, entrectinib generated a robust and durable response in a patient with GOPC-ROS1 fusion melanoma6 and similar responses have been noted in ROS1 fusion IMT.7 Basket clinical trials of ROS1 inhibitors are now ongoing. RET gene fusions are targetable alterations in NSCLC as well as other malignancies, and now improved, highly RET-selective inhibitors under development with encouraging activity.8 NRG1 gene fusions represent another opportunity for a tumor agnostic development. Although first described in NSCLC (specifically, invasive mucinous adenocarcinomas),9 these novel fusion genes that signal via HER2/HER3 heterodimers have been described across numerous tumor types, including pancreatic, ovarian, and other cancers, albeit at a low estimated frequency of 0.2%.10 This low frequency is a common reason cited to not pursue such strategies, but given the immense heterogeneity of cancer it is likely that we will further fragment cancer types based on their underlying biology. Additional tumor agnostic targets include ALK gene fusions, HER2 mutations, EGFR mutations (including exon 20 insertions), FGFR1/2/3 fusions, BRAF fusions, MET (exon 14 skipping, gene amplification, and fusions), and others. Indeed, several KRAS mutant selective inhibitors are under development and may open the flood gates for tumor agnostic trials given the frequency of mutations in this oncogene. Success of tumor agnostic strategies will be dictated by appropriate biomarker selection, which may differ for each tumor types, robust testing methods that capture the majority of oncogenic variants (NRG1 is a good example that is not currently covered on many assays), and implementation of panel-based next generation sequencing applications in more routine practice. While it is likely that we already have the testing capability and even the appropriate drugs to to target these tumor agnostic oncogenes, infrastructure changes at institutions may need to be enacted to allow for clinical trial teams that enroll from many disease types, similar to existing phase I teams. The NSCLC community of oncologists, researchers, pathologists, patient advocates, and commercial partners has had immense success in realizing the dream of precision oncology strategies and can lead the way to distribute the knowledge gained over the last decade in precision oncology strategies

PL01 NEW QUESTIONS WITH IMAGINATIVE ANSWERS
SUNDAY, SEPTEMBER 8 08:15–09:45

PL01.02 THE EVOLUTION OF TISSUE TESTING FOR IMMUNOTHERAPY - WHERE NEXT?

K. Kerr

University of Aberdeen, School of Medicine and Dentistry, Aberdeen/United Kingdom

Biomarkers have, to date, had an uneasy relationship with immunotherapy in lung cancer, a conflict between the degree of biomarker expression (largely PD-L1) being related to treatment efficacy, and a desire to give these drugs to everyone, either as monotherapy or, increasingly, in combination with other drugs. PD-L1 immunohistochemistry (IHC) is well established as a companion or complementary diagnostic, depending on indication, and tumour mutational burden (TMB) is an item of interest, with a surrogate, MSI-high, approved by the FDA in a tumour-type agnostic setting for second/greater line therapy. Where is PD-L1 testing going? PD-L1 IHC will remain a useful test. PD-L1 IHC scoring in cytology-type samples has been validated outside clinical trials and will become accepted in daily practice. New IHC clones will challenge the place of existing ones, hopefully validated by comparative study and EQA. Data are emerging on the clinical validity of PD-L1 scoring on small amounts of tumour (the heterogeneity issue), how few cells can be used, and the clinical impact of scoring PD-L1 on insufficient material. Tumour Mutational Burden Difficulties with the PD-L1 IHC biomarker drove the search for alternatives and TMB, as a several times removed surrogate of tumour immunogenicity, emerged. The place for TMB in the diagnostic algorithm remains uncertain but clinical trials looking at tumour tissue or blood TMB continue to provide promising, if confusing, results. Many of the issues with PD-L1 IHC are also in play with TMB. There is no consensus about what is 'high TMB'? TMB is another biological continuum, like PD-L1 expression, so the creation of a binary high vs low categorization potentially ignores

relative biological significance of different levels. There is huge variability in the methodology used to derive or predict TMB, the amount of the genome screened, different definitions of a 'mutation', different next generation sequencing platforms, different contexts (tumour tissue vs blood) and a lack of published data on how these different TMB assessment approaches vary. Anecdotal reports so far indicate substantial variation. As a predictive biomarker in this setting, TMB works; it enriches a treatment group for benefit. But we have seen relatively little comparative data to suggest superiority over any other singular biomarker in this treatment area. TMB is a crude predictor of tumour neo-antigenicity and perhaps we should look to more specific measures of this aspect of sensitivity to immunotherapy. It is possible to predict probable neo-antigenicity from deep analysis of sequencing data. Neo-antigens should be clonal, rather than subclonal, to maximize their immune impact. Are their particular genes whose alteration would predict greater (or lesser) tumour 'visbility' to the immune system, be they involved in DNA repair, maintaining genome stability or integrity, antigen processing and presentation, or more likely to generate immunogenic proteins? Other factors such as loss of heterozygosity at MHC coding genes may also provide useful information. So, it may well be possible to refine our assessment of TMB into a more specific and meaningful metric. This then raises the question of whether it is practical to do so, and whether this provides clinically useful information. Tumour inflammation For immune checkpoint inhibitors (ICI) to work, a tumour specific immune response must be 'available' and somehow inhibited by the checkpoints being therapeutically targeted. Assessments of tumour inflammation, as a presumptive sign of such an available but inhibited immune response, have been successfully used to enrich a treatment group for benefit from ICI therapy. In lung cancer, these assessments of inflammation have been relatively complex assays of immune gene signature expression using mRNA extracted for fresh/frozen tumour tissue. Initially large panels of immune response-related genes have been reduced to single digit-sized panels. Interferon gamma seems to be important as is, unsurprisingly, PD-L1. The same questions arise with respect to immune gene signatures. Is this any better than a more simplistic approach such as PD-L1 IHC? Evidence is at best marginal, that it would be superior. Is this practical and affordable in a daily practice setting? Probably not. Are there alternative ways to derive the same information? Probably yes. In other tumour sites, a morphological assessment of tumour inflammation has been more keenly pursued than in lung cancer. This approach has tended to focus on the presence and location of the immune cell infiltrate and to some extent, on the nature of the infiltrating cells. When tumour sample area allows, immune cell activity at the tumour-stromal interface, and the presence of CD8-expressing T cells have been associated with better responses to ICI. There is much more that could be investigated, especially in relation to other immune-active or immune-suppressive cell types and their location within the tumour and its microenvironment (TME). Immunohistochemistry is readily available, but in order to understand the complexity of this process and find new biomarkers, in limited tissue samples, multiplex IHC and digital pathology analysis tools will almost certainly be required. These tools already exist but the challenge will be generating the data in relation to clinical response and then deployment in daily practice. Other regulation in the TME Other factors in the TME, such as tissue hypoxia and lactate dehydrogenase, are relevant biomarkers, indicating an immune-suppressive environment, and potential resistance to ICI therapy. Other factors like IDO, and other immune checkpoints like LAG3 and TIM3 may also confer resistance to current ICI therapy and provide new therapeutic targets. Conclusion There is much more to be learned about factors that regulate responsiveness to ICI therapy. The multifactorial complexity of the immune response suggests that combinations of biomarkers are more likely to provide better prediction of therapeutic benefit. Many of these factors are more likely to be continuous variables rather than binary metrics, and oncology will have to learn to deal with this situation, perhaps more akin to a complementary rather than a companion diagnostic, leading to more nuanced therapeutic decisions. It remains to be seen whether oncology, regulatory authorities or industry has an appetite for such an approach. References Blank CU et al. Science 2016;352,658 Camidge DR et al. PL01.03 WILL THE IMMUNOTHERAPY WITH NEWER BIOMARKERS, COMBINATION THERAPY OR NEW TECHNOLOGY EVENTUALLY CURE LUNG CANCER?

T. Mitsudomi

Kindai University Faculty of Medicine, Osaka-Sayama/Japan

The recent introduction of immune checkpoint therapy has greatly changed the clinical practice of non-small cell lung cancer (NSCLC). A battery of clinical trials showed the superiority of either PD-1 antibody monotherapy or PD-1/L1 antibody combined with chemotherapy as a first-line treatment of NSCLC over standard platinum doublet chemotherapy that has long been a standard of care. Hence, most if not all of NSCLC patients receive PD-1/L1 antibodies unless contraindicated due to coexisting immune-related comorbidities. The recent update of the Keynote-001 trial showed that 5-year survival of the high expressors of PD-L1 treated with pembrolizumab as a first-line treatment was 23%. Especially, the 5-year survival rate of patients who received the first-line pembrolizumab more than 2 years was 79%. This really indicates that at least some of the NSCLC patients may be cured by monotherapy of PD-1 antibodies. Conversely, about three fourth of patients, even with high expression of PD-L1 cannot survive for more than 5 years. This is natural considering the complexity of immunologic mechanisms against cancer. To be eliminated effectively by PD-1/L1 treatment, cancers should express their unique antigens typically generated by somatic mutations in the context of MHC. Therefore, the adequate quantity as well as the adequate quality of somatic mutations and intact antigen presentation, are prerequisite for immune response. When abnormal peptide is recognized by immune cells, adaptive expression of PD-L1 on the tumor cells occurs by secretion of interferon γ by T cells as a negative feedback that dampens antitumor immunity, Upon binding of PD-L1 with PD-1 on T cells downregulates T cell function. This tumor microenvironment (TME) is the best candidate for anti-PD-1/PD-L1 therapy. However, not all cancer has this TME. Besides PD-1/L1 systems, there are many other molecules such as CTLA4, TIGIT, TIM3, LAG3, etc. that negatively regulate the immune response. Regulatory T cells and myeloid-derived suppressor cells (MDSC) are also major players of immunosuppressive TME To overcome these immunologic evasions, many strategies are being extensively sought. To enhance immune recognition of mutations and to prime new response, polypeptide or RNA-based vaccines that contain mutation-derived epitopes are being tested. For tumor cells that lost HLA molecules, enhancement of NK cell activities through NKG2A antibody or anti KIR antibody may be effective. To overcome adaptive immune resistance by molecules other that PD-1, use of blocking antibodies against above-mentioned other co-inhibitory molecules or agonistic antibodies against co-stimulatory molecules such as ICOS, GITR, 4-1BB, OX40, etc. is a rational way. Finally, to reverse immune suppressive TME, use of antibodies against CSF-1R and CCR4 to suppress MDSC and regulatory T cells, respectively, may be effective. Antagonists for immunosuppressive molecules such as adenosine A2AR, IDO, TGFb, etc are also expected to enhance tumor immunity. Will the Immunotherapy eventually cure lung cancer? Currently, I have to say "Yes, for some but not sure for every patient". In this talk, I would like to discuss ongoing efforts to further improve outcomes of immune-therapy of lung cancer and future perspectives.

Keywords: future strategy, Immunotherapy, new combination

PL01 NEW QUESTIONS WITH IMAGINATIVE ANSWERS
SUNDAY, SEPTEMBER 8 08:15–09:45

PL01.04 ARTIFICIAL INTELLIGENCE, BIG DATA AND LUNG CANCER: READY TO IMPLEMENT?

H. Aerts

Harvard-DFCI, Boston/United States of America

A critical barrier present in cancer research and treatment today is when and how to act based on the information provided from tumor data. One important reason for the slow progress in the fight against cancer, is the fact that cancer is a "moving target". It is constantly evolving and diversifying, changing its phenotype, its genomic composition, and through metastatic spread, even its location. This

is even more true when subjected to the pressure of therapeutic intervention, where cancer evolution rapidly explores and exploits resistance mechanisms, potentially even aided by the mutagenic nature of cancer treatments, leaving the treating oncologist chasing a constantly changing disease. Artificial Intelligence (AI) and Deep Learning technologies have recently led to revolutionary advances in areas ranging from computer vision to speech recognition - tasks that up to a few years ago could only be done by humans. AI has the potential to fundamentally alter the way medicine is practiced, as it excels in recognizing complex patterns in medical data and provides a quantitative, rather than qualitative, assessment of clinical conditions. AI-powered radiographic-biomarkers ("radiomics") may quantify non-invasive information of the cancer phenotype that is clinically actionable, and may further improve diagnosis, characterization, and longitudinal tracking through therapy. AI methods are precise and allow specific quantification of features not otherwise quantifiable by human experts. Radiomic-analysis is performed on the entire tumor as compared to just a small sample for molecular analysis and provides a non-invasive window into internal growth pattern of the tumor (including internal textural heterogeneity, macroscopic necrosis, and viable tumor mass). Radiomics can thus quantify the phenotypic state of a tumor within its evolutionary process, thereby sidestepping issues relating to biopsies. This is particularly important for patients with cancer, where different cancer lesions can express different microenvironments that could ultimately lead to heterogeneous response patterns. Despite the remarkable success of novel cancer therapies, the clinical benefit remains limited to a subset. Cancer therapies are often expensive and could bring unnecessary toxicity, there is a direct need to identify beneficial patients, but this remains difficult in the clinic today. Radiomics biomarkers could provide this information on a lesion and patient level using standard-of-care CT scans. Unlike biopsy assays that - by definition - only represent a sample within the tumor, imaging can depict a full picture of the entire tumor burden, providing information of each cancer lesion within a single non-invasive examination. Another field that will be impacted by AI and big data is radiation oncology. Radiation oncology as a therapeutic specialty presents itself as an exemplary field that will be impacted by AI automation. Especially as much of the current radiation therapy work flow requires time-consuming, manual labor by both radiation oncologists and a team of medical staff including medical physicists, certified medical dosimetrists, and radiation therapists. The growing complexity of the human-machine and human-software interactions in conjunction with the increasing incidences of cancer have created a workforce shortage throughout the world. In fact, variations in the radiation treatment planning process can lead to significant differences in the quality of care, and negatively impact overall survival even in clinical settings where extra care is given to standardizing segmentation and planning approaches. Furthermore, the knowledge and experience gap between more developed and under-resourced health care environments poses an enormous public health challenge and represents one of the great global inequities in cancer care. In this talk, Dr. Aerts will discuss recent developments from his group and collaborators performing research at the intersection of artificial intelligence big data, and oncology. Also, he will discuss recent work of building a computational image analysis system to extract deep learning algorithms and use these to build radiomic signatures. The presentation will conclude with a discussion of future work on building integrative systems incorporating both molecular and phenotypic data to improve cancer therapies.

PL03.02 BRINGING IMMUNOTHERAPY INTO THE CURATIVE SETTING: EMERGING DATA ON NEOADJUVANT STRATEGIES

J. Chaft

Memorial Sloan Kettering Cancer Center, New York/United States of America

Immunotherapy with checkpoint inhibitors targeting PD-1 and PD-L1, as monotherapy or in combination with chemotherapy, have become standard of care in all patients with advanced lung cancer who do not have an actionable oncogene or contraindication.1, 2 Similarly patients with unresectable stage III non-small cell lung cancer who do not progress through concurrent chemoradiotherapy have improved progression free and overall survival with anti-PD-L1 consolidation therapy.3 In early-stage disease, four randomized phase 3 studies are evaluating the role of adjuvant immunotherapy following standard of care chemotherapy. As is the nature of adjuvant investigation, these studies require years of clinical follow-up and will not mature until sufficient recurrence and/or death events occur. Neoadjuvant therapy has many advantages to the patient and for the sake of science. As a therapy, preop treatment is better tolerated and can be monitored for efficacy by imaging and pathologic regression. In terms of research, the early pathologic response endpoint may accelerate trial readouts. Investigation into pathologic response as a surrogate for survival in lung cancer is ongoing.4 The true excitement about neoadjuvant investigation with immunotherapy and/or chemo-immuno combinations, is the theoretical therapeutic superiority of this approach over an adjuvant approach. This is hypothesized to be due to the tumor with its associated mutation specific neoantigens *in situ* during exposure to the PD-1 treatment, enabling a more robust tumor specific immune response. In pre-clinical mouse models, PD-1 monotherapy is more effective when administered neoadjuvantly versus adjuvantly.5 The first experience with neoadjuvant PD-1 therapy in NSCLC was a small pilot study performed for safety and feasibility of this approach. No unexpected safety signals were noted and unanticipated pathologic regression observed.6 Two additional series with neoadjuvant immunotherapy have been presented, the Lung Cancer Mutation Consortiums experience with PD-L1 monotherapy and the MD Anderson study of PD-1 +/- CTLA-4 therapy. Both studies confirmed this approach is both safe and induces pathologic regression (at times pathologic complete response) in some patients.7, 8 Correlative studies to try to identify predictors of response and resistance are ongoing. PD-L1 expression is not as clearly predictive in this patient population as in advanced disease. Shortly after PD-1 monotherapy was demonstrated to be safe and have some anti-cancer efficacy, many other monotherapy and combination studies launched. Two combination studies rapidly accrued. The combination of carboplatin, a taxane, and a PD-1/L1 agent have been demonstrated by two groups to induce major pathologic regression in the majority of patients.9, 10 In the Spanish Lung Cancer Group study, complete pathologic response was seen in more than 50% of resected patients.10 These studies have spurred a tremendous interest in the best neoadjuvant therapy. There are 4 international phase 3 studies enrolling patients to receiving neoadjuvant chemotherapy with or without immunotherapy (NCT03800134, NCT03456063, NCT03425643, NCT02998528). Many of these studies have pre-specified pathologic response co-primary endpoints that will be evaluable well before classic clinical endpoints. These studies will help substantiate the role of immunotherapy in the preoperative setting and pathologic response as a possible surrogate endpoint. As the international adjuvant immunotherapy efforts wrap up, the research community should commit to enrolling patients on neoadjuvant studies. This is our best chance to improve cure rates in early stage lung cancer – to identify effective therapy for those cancers of a clinical stage to justify induction therapy and adjuvant therapy for those incidentally upstaged at the time of surgery. Within these therapeutic studies are essential biomarker efforts. These efforts are poised to be successful and position the research community to extend investigation into the earliest stages of non-small cell lung cancer, looking to improve cure rates for all stages of disease.

PL03.03 THE DISPARITY OF LUNG CANCER PREVENTION, DIAGNOSIS AND TREATMENT AROUND THE WORLD... WHAT IS THE ROLE OF IASLC

S. Ramalingam

Emory School of Medicine, Atlanta/United States of America

Lung cancer is a global health problem that results in over 1.8 million deaths globally each year. Diagnosis at an advanced stage, lack of effective treatment options and disabling co-morbid conditions, have all contributed to the poor outlook for patients with lung cancer. However, there is now new hope in the global fight against lung cancer. Improved understanding of the biology of the disease, early diagnosis and effective therapies have contributed to growing optimism. The International Association for the Study of Lung Cancer (IASLC) has been at the forefront of research and education by bringing together committed scientists, physicians, care providers, epidemiologists, nursing staff and patient communities to increase awareness, develop improved staging systems, fund research for early career researchers, promote development of novel therapies, and educate healthcare professionals at all levels. Tobacco smoking contributes to approximately 85-90% of all cases of lung cancer; while the prevalence of smoking has reduced in many developed countries, it appears to be on the upswing in developing nations. More recently, the introduction of electronic nicotine delivery systems (ENDS) has raised the possibility of creating a new generation of the population addicted to nicotine. Any efforts to reduce the burden of lung cancer has to start with educating the public about the health hazards related to smoking, tobacco cessation programs and reducing the access of teenagers and young adults to tobacco products. Early detection by adopting screening programs will be another important strategy to reduce the burden of lung cancer. In recent years, the reduction in mortality related to lung cancer by adopting low dose CT screening in high risk individuals has been proven beyond doubt. Despite this evidence, only a minority of eligible patients are being screened for lung cancer, even in developed nations. To increase adoption of screening, we have to collectively engage in educating the primary care physicians, subjects at risk and the entire health care community. Diagnosis of lung cancer at earlier stages will result in greater likelihood of cure due to the exciting advances that have taken place in the management of patients with stages I, II and III NSCLC. Even for patients diagnosed with advanced stage lung cancer, long term survival is possible; precision therapies directed to oncogenic molecular events, immune checkpoint inhibitors and multi-modality treatment approaches have all contributed to the recent progress. For patients with mutations in the epidermal growth factor receptor and aberrations in the anaplastic lymphoma kinase gene, the median survival for stage 4 disease is now measured in years with the use of specific targeted treatment approaches. There

are at least five genomic targets in lung adenocarcinoma that can be treated with specific tyrosine kinase inhibitors. It is likely that more genomic mutations will join the list of treatable aberrations, thanks to the rapid pace of drug development. Molecular testing remains critical to the ability to personalize therapies for patients with lung cancer. A recent survey conducted by the IASLC across the world noted several barriers to routine adoption of molecular testing. Finally, access to cutting-edge therapies is a major challenge in several parts of the world. Rising costs of healthcare and medicines have resulted in the inability for patients to receive optimal care. Our efforts to improve lung cancer outcomes and reduce the burden of this disease will have to address every one of these issues. The IASLC is launching an ambitious program to double the 5-year survival rate for patients with lung cancer later this year. This will be accomplished by a multi-pronged approach to promote early detection, optimal staging and diagnostic testing and by addressing survivorship issues. A new staging system seeks to integrate molecular knowledge to traditional clinical staging in order to provide precise prognostic information. Investments in improving the sensitivity of CT screening, promoting universal standards for CT imaging and partnering with other societies to increase awareness regarding early detection will all be important components of this strategy. The IASLC has made major contributions to diagnosis of lung cancer by developing a new pathology classification system for lung cancer; it has also conducted original research to improve biomarker testing and promote education on molecular diagnosis. In the upcoming years, the IASLC will seek to study the correlation between major pathological response with neo-adjuvant therapy and overall survival. This will allow for earlier utilization of exciting novel agents to be used as part of curative therapies for early stage NSCLC. The IASLC will also promote research on issues specific to survivorship; as long-term outcomes for lung cancer patients becomes a reality, it is important to learn about coping with physical and emotional challenges that can be related to their journey. Very little work has been conducted to date on this topic. In conclusion, the time is ripe for us to launch a collective campaign to reduce the burden of lung cancer globally. The IASLC will partner with like-minded organizations, and engage its membership to aggressively pursue innovative approaches that will ultimately result in lower number of patients diagnosed with lung cancer, and improved survival and quality of life for patients afflicted with lung cancer.

TUESDAY, SEPTEMBER 10 09:15–10:45

PL03.04 LUNG CANCER AND TUBERCULOSIS: PARALLEL LIVES

T. Molnar

University of Pécs, Pécs/Hungary

It is a Battlefield. Searching for parallelisms, using historical analogies is a well established method in many fields of soft sciences, medical humanities included. A challenge of seemingly repetitive failure patterns and paradigm shift structures are to be answered in the following imaginary experiment. The aim is the creation of a mental model where understanding of developments and mistakes in treatment of tuberculosis might support our fight against lung cancer (1). The two diseases are existing parallely – one mainly for the poor and young and the other for the richer and older. History of tuberculosis follows the classic algorhythm: diagnostic (Villemin, Virchow), casuistic (Koch) and therapeutical (Waksman/ Streptomycin) stages. The therapeutical phase of lung cancer has been reached without identified cause of the disease. Eradication of the macrosocopic focus by physical interference with the involved tissue mass, in both diseases preceeded medical treatment. Causation is not an absolute sine qua non of an effective treatment, as the tuberculosis-lung cancer analogy also proves. While lung cancer seems to be controlled by an emerging array of new drugs, tuberculosis poses a new challenge. Tuberculosis of the lung is a systemic disease, best treated by drugs with additional surgical removal of the focus of the disease as a last option. The disease has a fairly good chance of around 90% of to be cured (2). The prognostic factors include the functional and immunological reserves of the patient. Stage I to III lung cancer is a local manifestation of a systemic disease without sufficiently identified aetiology. Therapy response is understood at cohort level, but it is unpredictable where the individual patient's fate is concerned. For reasons unknown, mechanical eradication offers the best chance for cure in early stages of the tumour. Some parallelism between tuberculosis and lung cancer might be of interest. In Search of a Character If progress takes a standstill categorization, fever takes over. Lymphnodes are the central elements of the Ghon and Ranke complexes.(3) of the tuberculous lung. The TNM system, a topology approach gyrates around the N status as well. (4). The desire to find a strong characteristic prognostic/predictive element resulted in the Gaffky index (5). The number of Koch bacillus in the sputum as a prognostic tool failed to validate the theory. The discussions of stations and size of lymphnodes in lung cancer (6) might share the fate of the Gaffky index. A Burnt out Case? There are disturbing similarities in the phenomenon of a late relapse/recurrence in both diseases. The dormant Koch bacillus vs exogenous reinfection debate (7) is paralleled by the dormant cancer cell hypothesis (8). Journey without Maps Circulating Koch bacillus, and their prognostic value hotly debated in the 1920s, are comparable to the circulating tumor cell question. The bloodstream journey polemic settled down by 1950, the "seed and and soil" theory of cancer cells is subject of intense research. The Heart of the Matter Till the 1960s all tuberculosis cases seemed to be the same, until atypical tuberculosis was identified and the *Mycobacterium xenopi* lost its stigmatising power (95). Certain phenotypes of the adenocarcinoma *in situ* behaves definitely in a more benign way than any other cell type NSCLC. In 2019, we still do not know what is the single causative agent (if it exists at all) of NSCLC (if it exists at all as a single entity). The Copernican revolution in tumour biology is still awaited. The Power and the Glory Tuberculosis taught us, that the disease affects the body and the soul as well, reflecting to the society around the patient as well. Lung cancer treatment also depend on the immune status of the individual as well as on the protective capabilities of the science and the society. Affordability and avaibility of anticancer treatments/ drugs are key words yet not interchangeable (8). Onco-economy is as a powerful factor as gene sequencing. A scalpel for sale Our techniques to treat lung cancer are rooted in surgery for tuberculosis (1). VATS techniques take their origin in Jacobeus' thoracoscopy and Veress needle. Modern thoracic surgical staplers are derivates of the "Russian machines", Petz staplers adjusted to tuberculotic bronchi. Thoracic surgery practiced in local anesthesia for many decades, is genuine awake/non-intubated thoracic surgery of today. The recent debate over neoadjuvant *vs.* adjuvant therapy reflects to the bygone dispute on resection before or after antituberculous medical treatment. The different modalities are no mutually exclusive options, but complementary ones. The End of the Affair: Conclusion. The main message of tuberculosis to present day oncopulmonologists is that no one can forget the interaction between tumour and patient and his/her socioeconomic status around the pathologically identified focus. PL04.02 WHAT DOES SURVIVORSHIP MEAN IN THE WORLD OF IMMUNOTHERAPY (PHYSICAL AND FINANCIAL)?

M. Turner

Johns Hopkins Kimmel Cancer Center, Baltimore/United States of America

With improvements in diagnostic, therapeutic, and supportive therapies, the number of cancer survivors continues growing with over 20 million cancer survivors worldwide and an estimated 2/3 of adults with a cancer diagnosis who are anticipated to be alive in 5 years[1]. Due to this increase in survivors, major medical societies such as American Society of Clinical Oncology (ASCO), Institute of Medicine (IOM), and the Society for Immunotherapy of Cancer's (SITC) have highlighted the need for strategies to improve the ongoing care of survivors and survivorship plans.[2] The 4 basic tenets of a survivorship plan are surveillance, prevention, intervention and coordination. Surveillance is aimed at monitoring for recurrence, second cancers, and long term toxicities, prevention of these sequelae if possible, intervention if they are found, and lastly coordination between hospital and community-based doctors is essential for this plan to be effective.[3] These needs are typically communicated to the patient's general practitioner (GP)/primary care physician (PCP) by a "care plan" that outlines the patient's oncology treatment course, potential long-term toxicity, the frequency of follow up visits, scans and links to community resources. New cancer therapies such as immunotherapy has resulted in significantly improved overall survivals in many advanced cancers, including those that had formerly been considered refractory.[6,7,8] However, the short-, intermediate-, and long-term complications of these therapeutic agents are still being identified. Immune-mediated events, for example, can occur immediately after therapy initiation or even up to two years post treatment as a consequence of overstimulation of the immune system leading to autoimmunity with the potential for permanent or long-term sequelae.[4,5] References: 1. https://cancercontrol.cancer.gov/ocs/statistics/statistics.html 2. https://www.canceradvocacy.org/ 3. PL04.03 THE RELEVANCE OF AN INTERNATIONAL DATABASE FOR THE STUDY OF THYMIC NEOPLASMS

V. Bolejack

Cancer Research and Biostatistics, Seattle/United States of America

Introduction: Until the 8th edition of the AJCC/UICC TNM classification of malignant tumours went into effect, no official stage classification was available for thymic malignancies. Some classification systems had been proposed but were generally developed from a limited number of patients and not usually tested in an independent dataset. The system developed by Dr. Akira Masaoka in 1981 did undergo external validation and was widely adopted. However, the adoption of these proposed systems in different institutions and regions was hampered by a lack of uniform nomenclature and varying interpretations of definitions. The current (8thedition) TNM stage classification for thymic malignancies endorsed by AJCC and UICC was informed by a database with 10,808 cases of thymic malignancies from 105 sites worldwide, compiling cases contributed by ITMIG (including patients from North and South America, European, and Korean (KART) and Chinese (ChART) institutions), Japan (JART), and Europe (ESTS) with funding and coordination by IASLC and Cancer Research and Biostatistics (CRAB), with the specific intent of developing a TNM based staging system for these malignancies. Methods and materials The IASLC Stating and Prognostic Factors Committee - Thymic Domain (SPFC-TD) conducted a web-based cross-sectional survey to assess the implementation of the 8thEdition TNM staging system in the thoracic community. The survey was sent to the major thymic organizations (ITMIG, ESTS, KART, ChART, RYTHMIC, JART) in addition to IASLC membership. A new database to inform the 9thedition TMN staging system is under development to provide updated follow-up from the institutions contributing to the 8thedition database, add additional institutions, and add new cases collected prospectively. Results According to the survey results, the TNM stage classification of thymic tumors has gained a reasonable acceptance in the scientific community, while the Masaoka stage system remains widely employed. An increased attention to the N descriptor seems to have been incorporated. There is high awareness of the new staging system. The current efforts of the Thymic Domain of the IASLC Staging and Prognostic Factors Committee focus on expanding and updating the database used for the 8thedition to further refine the stage definitions and includes updated follow-up on patients from Turkey, the ESTS, JART, ChART and KART, plus data collected prospectively from ChART. Conclusion The database created to inform the 9thedition of TNM staging for thymic malignancies will allow for refinement and adjustment of the 8thedition system and attempt to address any perceived deficiencies of the current system. An overview of the current state of the database will be presented at the meeting in Barcelona.

TUESDAY, SEPTEMBER 10 16:15–17:00

PL04.04 PROGNOSTIC FACTORS IN MALIGNANT PLEURAL MESOTHELIOMA

M. Kirschner

University Hospital Zurich, Zurich/Switzerland

Malignant pleural mesothelioma (MPM) is a disease for which we are facing difficulties and challenges at many levels from diagnosis over treatment selection and prediction of treatment response to prediction of the prognosis of individual patients. Besides the necessities to obtain an accurate and early diagnosis and to be able to predict the response to a specific treatment, it is equally important to be able to estimate the overall prognosis of a patient as this will also affect treatment decisions. Looking at the research efforts of the last two decades, we see an abundance of studies investigating prognostic markers for MPM, yet to date the most reliable predictors of disease outcome are still the clinical and pathological parameters, which have been used in the past. Probably the most accurate prognostic factor for MPM is the histopathological subtype, with epithelioid MPM being associated with the best prognosis followed by the biphasic subtype and sarcomatoid histology. In addition, it is well recognised that patients presenting with less advanced disease, of younger age and female gender are generally doing better. Some of these factors were combined with additional proposed predictors of outcome into scoring systems suggested by the European Organization for Research and Treatment of Cancer (EORTC, [1]) and the Cancer and Leukemia Group B (CALGB, [2]). Both scores have been subsequently validated and still hold true today, over 20 years later. Since then, many studies have attempted to identify additional prognostic biomarkers. One area of extensive research is the investigation of changes in blood cell ratios, which can be linked to the inflammatory and/or nutritional status of the patients [3, 4]. In terms of inflammation-related indicators of poor outcome, elevated C-reactive protein (CRP), a high neutrophil-to-lymphocyte ratio, and a low lymphocyte-to-monocyte ratio (LMR) have been proposed. Some of these inflammatory markers have also been combined with factors reflecting the nutritional status of patients. For example, has the combination of CRP and albumin been suggested to have prognostic value, as shown in the CRP-to-albumin ratio (CAR) and the modified Glasgow Prognostic Score (mGPS). Another proposed combination is that of albumin and lymphocytes into the Prognostic Nutritional Index (PNI). Additionally, radiological factors, such as tumour volume or pleural thickness measured by CT or MRI alone or as part of prognostic scores (e.g. in combination with other factors such as in the multimodality prognostic score [5]), as well as radiomics approaches have shown prognostic potential [6]. While many of these proposed prognostic factors are often routinely collected during standard clinical work-up and blood tests, prospective

testing in a clinical setting has yet to be attempted. A second area of extensive research in the last decade has been molecular factors, namely the expression of proteins, genes, and microRNAs [3]. Initially, the majority of studies focused on the potential prognostic role of protein expression in tumour tissue. Here, rather frequently, the expression of tyrosine kinases such as epidermal growth factor receptor (EGFR) and c-Met has been investigated, due to the additional potential of targeting those using tyrosine kinase inhibitors. In addition, many cell cycle and apoptosis-related proteins such as p21, p53, survivin or PTEN were evaluated, but in many cases these proteins did not reach significance in multivariate analyses, highlighting that they do not represent independent markers. Other proteins, such as ERCC1 and TS, the target of the antimetabolite drug pemetrexed, did not show consistent results between various studies, hence none of these proteins are used routinely in the clinic. On the level of gene expression, already 15 years ago a 4-gene signature was proposed, which was subsequently independently validated, but never in a prospective fashion. In addition to gene expression, microRNAs have also been proposed to hold prognostic value, but again, independent validation is thus far lacking. While many candidate prognostic biomarkers have been proposed, these tend to be dependent on the histological subtype, and the identification of factors predictive of outcome within the individual histological subgroups of MPM patients remains a major challenge. However, with more genetic profiling of larger datasets becoming available also in MPM, investigators have started to address this issue. By aiming to genetically subclassify pathologically purely epithelioid or sarcomatoid tumours, this resulted in the C1/C2 classification [7] and the e-score and s-score classification [8], as well as the 4 cluster iCluster classification generated based on TCGA data [9]. Besides providing potential novel prognostic factors, the molecular characterization of MPM can also provide us with urgently needed deeper insights into the biology of the different subgroups of MPM, which is likely to allow us to identify novel treatment targets together with respective markers predictive of response. Nevertheless, these exciting recent findings remain to be independently validated, most importantly in a prospective fashion. A closer look at the literature of the last two decades, however, shows us that rather than aiming at validation of proposed prognostic factors, we are inclined to identify novel candidates. In order to move these promising novel candidates from the bench to the bedside, international collaboration to increase cohort sizes as well as prospective validation will be crucial.

CS01 CONTROVERSIES IN NSCLC OMD
MONDAY, SEPTEMBER 9 11:00–12:30

CS01.01 "HUNTING A GHOST FOR 25 YEARS – WILL WE EVER CATCH OMD?" - NO

T. Treasure

University College London, London/United Kingdom

Oligometastatic disease (OMD) is no more and no less than what it say on the label. It is cancer with few metastases, no more than can be counted on the fingers of one hand. A few metastases can be locally eradicated with surgery, image guided thermal ablation (IGTA) or with stereotactic ablative radiotherapy (SABR) but beyond five it becomes increasingly impractical to attempt local control. Total eradication is unlikely and systemic treatment makes more sense. So five or fewer identified metastases fit a working definition of OMD as treatable by local interventions. 'Framing' disease according to suitability for treatment has always been part of clinical practice. Diagnostic frames shift over time. A classic example is the emergence of 'ESRD' (end stage renal disease) as a diagnosis. 18thC diagnoses depended on clinical descriptions. 'Dropsy' was illness characterised by water retention; what we call oedema. William Withering observed that some of those sick with dropsy were helped by infusions of foxglove. Later Richard Bright discovered protein in the urine of others. At autopsy he found shrivelled kidneys and dropsy had to be reframed, depending on whether it was the heart or the kidneys that were failing. Aetiology, pathophysiology, and histology sequentially framed the many types of kidney disease through the 1960s but effective treatment only became available with dialysis and transplantation. Long-term survival was possible but was too costly for nearly all individuals and their families. In 1972 US Congress passed Public Law 92-603 which framed a new diagnosis: ESRD. Patients with end stage renal disease were entitled to federal funding. In 1974 ESRD appeared for the first time in PubMed in a paper about public financing. ESRD has been used in titles or abstracts 15,282 times since and runs at over a thousand citations a year. Hellman and Weichselbaum proposed the term 'oligometastases' in 1995 to describe a clinical state between freedom from metastases and their 'extensive and widespread' presence. (Figure) A search for <oligometas*> reveals very few publications for about 10 years. Improving resolution of CT, and then PET imaging, allowed the counting of macroscopic metastases by being more confident of the *absence* of further macroscopic metastases. That was a prerequisite to diagnose OMD. Weichselbaum had in mind that "recognition .. of a state of oligometastases is necessary to invite active clinical investigation of new and potentially curative therapeutic strategies". In practical terms it is the therapeutic opportunity that makes OMD a useful working diagnosis, summarised as few enough to 'zap'. In 2015 Joseph Salama surveyed radiation oncologists on their clinical practice and opinions; 99% of 1007 regarded OMD as something for them to treat. It is the feasibility of treatment which characterises OMD. Many diseases are framed and reframed by whether they are amenable to treatment. A familiar example was the emergence of non small-cell lung cancer (NSCLC) as a diagnostic frame. In the 1970s, adenocarcinoma, squamous cell, and large cell anaplastic cancer had 25-30% five-year survival after lobectomy, but surgery for small-cell cancers nearly always failed. Conversely chemotherapy for lung cancer, then associated with modest responses, caused small-cell carcinoma to melt away, if only temporarily. It may seem strange to frame a disease by *what it is not*, but that is how NSCLC was framed. Lung cancer was dichotomised on the basis of response to treatments. We used use 'SBE' for subacute bacterial endocarditis and 'CVA' for cerebrovascular accident. In the modern world of heart surgery and antibiotic resistance, SBE is no longer a serviceable diagnostic frame. We must be specific about organisms, underlying lesions, and prostheses. With therapeutic interventions available for stroke we have to distinguish bleeding from embolism. The catch-all term 'CVA' will no longer serve. In time NSCLC will no doubt be unbundled on the basis of tumour markers, genomics, and targeted treatments. But in an era when we talk of precision medicine, it is remarkable that the 99 patients in SABR-COMET had more than five different primary and secondary sites, bundled as OMD. At Guy's our lung cancer meetings were chaired by a lady radiologist who steered us with incisive clarity. She and I discussed treatment of metastases. She was just back from a trip to the US where she had many similar conversations. "It always ends up with the same question" she told me "Can you charge for it?". So that is the reality. The 1007 radiation oncologists will view the SABR-COMET trial results as the evidence they need. People with ESRD demonstrably survive due to treatment but OMD does no more than identify patients at the tail of the survival distribution, those most likely to live a while longer. Attributing their survival to treatment of a few metastases that can be seen is largely illusory. If sound biological science is the Ghost we seek, we haven't caught it yet.

CS01.02 "HUNTING A GHOST FOR 25 YEARS – WILL WE EVER CATCH OMD?" - YES

J. Belderbos

The Netherlands Cancer Institute, Amsterdam/Netherlands

The treatment options for NSCLC patients with a limited number of metastases at diagnosis (oligometastatic disease) have increased the past decade. The focus lies at combining systemic- and local radical treatments. With the introduction of oligometastatic disease (OMD) as a separate entity, a more radical treatment approach is increasingly applied. For OMD we distinguish synchronous OMD (in case of OMD at diagnosis) and metachronous OMD (in case of a limited amount of metastases as first event of an initially locally limited disease). There is also the term oligometastatic progression in which case during systemic treatment of a pluri-metastatic disease only few metastases progress. Finally there could be a situation called oligo persistence in case of remaining metastatic lesions. The existing literature is seriously flawed by the lack of consensus on the definition of oligometastatic disease. Often a maximum of 2-3 metastases are referred to as oligometastatic disease, but ≤5 metastases are also selected and considered for radical treatment. Important developments of local consolidative therapies in OMD Since 2016 several retrospective and prospective trials reported favorable progression free survival (PFS) for OMD treated with systemic therapy followed by local consolidative therapy (LCT). The intrathoracic disease is generally locally treated with radical radiotherapy or resection. Treatment of the metastases consists of radical or stereotactic radiotherapy, surgical resection or local ablative therapies. In an observational study radical local treatment for a selected group of NSCLC patients (n=91) with good performance status presenting with synchronous oligometastatic disease resulted in 14 months PFS and 32 months overall survival (OS).These results are comparable to outcomes for stage III NSCLC disease. De Ruysscher et.al. [2] reported a prospective single arm phase II study for synchronous oligometastatic disease treated with radical local treatment (radiotherapy or surgery) after first line chemotherapy. The median PFS and OS in this study were 12.1 months and 13.5 months respectively. After 24 months 15% of the patients did not show disease progression. In a trial Iyengar et al [4] randomized 29 metastatic NSCLC patients with up to 6 sites of extracranial disease (including primary) and a good performance. After induction chemotherapy non-progressive patients were randomized for maintenance chemotherapy or stereotactic

radiotherapy. In an unplanned interim analysis, the median PFS was 9.7 months in the stereotactic radiotherapy arm versus 3.5 months in the maintenance chemotherapy arm. In a randomized phase II trial Gomez included 49 patients with stage IV NSCLC with three or fewer metastases, and no progression after first-line systemic therapy. The trial investigated LCT with stereotactic or conventionally fractionated radiotherapy or surgery versus maintenance therapy or observation. Patients in the LCT arm experienced improved PFS as well as improved OS [5].The trial was closed early because of a significant PFS and OS benefit in the LCT arm. With a median follow-up time of 38.8 months the PFS benefit with additional local therapy was 14.2 months versus 4.4 months in the maintenance therapy/observation arm (p=0.022). They also reported an impressive OS benefit in the LCT arm: 41.2 months versus 17.0 months (p=0.017). This OS benefit was achieved despite the fact that 41% of the patients in the maintenance therapy/observation arm crossed over to the local consolidative therapy arm at the time of progression. No additional grade 3 or greater toxicities were observed. It is important to know that these studies were performed in the pre-immunotherapy era. In patients with metachronous OMD (controlled primary tumour and 1-5 oligometastatic lesions) the effect of LCT on survival, toxicity, and quality of life in 99 patients was recently reported in the SABR-COMET trial: a randomized, phase 2 trial [4]. Patients were randomly assigned (1:2) to receive either palliative standard of care treatments alone (control group), or standard of care plus stereotactic or conventional radiotherapy to all metastatic lesions (SABR group). Median overall survival was 28 months in the control group versus 41 months in the SABR group (p=0.090). Several reasons could explain the benefit by adding LCT for OMD in these trials: 1) LCT potentiates the effects of systemic therapy 2) By reducing the residual tumor burden, LCT delays the growth of distant micrometastatic disease 3) LCT reduced the amount of treatment-resistant lung cancer cells 4) Necrosis caused by LCT allows the immune system to induce an immune-specific reaction that affects distant cancer cells **Conclusion:** The synergy of local consolidative therapies combined with systemic treatments in oligometastatic patients is currently one of the most exciting developments in lung cancer treatment. CS01.03 TECHNICAL REASONS OF LOCAL TREATMENT DEFINE THE LIMITS OF NSCLC OMD IN TERMS OF NUMBER OF METASTASES, NOT A FIXED NUMBER

M. Scorsetti

Humanitas University, Department of Biomedical Sciences, Rozzano/Italy

Currently there is no consensus on the definition of oligometastatic disease in NSCLC, with 3 or 5 lesions historically considered as the upper limit [1]. A low number of metastases, indeed, is a good although not perfect surrogate of the biology behind the oligometastatic state. In real life practice, the number of metastatic lesions is often misleading, since it is possible to find patients with more than 5 metastases affected by a slowly progressing disease, potentially taking advantage from local treatments. On the contrary, patients affected by just one or two metastases can progress very rapidly with a dismal prognosis, despite the apparent low disease burden. Since the number of metastases is not a perfect indicator of oligometastatic state and biomarkers really able to identify this disease are lacking, there is a trend favoring the technical feasibility of local treatment over the number of metastases to treat. This approach has pros and cons. On one side, the idea of killing all visible cancer cells independently by their number is appealing and possibly with a positive impact on patient prognosis. On the other side, clinical data supporting such an aggressive local treatment have still a low level of evidence. Moreover, the definition of "technically feasible" is quite vague, particularly in the world of radiation oncology. Indeed, radiotherapy is strongly related to technological development. The innovations in this setting have dramatically increased the possible indications of radiotherapy, also for oligometastases. With state of the art radiotherapy, we are now able to treat virtually all sites in the body and it is becoming really difficult to define an upper limit to the number of lesions that can be treated. However, this is feasible only with advanced technologies, like image guided radiotherapy (IGRT), motion management (4D CT, gating, tracking, etc.), and heavy particles in particular clinical settings (retreatment for instance). This trend is creating a gap between Radiation Therapy Departments, since some treatments are becoming safely deliverable only in well selected Institutions with high expertise in this field. Despite all recent technological achievements, some clinical settings remain in which the risk-benefit ratio should be carefully weighted before delivering ablative dose to a metastatic patient. For instance, there are still uncertainties in the treatment of central lung lesions abutting on the main bronchus [2] or, changing scenario, the amount of remaining healthy liver is still limiting liver metastases treatment in some situations [3]. More importantly, the goal of local treatment of an oligometastatic patient should be to change the natural history of the tumor, independently from the number of metastases we are able to treat. Treating all the metastases, even though safely feasible, remains just a technical exercise if no impact on prognosis, quality of life or symptoms control is achievable. Oligometastatic disease has definitely a different biology, and every effort should be in the direction of identifying this biology [4]. Technologies have developed faster than our clinical and biological knowledge, and this should be kept in mind. In conclusion, the number of metastases remains a good clinical indication of oligometastatic state, but this number should not be an insuperable limit in clinical practice. Technical feasibility of local treatments (as radiotherapy) should be always carefully weighted accounting for risk-benefit ratio. Being able to treat any number of metastases should not be considered as a good reason for doing it indiscriminately. Physicians should always consider the clinical and biological reasons for a local ablative treatment in a metastatic patient, independently by technical issues. [1] Hong JC, Salama JK. CS01.04 NSCLC OMD IS DEFINED BY A FIXED MAXIMUM NUMBER OF METASTASES, NOT TECHNICAL REASONS OF LOCAL TREATMENT

G. Wright

Peter MacCallum Cancer Centre, Melbourne/Australia

Other than a select group of patients with solitary brain metastases and cT1-2a N0 resectable primary cancers, the idea of aggressively ablating metastatic non-small cell lung cancer (NSCLC) has always been considered unconventional. The resectable solitary cerebral metastasis has traditionally yielded better results than any other

M1b disease, and this has been put down to careful selection and perhaps a different biology in these rare cases. It wasn't until the publication of a large individual patient data meta analysis in 2014[1] that more general treatment of OMD could be benchmarked and taken seriously enough to consider clinical trials. This confirmed that in select populations, long-term survival was achievable by surgical or radio-ablation of a small number of metastases. Only 1.9% of the series had more than 3 metastases and only 3% of the series had multi-organ disease. A main finding of multivariate analysis was that those with any nodal disease (effectively another metastatic site) did poorly. The definition of the oligometastatic disease state (OMD) has always been elusive. In principle, it is defined as M1a-c disease with low metastatic burden (usually up to three or five lesions) and limited organ involvement (usually up to two sites). It is considered an intermediate condition between truly localized disease and widely metastatic disease. The reporting bias of 1-3 metastases seen in so many published treatment series is tacit acknowledgement that OMD only encompasses three or fewer metastases, and probably to just a single organ. Our own IALSC TNM staging system recognizes this in our M1 sub-stages. Unlike oligo-metastatic colorectal carcinoma, sarcoma or renal cell carcinoma, which have reproducibly achieved long term survival after pulmonary metastasectomy (and/or hepatic metastasectomy) for several decades, the pace of disease and apparent inevitability of shortened lifespan in a patient with metastatic NSCLC has led to self-regulation of this practice for our tumour specialty. The relatively poorer average cardio-pulmonary fitness of patients with lung cancer and the maxim of 'first do no harm' largely tempered any enthusiasm. As surgery has become increasingly less invasive/morbid, and therapies such as stereotactic ablative body radiotherapy (SABR) and radiofrequency ablation have become more readily available, the temptation is to expand indications for intervention well beyond their evidence base and/or cost-benefit ratio. The last 5 years has seen a proliferation of publications of eyebrow-raising SABR series outside of any clinical trial protocols. This is a slippery slope that surgeons have been accused of sliding down in pulmonary metastasectomy for colorectal carcinoma[2]. We must not let our enhanced ability to inflict therapy dictate whether or not a condition is appropriate to treat. The definition of OMD cannot be stretched arbitrarily to match our technological capabilities or we will waste huge resources and inevitably cause some harm by way of futile overtreatment. The 'breakthrough' SABR-COMET trial[3] has invigorated discussion and enthusiasm for treating NSCLC oligometastatic disease on the basis that overall survival was superior with ablation of OMD (41 months) compared to the control group treated with palliative measures (28 months). This enthusiasm does need to be tempered by a few salient observations. Firstly, this was a phase 2 trial of mixed histologies with 66 recruits in the treatment arm and 33 in the control arm. In all, only 18 enrolled patients had NSCLC, with 12 in the treatment arm. It is indeterminate from the paper how well these particular NSCLC patients performed and the confidence intervals would be wide. The follow-up tail becomes decidedly 'bushy' after 1 year due to censorship. There were three treatment-related deaths and four other serious adverse effects not seen in the control arm. The control rate was less optimistic than in Rusthoven's phase 1 trial[4], with 75% having no progression in targeted lesions (compared to 49% in the control arm). The most telling information supporting the ≤3 metastasis OMD hypothesis is the number of metastases and number of organs involved in the recruited SABR-COMET patients. Only 7 recruits had more than 3 metastases, with 5 of these receiving SABR. It is not clear if ANY of these had NSCLC, but these are not dissimilar numbers to the aforementioned NSCLC meta analysis[1]. Historically, there is far more data on survival after metastasectomy for series excluding NSCLC. Only 1% of pulmonary metastasectomies in the International Registry of Lung Metastases[5] had NSCLC and some may have been second primaries. Whilst 26% of cases had ≥4 metastases resected, this was largely confined to sarcoma and germ cell tumours, where aggressive resection and re-resection is considered standard of care. Their survival was still inferior to patients with either solitary or 2-3 metastases. This is despite the likelihood that patients with ≥4 metastases are "hyper-selected', based on survival characteristics such as performance status, younger age, excellent fitness, anatomical location and favourable observed tumour behaviour. This creates a false impression that this group is receiving not dissimilar survival benefit as the cohort with ablation of 1-3 metastases. OMD as a hypothesis is very reasonable and deserves to be tested. Diluting the potential benefits by expanding that definition to match our technological wizardry is not. Clinical trial resources would be better mobilized to further study surgical and/or SABR metastasectomy in lung cancer with ≤3 metastases in a single organ before expanding umbrella trials to ≥4 metastases.

ES01 WHAT IS THE ROLE OF CHEMOTHERAPY IN THE ERA OF IMMUNOTHERAPY IN ADVANCED NSCLC?
SUNDAY, SEPTEMBER 8 10:30–12:00

ES01.01 CHEMOTHERAPY IS STRICTLY ADDITIVE TO IMMUNOTHERAPY

J. Vansteenkiste, E. Wauters

University Hospitals KU Leuven, Leuven/Belgium

Historically, chemotherapy was the only systemic therapy for advanced NSCLC. Over the last decades, effective targeted therapy has been developed. EGFR is the prime target since 20 years now [1], and is followed by an increasing number of targetable rare oncogenic driver mutations. This decade, the phase I trial of nivolumab – including NSCLC patients – started recruitment on July 1, 2011 [2]. Since then, immunotherapy with immune checkpoint inhibition (ICI) has become the third pillar in our therapeutic armentarium, with a very rapid development for relapsed, and thereafter for untreated advanced NSCLC. Most patients with non-oncogene addicted advanced NSCLC will nowadays have both chemotherapy and ICI, either in a concurrent or sequential way. This raises the question whether their interaction is synergistic or additive, favoring the former versus the latter approach. We will look at this from the perspective of adverse events, mechanistic background, and clinical trial outcomes. There is not much overlap between the typical and common adverse events (AEs) of chemotherapy or ICI. The former are mostly bone marrow inhibition, nausea/vomiting, mucositis, hair loss and neuropathy. ICIs are well tolerated, with no or mild AEs in most patients, but may induce immune related AEs mostly in skin or endocrine organs, liver, lungs or kidneys. Hence, there is little difference in overall adverse event profiles when the chemotherapy+ICI (chemo+ICI) and chemotherapy+placebo (chemo+PL) arms from randomized trials are compared. In the Keynote-189 trial - an example with the anti-PD-1 agent pembrolizumab – overall grade 3 to 5 AEs were present in 67.2% and 65.8% of patients with chemo+ICI and chemo+PL, respectively [3]. Grade 3 to 5 immune-related AEs, as rated by investigators blinded to the assigned therapy, were 8.9% for chemo+ICI, while 4.5% for chemo+PL. AEs leading to discontinuation of all treatment were 13.8% and 7.9%, respectively. Hence, irAEs acted additive to the overall AE profile. The notable exception in this trial was renal toxicity. There was a low frequency of auto-immune nephritis (1.7%), but there was a 5.2% incidence of acute kidney injury in the chemo+ICI arm, compared to 0.5% in the control arm. In the IMpower-133 trial – an example with the anti-PD-L1 agent atezolizumab – overall grade 3 to 5 AEs were present in 67.2% and 63.8% of patients with chemo+ICI and chemo+PL, respectively [4]. All grade immune-related AEs, as rated by investigators blinded to the assigned therapy, were 39.9% for chemo+ICI, and 24.5% for chemo+PL. So, here again a rather additive pattern in AE profile is put forward. Chemotherapy has long time been regarded as immunosuppressive and incompatible with immunotherapy. To improve on the rather low response rate with ICI alone, recent trials focused on the combination of chemo+ICI, trying to exploit the immune modulatory (synergistic) effects of chemotherapy both on the tumor cells and immune cells. The details of this interaction are beyond the scope of this abstract, but a central one is immunogenic cell death (ICD) by chemotherapy. In contrast with necrotic/apoptotic cell death, ICD is characterized by immune-promoting features on dendritic cells and macrophages, by means of inducing calreticulin expression on tumor cells, release of adenosine triphosphate in the extracellular space and of high mobility group box 1 protein from the nucleus of the cancer cell. ICD, however, has been associated with only a limited number of chemotherapeutic agents used in clinical practice, such as doxorubicin, mitoxantrone, oxaliplatin and cyclophosphamide [5]. None of these agents is part of the modern chemotherapeutic armentarium for NSCLC. Recent phase III trials with chemo+ICI versus chemo+PL demonstrated a convincing benefit in response rate, progression-free survival (PFS) and overall survival (OS) with the combination (e.g. [3]). Of note, there are no randomized data comparing the combination of chemo+ICI in a concurrent versus a sequential way. Ideally, such a trial should have several arms: one with the concurrent use of chemo+ICI in all PD-L1 tumors; a sequential one with pembrolizumab followed by chemotherapy in PD-L1 >=50% tumors; and one with the sequential use of a chemotherapy and then ICI in PD-L1 <50% tumors. The primary endpoint preferably should be PFS2 in a intention-to-treat analysis. In the absence of such data, there is no definitive evidence that one or the other strategy is superior, and we can only make speculations about this question. At the meeting, we will present suggested algorithms based on the comparison of PFS from several recent trials. Especially the PFS2 analysis of the Keynote-024 [6,7] and KN-189 [3,8] trials are helpful in this respect. Even if there are many caveats with this approach, it may be helpful to guide clinical practice between concurrent and sequential treatment strategies. References 1. Vansteenkiste J, Wauters E. SUNDAY, SEPTEMBER 8 10:30–12:00

ES01.02 CHEMOTHERAPY ENHANCES THE EFFICACY OF IMMUNOTHERAPY

N. Leighl

Princess Margaret Cancer Centre, University Health Network, Toronto/Canada

Combination chemotherapy with anti-PD-1 therapy has now become standard of care as first-line therapy in patients with advanced NSCLC. Several trials demonstrate the improvement of combination therapy versus chemotherapy alone, but trials comparing immunotherapy +/- chemotherapy are ongoing (e.g. INSIGNA, CCTG BR.34, Checkmate 9LA, Checkmate 227). Several preclinical studies suggest that adding chemotherapy to immunotherapy is additive. Chemotherapy has been shown to disrupt immunsuppressive cell activity, for example regulatory T cells (Treg), myeloid-derived suppressor cells (MDSC) and tumour associated macrophages (TAM) in preclinical studies (reviewed in Yan et al. Frontiers in Immunology, 2018). Chemotherapy may also promote immune responses via induction of tumor cell death, upregulation of MHC Class 1 expression and dendritic cell maturation. Lara et al recently reported activity both preclinically and clinically when combining gemcitabine with anti-PD1 therapy in mesothelioma, despite lack of activity of either as a single agent (Lara et al. Clin Cancer Res 2018). A key question in the first-line setting for those eligible for anti-PD1 monotherapy (PDL1 TPS >=50%) is whether the addition of chemotherapy is of benefit. Keynote 024 demonstrates superior survival, progression-free survival and response in this population compared to platinum doublet therapy, with a response rate of 45%. Overall response rates in the Keynote 189 and 407 trials in the subgroup with PDL1 TPS>=50% were 60% and 63% for chemotherapy plus pembrolizumab. Despite consensus that some patients clearly benefit from combination therapy while others likely can receive anti-PD-1 monotherapy, it is unclear how to select patients for each strategy. Ongoing studies are currently examining this question, such as the US cooperative-group-led INSIGNA trial (NCT03793179). In this study, patients with advanced PDL1 TPS>=1% nonsquamous NSCLC will be randomized to receive either (1) pembrolizumab monotherapy followed by pemetrexed/platinum upon progression; (2) pembrolizumab monotherapy and upon progression, the addition of pemetrexed/

platinum to pembrolizumab; and (3) pembrolizumab/pemetrexed/platinum followed by maintenance pembrolizumab/pemetrexed with investigator's choice of treatment upon progression. It is hoped that this study will provide answers in how to best select patients for either strategy.

ES01.03 CHEMOTHERAPY DIRECTLY TARGETS THE IMMUNE SYSTEM TO IMPROVE EFFICACY

D. Tan

National Cancer Centre Singapore, Singapore/Singapore

Multiple phase III trials support the use of combination chemotherapy with immune checkpoint inhibitors in the first line setting. Yet the exact mechanism of synergy is poorly understood. In this third instalment of three talks dissecting this topic, the focus will be on the impact of chemotherapy on the immune system, ranging from its effect on recognition of tumor antigens, circulating immune cells and/or cytokines, as well as on immune cells in the tumor microenvironment. Elucidating the mechanism of action can delineate more tailored approaches to first line therapy, including the use of single agent checkpoint inhibitors or alternative/ additional combinations that further enhance the immune response.

ES01 WHAT IS THE ROLE OF CHEMOTHERAPY IN THE ERA OF IMMUNOTHERAPY IN ADVANCED NSCLC?
SUNDAY, SEPTEMBER 8 10:30–12:00

ES01.04 IMMUNOTHERAPY, RADIOTHERAPY AND CHEMOTHERAPY COMBINATION: A POTENTIAL NEW STANDARD?

M. Perol

Department of Medical Oncology, Centre Léon Bérard, Lyon/France

The advent of immunotherapy in lung cancer with immune checkpoints inhibitors (CPIs) has first involved stage IV non-small cell lung cancer (NSCLC), recently in combination with cytotoxic chemotherapy in first-line setting. The rationale to combine chemotherapy with CPIs is theoretically based on the chemotherapy-induced immunogenic cell death triggering an immune response and the modification of the tumor microenvironment (TME) by depletion of immunosuppressive cells. Radiotherapy remains one of the main components of the NSCLC treatment, from early stages with stereotactic ablative radiotherapy (SABR) and locally advanced stage III NSCLC in combination with chemotherapy to stage IV disease for the local palliative treatment of metastatic sites. Radiation therapy (RT) techniques have been considerably improved with image-guidance, and technological developments in linear accelerators, allowing now a very precise delivery of radiation. Radiation biology has been mainly concentrated on radiation-induced DNA damage with irreparable double strand break, leading to cell cycle inhibition and cell death. There are also a rationale and a preclinical evidence to expect a synergy between RT and CPIs. RT can also cause immunogenic cell death by direct cytotoxic effects, resulting in the release of tumor-associated antigens (TAAs) and danger signals (DAMPs: damage associated molecular pattern) that can be recognized by toll-like receptors, thus facilitating the presentation of TAAs to CD8+ T cells by MHC I. The dendritic cell activation and up-regulation of interferon pathway also enhance TAAs presentation to immune cells and up-regulate MHC-1 expression on tumor cells. Radiotherapy can therefore act as an auto-vaccine, activating the dendritic cells, broadening up the immune repertoire of T cells and increasing the "visibility" of TAAs. Beside this promotion of priming and activation of cytotoxic T cells, RT upregulates PD-L1 expression in the TME. Nevertheless, the modification of TME induced by RT may be equivocal with on one hand an increase in the CD8+ T cells recruitment by up-regulation of adhesion molecules, but on the other hand, the promotion of immune tolerance via the recruitment of MDSCs and Treg cells. Moreover, RT activates the immunosuppressive TGF-β pathway by reactive oxygen species. In addition to the potential synergism in terms of local control, the RT might also mediate an abscopal effect, describing the tumor regression of lesions distant from the irradiated volume, due to circulating of T cells locally activated by RT. This phenomenon has been experimentally demonstrated in preclinical models and occasionally reported in case reports. In stage IV NSCLC, the impact of RT delivered on a metastatic site or on the primary tumor on CPIs anti-tumor effect has been suggested by the retrospective analysis of the Keynote 001 phase I trial of pembrolizumab showing that patients who received radiotherapy before pembrolizumab had a better overall survival (OS) and progression-free survival (PFS) than those patients who did not receive radiotherapy. Many ongoing trials are exploring the possibility to "boost" the activity of CPIs by the addition of local RT, especially SABR; these trials have to face many challenges in terms of treatment timing, radiation dosing, and minimization of the RT toxicity on local and circulating T-cells. The main advance was brought in stage III NSCLC by the Pacific study which evaluated the impact of a treatment consolidation with durvalumab (anti-PD-L1), administered during 1 year after completion of concurrent chemoradiation therapy. This trial was a double-blinded, 2:1 randomized versus placebo study; randomization was authorized between 1 and 42 days after the end of radiation therapy. PD-L1 status was not required for enrollment. The majority of the 713 included patients were male, smokers and received a dose of radiotherapy between 54 and 66 Gy. The addition of durvalumab after concurrent chemo-RTsignificantly improved both PFS (median 17.2 vs. 5.6 months, HR 0.51 95%CI, 0.41-0.63) and OS at the first interim analysis (median not reached vs. 28.7 months, HR 0.68 99.73%CI, 0.469-0.997). The effect of durvalumab was mainly due to a reduction of metastatic relapses, including brain metastases. Subgroups analysis showed a trend toward a greater magnitude of PFS and OS benefit for patients randomized early after completion of radiotherapy (<14 days). The exploratory analysis of the impact of PD-L1 expression on the magnitude of benefit was planned with a cutoff at 25% for tumor cells. Knowing that 37% patients had no PD-L1 assessment, the analysis showed a PFS benefit in both subgroups of patients and no OS benefit for patients with PD-L1<25%. At the request of EMA, an additional unplanned subgroup analysis at the cutoff of 1% showed no PFS benefit and a trend toward a worse survival with durvalumab for the PD-L1<1% tumors, due to an unexpected very good survival for patients randomized in the placebo group in this small subset of patients. While FDA approval of durvalumab was unrestricted, the European label is limited to the PD-L1≥1% tumors, even if the statistical validity of the subgroup analysis is questionable. The risk of pneumonitis after radiation therapy was slightly increased in the durvalumab arm without significant augmentation of grade ≥3 events. Pacific was the first study demonstrating the potential for CPIs to obtain a potential synergy with radiation therapy, defining a new standard of care for these patients. However, further already ongoing clinical research will have to address the questions of a similar benefit with sequential chemoradiation therapy and of the optimization of this potential synergy by administering immunotherapy concurrently with thoracic radiotherapy as suggested by preclinical data. Potential long term toxicities must also be carefully assessed. Another area of further development of RT and CPIs combinations actually investigated is the incorporation of immunotherapy after SABR in the treatment of early stage NSCLC. The combination of RT and immunotherapy has proven effective in preclinical studies and in stage III NSCLC. A lot of challenges still exist to harness the combination of chemotherapy, RT and CPIs, especially in terms of timing, irradiated volume, fractionation, and dose that likely play a major role in the modulation of the RT different effects on the tumor cells, the immune response and the TME.

SUNDAY, SEPTEMBER 8 10:30–12:00

ES02.01 BIOMARKER TESTING IN LA DISEASE

H. Yu

Memorial Sloan Kettering Cancer Center, New York/United States of America

Routine biomarker testing in metastatic lung cancer has led to enormous improvements in outcomes for our patients with metastatic lung cancers. Oncogene testing has allowed us to identify the 50% of patients with metastatic lung cancer that are eligible for targeted therapies1. Consistently, targeted therapy for EGFR, ALK, ROS1, RET, BRAF have demonstrated superior progression-free survival compared to standard cytotoxic chemotherapy2. Identification of these genomic biomarkers has provided additional treatment options for our patients that are more effective and less toxic than standard treatments. In addition, serial biomarker testing allows us to also identify mechanisms of resistance to targeted therapy which can then inform subsequent treatment decisions. PDL1 testing is also routinely performed in the metastatic setting and assists us in identifying patients that may benefit from immunotherapy alone instead of first-line combination immunotherapy and chemotherapy treatment3. PDL1 testing allows us to predict likelihood of response to immunotherapy and selects patients that we can de-escalate treatment; patients with high PDL1 expression derive benefit from treatment with immunotherapy alone. Routine utilization of biomarker testing in metastatic lung cancer is easily the most importance advancement in this field to date. Current recommendations: Biomarker testing for patients with locally advanced lung cancers is currently not recommended in the NCCN guidelines or any expert guidelines. This is likely because the current management for locally advanced lung cancers do not incorporate the use of biomarkers. Patients currently receive adjuvant durvalumab after concurrent chemoradiation for stage 3 disease irrespective of PDL1 status. Currently, adjuvant targeted therapies after definitive resection or radiation are not recommended in the NCCN or other cancer care guidelines. Oncogene testing: The risk of recurrence for early stage lung cancers remain high. After surgical resection, adjuvant chemotherapy for high risk stage 1B, stage 3 and stage 4 and post-operative radiation for patients with mediastinal lymph node involvement are both recommended are they improve survival. Despite this, there is a large subset of patients that will have recurrent disease. Because of their demonstrated superiority over chemotherapy in the metastatic setting, there is great interest in assessing whether adjuvant targeted therapies would improve outcomes in the locally advanced disease setting. EGFR mutant lung cancer is the largest oncogene subset in which the bulk of previous studies have been done. However, all studies to date have been subsets of larger unselected patients (RADIANT study) or single arm studies (SELECT study). These smaller studies have shown a disease-free survival benefit but have been underpowered to demonstrate a survival benefit. There are several well-designed large studies ongoing that will definitively demonstrate whether adjuvant EGFR inhibitors improve overall survival. The ALCHEMIST study is a phase 3 randomized cooperative group study assessing erlotinib versus observation for patients with stage IB-IIIA resected lung cancers; accrual is ongoing. The ADAURA study is a randomized phase 3 study where patients with stage IB-IIIA resected lung cancers are randomized to osimertinib versus placebo for 3 years with a primary objective of DFS and a secondary objective of overall survival. These studies will help answer the question as to whether adjuvant targeted therapy should be utilized. PDL1 testing: In stage 3 lung cancers, more than 60 percent of patients will ultimately die of their lung cancer4. Adjuvant durvalumab has improved outcomes with a clear improvement in overall survival but many patients still recur and ultimately die of their disease. An unplanned subset analysis of the PACIFIC study suggests that patients with PDL1 0% expression may not derive benefit from durvalumab. Further assessment will be needed to ascertain whether PDL1 expression can be used to select patients who would derive benefit from adjuvant durvalumab. Due to their efficacy in the metastatic setting, there are a significant number of studies looking at immunotherapy as both neoadjuvant and adjuvant treatment for locally advanced disease. Just as we utilize PDL1 as a biomarker that helps select appropriate therapies in the metastatic setting, I see similar use of PDL1 in the future in the locally advanced setting. Future directions: As personalized medicine infiltrates our care of patients with lung cancers, we will need biomarker results for patients with locally advanced lung cancer to better tailor and personalize their care. In particular, if the EGFR TKI studies demonstrate improved overall survival with adjuvant EGFR TKI, we will certainly need to incorporate biomarker testing as standard of care for locally advanced disease. In addition, because a significant portion of patients recur, already having molecular test results available which were done on their surgical sample, makes their care later more stream-lined. We also need to assess whether PDL1 is a useful biomarker to select patients for immunotherapy in the adjuvant setting. Results from ongoing clinical trials will provide definitive answers. ES02 MANAGEMENT OF ONCOGENE ADDICTED PATIENTS WITH STAGE III NSCLC
SUNDAY, SEPTEMBER 8 10:30–12:00

ES02.02 MANAGEMENT OF EGFR LA DISEASE

K. Park

Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul/Korea, Republic of

The standard of care for the locally advanced non-small cell lung cancer(LA-NSCLC) is concurrent chemoradiotherapy(CCRT). Recently, the addition of consolidation immune checkpoint inhibitor following CCRT demonstrated improved outcome and is now recommended as the new standard of care for this heterogeneous group of LA-NSCLC patients. In advanced/metastatic setting EGFR mutation (+), NSCLC cancer patients define a unique subset with a dramatic response to the EGFR TKIs. Currently, molecular profiling of tumor tissue for EGFR mutations (as part of multiplex testing) is a routine procedure at the time of initial diagnosis of patients with recurrent or metastatic NSCLC. For advanced or metastatic EGFR mutant NSCLC patients EGFR TKI therapy is the treatment of choice and the median overall survival is > 30 months. Despite the great success of EGFR TKI in metastatic NSCLC, the role of EGFR TKIs in LA-NSCLC is less well defined and controversial. Early clinical trials in *unselected* NSCLC patients failed to demonstrate the benefits of EGFR-TKIs as an adjuvant treatment. The first prospective randomized phase III trial to investigate the role of EGFR TKI in earlier stage NSCLC includes the SWOG 0023 study (J Clin Oncol 2008;26:2450-6) which failed to support the role of maintenance gefitinib (versus placebo) following definitive chemoradiation in unresectable stage III NSCLC. The CALGB 30106 phase II study also failed to show the benefits of adding gefitinib to sequential or concurrent chemoradiotherapy in unresectable stage III NSCLC (J Thorac Oncol 2010;5:1382-90). And the randomized prospective placebo-controlled adjuvant gefitinib trial in *unselected* patients with stage IB–IIIA resected disease (BR.19) was prematurely closed (J Clin Oncol 2013;31:3320-6). Another randomized double-blind trial in adjuvant NSCLC with tarceva (RADIANT) in patients with completely resected state IB to IIIA NSCLC whose tumors expressed EGFR protein by immunohistochemistry or EGFR amplification by fluorescence in situ hybridization did not show prolonged DFS (J Clin Oncol 2015;33:4007-14). The prognostic or predictive value of EGFR mutation in early stage NSCLC patients is not well defined. In a retrospective single institutional analysis (J Thorac Oncol. 2012;7: 1815–1822), patients with resected stage I–III lung cancers and EGFR mutation have a lower risk of death compared to patients without EGFR mutation. There was a trend toward improvement in DFS among individuals with resected stages I to III lung adenocarcinomas harboring mutations in EGFR exon 19 or 21 who received adjuvant EGFR TKI therapy (J Thorac Oncol 2011;6:569–575). There have been recently reported several *prospective* trials of adjuvant EGFR TKI in early stage NSCLC patients enriched with EGFR mutation. CTONG1104 study (ADJUVANT), a randomized, open-label, phase III trial of adjuvant gefitinib for 24 months versus intravenous vinorelbine plus cisplatin for 4 cycles in patients with completely

resected (R0), stage II–IIIA (N1–N2), EGFR-mutant (exon 19 deletion or exon 21 Leu858Arg) NSCLC, demonstrated that adjuvant gefitinib compared to cisplatin-based chemotherapy significantly increases disease-free survival, diminishes toxic effects, and improves HRQoL in patients with completely resected stage II–IIIA EGFR-mutant NSCLC (Lancet Oncol 2018; 19: 139–48). In the phase II SELECT trial, adjuvant erlotinib for 2 years in patients with resected stage IA to IIIA EGFR-mutant NSCLC after standard adjuvant chemotherapy with or without radiotherapy (J Clin Oncol 2019;37:97-104) showed an improved 2-year DFS. Patients rechallenged with erlotinib after recurrence experienced durable benefits. There are also some neoadjuvant trials of EGFR TKI for locally advanced NSCLC. RTOG 1306, a randomized phase II study of individualized combined modality therapy for stage III NSCLC (12-weeks of either erlotinib hydrochloride or crizotinib followed by chemoradiation therapy in stage III NSCLC with EGFR TK mutations or EML4- ALK fusion). The primary objective was to assess whether patients with unresectable LA-NSCLC treated with EGFR or ALK TK targeted agents based on molecular characteristics have a longer progression-free survival than those treated with standard care therapy alone. The study was, however, unfortunately prematurely terminated due to poor accrual (NCT01822496). CTONG 1103 is an open-label, randomized trial that compared the efficacy and safety of erlotinib versus gemcitabine plus cisplatin neoadjuvant therapy in patients with exon 19 or 21 EGFR mutations and untreated resectable stage IIIA-N2 NSCLC. The study did not meet the primary end point of ORR with 42 days of neoadjuvant erlotinib, but the secondary end point PFS was significantly improved (J Clin Oncol 37. © 2019; published at jco.org on June 13, 2019: DOI https://doi.org/10.1200/JCO.19.00075) There are also several ongoing clinical trials of EGFR TKIs in resected stage IB - IIIA NSCLC with activating EGFR mutations. The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial (ALCHEMIST) is a prospective randomized double-blind placebo-controlled trial to investigate the benefits of the addition of molecularly targeted agents after standard postoperative chemotherapy in patients with resected NSCLC (Clin Cancer Res:2015; 21(24); 5439–44). It is worth noting that the primary objective for the ALCHEMIST adjuvant trials is overall survival (OS). ADAURA, a randomized phase III trial (osimertinib vs. placebo in patients with stage IB-IIIA NSCLC, following complete tumor resection with or without adjuvant chemotherapy; NCT02511106) has been designed to assess the efficacy and safety of adjuvant osimertinib versus placebo in patients with resected stage IB-IIIA EGFR mutation-positive (Ex19Del or L858R) NSCLC. The primary efficacy objective is DFS. In brief, many neoadjuvant/adjuvant EGFR TKI trials in earlier stage of NSCLC have demonstrated its safety and feasibility with an improved DFS esp. in EGFR mutation(+) LA-NSCLC. However, the real question should be "Can we improve the 'overall survival' and thus ultimately the 'cure rate' of locally advanced NSCLC with EGFR mutation?" In order to address this issue, there remain several critical questions to be answered, e.g., who is most likely to benefit from adjuvant EGFR TKI, what is the optimal duration of adjuvant TKI, what is the best regimen, etc. Whether the earlier introduction of EGFR targeted therapy in less advanced NSCLC would lead to improved '*Cure Rate*' remains to be seen in future prospective trials in a larger number of EGFR mutation(+) patients.

ES02 MANAGEMENT OF ONCOGENE ADDICTED PATIENTS WITH STAGE III NSCLC
SUNDAY, SEPTEMBER 8 10:30–12:00

ES02.03 MANAGEMENT OF OTHER NON EGFR ONCOGENE ADDICTED TUMORS

C. Aggarwal

University of Pennsylvania, Philadelphia/United States of America

Stage III non-small cell lung cancer accounts for heterogeneous group of diseases, due to differences in tumor size, location number of nodes involved, and lymph node station involved. Stage III non-small cell lung cancer comprises 2 distinct stages, stage IIIA and IIIB disease that have different prognosis, and are usually treated differently. Approximately 15% of all patients with newly diagnosed non-small cell lung cancer present with stage III disease. Options for stage III non-small cell lung cancer include surgery, with lobectomy or pneumonectomy depending on the tumor stage, and lymph node involvement. Chemotherapy may be administered in the neoadjuvant, concurrent or adjuvant setting. Radiation therapy can be given in a concurrent, sequential approach, or may be administered in the postoperative fashion. Combination approaches are often used, and due to the significant need of multi-modality therapy, treatment decisions are usually made in a multidisciplinary setting. The optimal therapeutic approach for patients with stage IIIA non-small cell lung cancer remains controversial. For subset of patients with T3 to T4 N0-1 disease, and superior sulcus location, surgery remains a viable and preferred option. However, the optimal treatment for patients with stage III A, with bulky lymph node involvement, or multi station lymph node involvement including N2 disease, remains an area of ongoing controversy. Tri-modality approaches using preoperative chemotherapy, or upfront chemoradiation therapy followed by surgery have been evaluated (1). For patients with surgically unresectable, or medically inoperable disease, concurrent chemoradiation therapy has been established as the standard of care for patients spanning the spectrum of stage IIIA and IIIB disease. Recently, the PACIFIC trial demonstrated an improvement in progression free survival and overall survival with the administration of durvalumab as consolidation therapy (regardless of PDL-1 status) for patients who had not progressed after 2 or more cycles of definitive concurrent platinum-based chemoradiation therapy (2, 3). This approach represents a new paradigm in the management of unresectable NSCLC, and has now been adopted as standard of care. Management of Stage III patients with non EGFR oncogene addicted tumors is an area of active research. ALK or ROS directed oral tyrosine kinase inhibitors (TKIs) are not typically administered in the adjuvant setting outside of a clinical trial. There are several trials evaluating the use of targeted therapies. ALINA, is one such trial, that is a phase III study of alectinib versus chemotherapy as adjuvant therapy in patients with stage IB–IIIA anaplastic lymphoma kinase-positive ALK positive NSCLC (4). Another study is comparing adjuvant alectinib versus adjuvant platinum-based chemotherapy in patients with ALK positive NSCLC, here the alectinib is administered for 2 years (NCT 03456076). The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing (ALCHEMIST) trial is actively enrolling patients with operable NSCLC and will perform genetic screening of their tumors. Patients with *EGFR* mutation or *ALK* gene rearrangement in their tumor will be randomized to placebo versus erlotinib or crizotinib, respectively (NCT02194738). We await the results of these trials prior to routine incorporation of molecularly directed therapy in the management of locally advanced disease. References: 1. ES02.04 CONCURRENT, SEQUENTIAL AND COMBINATION IMMUNOTHERAPY REGIMENS IN LA-NSCLC

M. Provencio

Puerta de Hierro University Hospital, Majadahonda/Spain

Immunotherapy in Oncogenic-Addicted Stage III Patients At diagnosis of non small cell lung cáncer (NSCLC), at least 40% of patients are diagnosed at an advanced stage and a third locally advanced disease (stage III). The results of stage IIIA with induction treatment of clinical practice outside the clinical trial show a median survival of 22 months and a 3-year survival rate of 34%. Concurrent definitive chemoradiation has been established as the standard of care for unresectable stage IIIB (N3 disease) NSCLC, with a median overall survival (OS) of approximately 17 months. Strategies that have been investigated include induction chemotherapy, immunotherapy

(IO), concomitant chemoradiotherapy, intensified radiotherapy and adjuvant treatment. The role of IO in NSCLC with oncogenic-addicted tumors is so far unclear. In EGFR-mutation positive patients there seems to be a worse effect of IO compared to those patients without actionable mutations,; nevertheless, no safe conclusions can be drawn due to the lack of randomized trials addressing this clinical issue. The available information from second lines with IO in patients with actionable mutations, is currently found in 2 meta-analyses[1]. These meta-analyses show OS benefit between EGFR wild-type vs mutated patients with a Hazard Ratio (HR) of 0.67, p< 0.001, consistent in all the trials. There was no OS advantage for those with EGFR mutant tumors, with a HR of 1.11, p=0.54. Of note, data from other studies were not included in these meta-analyses. Study CA209-012 showed patients with EGFR mutation, overall response rate (ORR) 14% mutated vs 30% in wild type and PFS at 24 weeks: 14% vs 51% respectively[2]. In KEYNOTE-001, best ORR based on mutation status was 15.8% in patients with EFGR mutation vs 37.1% without mutation, and 60% were unknown. Overall PD-L1 subgroups, EGFR mutated patients had lower ORR than patients with EGFR-wild type tumors. ORR was 20 % in TPS > 50% and 0% in patients with TPS<1% vs 12.7% in EGFR wild type[3]. An update of this study, and median OS in patients with EGFR mutation was 6 months (mo) (95%CI, 4.4-8.8) and 12 mo (95%CI, 9.2-14.3) in patients wild-type[4]. In the Immunotarget Cohort study, patients with EGFR-mutation had response rates of 12% and PFS of 2.1 mo and with a positive correlation in patients with high expression of PDL1 and response. The BIRCH[5] study, also not included in the meta-analyses, provides us with similar information, with higher response rates in patients with higher expression of PDL1 (31% vs 23%), even achieving similar PFS to wild type patients (7.6 vs 7.7 mo) or OS with 28.5 mo (20.1, NE) in mutant vs 20.1 mo (15.5, 31.1) in wild-type. The phase II ATLANTIC trial testing durvalumab as third-line treatment included the largest cohort of EGFR mutant patients treated with IO after progression of TKI and chemotherapy. According to PD-L1 expression (< 25% or ≥ 25%), durvalumab achieved a response rate (RR) of 3.6% and 14.1%, a similar median PFS 1.9 months and a median OS of 9.9 months and 13.3 months, respectively[6]. Despite improvements in the treatment of stage IV NSCLC with the introduction and dissemination of checkpoint inhibitors, very little progress has been made in the treatment of stage III. The PACIFIC trial was the first study to show a clear benefit for the approach. Patients were enrolled regardless of PD-L1 expression, and those with EGFR mutations were also eligible. The subgroup of patients with EGFR mutations did not clearly benefit from durvalumab maintenance. These patients were equally represented in the durvalumab (6%) and placebo (5.9%) arms. The HR was 0.76 in this setting, and whether because of a small sample size or true lack of efficacy, the findings were not significant (95% CI, 0.35–1.64). In NADIM Study, a Phase II, with neoadjuvant chemotherapy and immunotherapy in stage III, unprecedented pCR rates observed (around 70%) and with down-staging around 90%. We did not include patients with actionable mutations, and we do not have information about other trials using chemo and IO. In KN 189 using combination of chemo and IO in stage IV, no sensitizing EGFR or ALK alteration were included. In the ImPOWER 150 study[7] comparing the use of bevacizumab plus atezolizumab plus carboplatin, plus paclitaxel versus carboplatin plus paclitaxel plus bevacizumab in first-line stage IV, provides interesting results in PFS, with a HR of 0.41 (95% CI: 0.22-0.78), in patients with common mutations (already treated with TKIs) in the arm with atezolizumab plus chemo better than the control arm. In the light of these results, we may conclude that other biomarkers such as a tumor mutational burden (TMB) could be used in the future, but low TMB is especially significant among the oncogenic alterations strongly related with never-smokers, such as EGFR mutation and ALK rearrangements. Therefore, these data suggest a role for actionable mutations testing in the stage III setting and for additional trials specifically targeting EGFR-mutant patients and stage III disease.

ES03.01 TARGETING ALTERED MICRORNA EXPRESSION IN MESOTHELIOMA

G. Reid

University of Otago, Dunedin/New Zealand

MicroRNAs (miRNAs) are an important class of noncoding RNA that post-transcriptionally regulate the expression of most protein-coding genes. In addition to central roles in normal biology, their aberrant expression in tumours contributes to all of the hallmarks of cancer. In common with other tumour types, changes in miRNA expression in malignant pleural mesothelioma (MPM) are characterised by a global downregulation, although elevated levels of some miRNAs are also found. While altered expression has been demonstrated for many miRNAs in MPM, relatively few have been functionally characterised. Early studies reported modest tumour suppressive activities of, among others, miR-29c, miR-31 and miR-145. More recently, miR-16, miR-193a and the miR-34 family were shown to have clear tumour suppressor activity; restoring the levels of these miRNAs leads to a range of effects including inhibition of cell growth, induction of apoptosis, reversal of drug resistance and reduced migration and invasion. In the case of miR-16 and miR-193a, targeted delivery of mimics to tumours in a xenograft model led to significant inhibitory effects on tumour growth. These results laid the foundation for the phase I MesomiR-1 trial, investigating the safety and optimal dose of a miR-16-based mimic delivered in anti-EGFR antibody-targeted bacterial minicells. This trial of 27 patients demonstrated safety of the treatment as well as initial signs of activity, with one objective response and stable disease in a further 15 patients. With miR-16 also impacting response to pemetrexed and contributing to PD-L1 regulation *in vitro*, restoration of miR-16 levels in combination with chemo or immunotherapy are potential future applications of this approach. Other miRNAs with pronounced tumour suppressor activity, including miR-137 and miR-193a, are further candidates for clinical development. The lower levels of miR-193a recently found to be associated with shorter overall survival in the TCGA study lend support to this notion. In contrast to the use of mimics to restore levels of miRNAs downregulated in MPM, inhibition of overexpressed miRNAs with antisense oligonucleotides is an alternative strategy for modulating miRNA levels. This approach is attractive as it may be amenable to local delivery, avoiding the problems associated with tumour targeting via systemic administration. While the number of miRNAs found to be consistently overexpressed in MPM is relatively small, recent studies suggest that their inhibition can have profound effects on MPM growth. One such example was the report of the effects of inhibiting the overexpressed miR-182 and miR-183. They are upregulated in MPM cell lines where they promote proliferation and invasion, at least in part due to suppression of FOXO1. Reducing their levels with miRNA inhibitors reversed these effects, with dual inhibition showing additive effects. An oncogenic role for miR-182 was first demonstrated in melanoma, in which this miRNA enhances migration, invasion and metastasis via inhibition of FOXO3 and MITF. Upregulation of miR-182 in melanoma is due to amplification (at 7q31) of a miRNA cluster which also contains the related miR-183 and miR-96. As this region appears to be more frequently lost in MPM, the mechanism for overexpression remains to be determined. Another miRNA with oncogenic activity in MPM is miR-24, which was identified via a screen of polysome-associated miRNAs and is upregulated in cell lines and tumour samples. This miRNA regulates a range of genes involved in cell adhesion and communication, many of which are associated with good prognosis, and miR-24 knockdown reduced migration and invasion *in vitro* and in vivo. Although the targets of miR-24 identified in this study had no obvious link to MPM biology, it is intriguing that in other cancers miR-24 regulates both transcripts produced by the *CDKN2A* locus. Whether other well known oncogenic miRNAs such as miR-155, miR-10b and miR-21

promote MPM tumour progression remains to be seen, but the initial results with miR-182, miR-183 and miR-24 warrant further pre-clinical development. Despite progress in the development of miRNAs as therapeutic targets for MPM, outstanding questions remain. Of particular relevance is the question of the cell of origin of dysregulated miRNAs. As tumour samples consist of a mix of cancer, stroma and immune cells, the source of miRNA contributing to changes in expression is unknown and thus impacts the interpretation of results. For example, altered expression of miR-223 was linked to changes in migratory behaviour of MPM, but in xenograft studies this miRNA is clearly derived from the stroma. Another confounding observation concerns the apparent contradictory findings from studies of the same miRNA. For example, miR-137 has clear tumour suppressor function in MPM cells *in vitro*, but its expression varies widely across MPM lines and is found at higher levels in tumours from patients with shorter survival. Similarly, miR-31 has growth inhibitory activity but higher expression is associated with poor prognosis in sarcomatoid tumours. There are also cases of different miRNAs showing apparent differences in MPM compared with other cancers. A prime example of this is miR-21; an oncomiR in most cancer types, but growth inhibitory when overexpressed MPM cell lines. Finally, because the activity of miRNAs typically leads to modest reductions in target genes, demonstrating in vivo effects is not trivial. In addition, because the miRNA being restored (or inhibited) is usually identical to its endogenous miRNA counterpart, measuring delivery can be difficult. Due to their short size, even novel sequences such as that used in the TargomiR study are difficult to definitively measure by RT-qPCR or RNA-seq. In summary, the changes in miRNA expression in MPM provide avenues to develop new therapetuic approaches. The successful phase I trial of TargomiRs demonstrated that miRNA targeting is feasible in MPM and while the majority of miRNA studies in MPM have focused on miRNA mimics, recent studies suggest that antisense inhibitors have similar potential. Notwithstanding the ongoing difficulties in delivering nucleic acid-based drugs, the recent FDA approval of the first siRNA therapy – together with ongoing clinical trials of a number of miRNA mimic drugs – means that gene silencing drugs have moved from concept to reality. Continued preclinical studies and early phase clinical trials are needed to determine the true potential of miRNA targeting in MPM treatment.

ES03.02 TARGETING CDKN2A IN MESOTHELIOMA

D. Fennell

University of Leicester & University Hospitals of Leicester NHS Trust, Leicester/United Kingdom

Interrogation of the genomic landscape in mesothelioma has revealed considerable inter-patient genomic heterogeneity, however development of molecularly targeted stratified therapy is currently in its infancy. Somatic copy number loss involving the chromosome 9p21-3 locus occurs at high frequency (45% deep deletion in the TCGA cohort), and its expression may be further suppressed by DNA methylation. 9p21-3 harbours CDKN2A. Conditional Knockout of CDKN2A is sufficient to initiate mesotheliomas in vivo consistent with a role in tumorigenesis. This is supported by emerging phylogenetic analysis in which 9p21-3 occurs as an early (clonal or truncal) homozygous event during tumour evolution, in around 20% of cases. Late homozygous and heterogzyous losses also occur, with evidence of parallel evolution. Importantly, CDKN2A is a major negative prognostic factor associated with earlier progression following surgical resection. CDKN2A encodes two genes; 1, the inhibitor of cyclin dependent kinases 4 and 6 known as p16ink4A, and 2. MDM2, an inhibitor of the p53-MDM2 interaction. Early preclinical studies showed that re-introducing p16ink4A transgene in a CDKN2A negative mesothelioma exhibited anti-tumour activity. Small molecule inhibition of CDK4/6 essentially phenocopies p16ink4a (in the presence of wild type RB1). Large scale drug-gene interaction studies have revealed CDKN2A dependent sensitivity to CDK4/6 inhibition suggesting a possible strategy in mesothelioma. We have therefore developed the MiST stratified umbrella trial (NCT NCT03654833) is therefore evaluating the CDK4/6 inhibitor abemaciclib in p16ink4a negative relapsed mesothelioma (arm 2) Loss of p14ARF expression promotes MDM2, an E3 ubiquin ligase targeting p53. Given the low mutation rate for p53 in mesothelioma (around 16% in the TCGA), MDM2 inhibitors may, in the context of p14ARF loss, de-repress p53 to mediate tumour suppression. Preclinical data supports this hypothesis which has translational potential. Co-deletion of the gene MTAP with CDKN2A is common, and coincident with around 80% of CDKN2A losses. MTAP (methylthioadenosine phosphorylase) may represent a potential molecular target in 9p21-3 deleted mesothelioma. This tumour suppressor salvages the essential amino acid methionine, as well as adenine, and plays a critical role in the polyamine salvage pathway. Recently it has been shown that loss of MTAP leads to an increase level in its substrate, methylthioadenosine (MTA). This metabolite directly interacts with and inhibits the epigenetic modifier, PRMT5 (protein arginine methyltransferase 5) that mediates symmetrical arginine di-methylation of histone H4 (H4R3me2s). A direct consequence of this is a reduction in the pool of functional PRMT5 enzyme, revealing a vulnerability to 1. Inhibition of PRMT5 expression or 2. Inhibition of PRMT5 substrate (SAM) synthesis via MAT2A (which converts methionine to SAM). 1st generation small molecule PRMT5 inhibitors are currently undergoing phase 1 clinical evaluation, however MTA dependent allosteric antagonism of such inhibitors presents a challenge to achieving efficacy. Small molecule transcriptional suppression may present a solution. Accordingly, using the connectivity map, we have identified quinacine as a PRMT5 transcriptional suppressor capable of suppressing PRMT5 transcription (which is c-jun dependent), mediating MTAP selective loss of viability with commensurate reduction in H4R3me2s, consistent with an on-target effect. In summary, 9p21-3 loss encompassing CDKN2A and MTAP is one of the most common genomic aberrations in mesothelioma. Novel strategies are emerging with significant translational potential to deliver targeted therapies for mesothelioma.

ES03.03 TARGETING NF2 IN MESOTHELIOMA

Y. Sekido

Aichi Cancer Center Research Institute, Nagoya/Japan

Malignant mesothelioma (MM), which arises from the pleural or peritoneal cavities, is a very aggressive tumor that is highly refractory to conventional therapies. Several key genetic alterations, including mutations of the *CDKN2A/ARF*, *NF2*, and *BAP1* tumor-suppressor genes, are associated with the development and progression of MM. Notably, activating oncogene mutations are very rare; thus, it is difficult to develop effective inhibitors to treat MM. *Neurofibromatosis type 2* (*NF2*) encodes the tumor suppressor protein moesin-ezrin-radixin-like protein (merlin), which is a member of the Band 4.1 family of cytoskeletal linker proteins. NF2-inactivating mutations, deletions, or rearrangements are harbored in 40%–50% of MMs and result in bi-allelic loss of protein function. Somatic *NF2* mutations are also frequently detected in sporadic schwannomas, meningiomas, ependymomas, and to a lesser extent, in other types of solid tumors. Merlin/NF2 primarily localizes to the plasma membrane where it mediates contact-dependent inhibition of proliferation in normal cells. Merlin/NF2 has also been shown to regulate multiple cell-signaling cascades including the Hippo pathway. The Hippo signaling pathway is involved in critical biological processes, including organ size-control, development, differentiation, tissue regeneration (via cell-growth restriction), cell division regulation, apoptosis, and cancer development. The 4 core components in this pathway, MST1/2, SAV1 (also called WW45), MOB1, and LATS1/2, have all been shown to act as tumor suppressors. Since MMs also exhibit genetic or epigenetic inactivation of Hippo pathway components, including MST1/2 and LATS1/2, merlin-Hippo pathway dysregulation is thought to play a key role in MM development and progression. Hippo pathway inactivation results in inactivation of the LATS1/2 kinases, which, in turn, induces constitutive activation (via underphosphorylation) of YAP1 and TAZ transcriptional coactivators. Underphosphorylation stabilizes YAP1 and TAZ and enables them to enter the nucleus where they bind to distinct transcription factors, including TEAD1-4, and regulate transcription of numerous target genes. We, along with other groups, have shown that constitutive activation of YAP1 and TAZ *in vitro* and *in vivo* confer malignant phenotypes in mesothelial cells, whereas their knockdown suppresses these phenotypes. Critical YAP1/TAZ target genes include prooncogenic cyclin D1 (*CCDN1*), forkhead box M1 (*FOXM1*), connective tissue growth

factor (*CTGF*), and cytokine-encoding genes such as *IL1B*, which have also been shown to enhance the malignant phenotypes of MM cells. Currently, several small molecules have been developed to directly target YAP1/TAZ coactivators, including YAP1-TEAD binding inhibitors. Targeting key YAP1/TAZ-inducible downstream genes, such as *IL1B* and *CTGF*, in the dysregulated Hippo pathway may also represent an alternative approach to inhibit MM progression. Furthermore, targeting stimulatory or inhibitory signaling pathways within the Hippo pathway, which include TGF-beta, Wnt, G-protein-coupled receptor (GPCR), mammalian target of rapamycin (mTOR) and mevalonate pathways, may be considered. Collectively, these evidences indicate that the Hippo pathway is a promising therapeutic target for MM treatment, particularly with regard to NF2-Hippo pathway inactivation, and supports the development of new strategies to effectively target YAP1/TAZ activation status as a promising therapeutic modality for this formidable disease.

ES03.04 PEGARGIMINASE TO TREAT MESOTHELIOMA

P. Szlosarek

St. Bartholomew's Hospital & Barts Cancer Institute, London/United Kingdom

Treatments based on targeting metabolism remain central to the management of malignant mesothelioma, an intractable malignancy with a median overall survival (OS) of ~12 months. The standard of care since 2003 is an antifolate drug (pemetrexed or raltitrexed) paired with a platinum salt which provides a 2-3 month median survival benefit. Arginine metabolism is dysregulated in mesothelioma with deficiency of the rate limiting enzyme argininosuccinate synthetase 1 (ASS1) three-fold higher in sarcomatoid and biphasic compared to epithelioid tumours. ASS1 inactivation via promoter methylation diverts the precursor aspartate for enhanced pyrimidine synthesis via carbamoyl-phosphate synthetase 2 (CAD), accounting in part for increased tumorigenesis. However, loss of ASS1 generates a collateral dependence on exogenous arginine for growth (auxotrophy) that may be exploited with arginine-degrading enzymes, such as arginine deiminase and arginase. A randomised phase 2 trial of pegargiminase (ADI-PEG20, pegylated arginine deiminase) monotherapy delivered as a weekly intramuscular (IM) injection (36mg/m2) in patients with ASS1-deficient mesothelioma (ADAM study; NCT01279967) revealed a 1.2 month progression-free survival benefit over best-supportive care (BSC) only (3.2 versus 2.0 months; hazard ratio of 0.56; and p=0.03). The restricted mean survival for OS, calculated due to early survival curve cross-over, was 15.7 months for the pegargiminase group versus 12.1 months for the BSC group, for a difference of 3.6 months (p=0.13). Pegargiminase was well-tolerated with a 13.6% grade 3-4 allergic rate, including anaphylactoid reactions and serum sickness, which were readily reversible and a low frequency of grade 1-2 reactions, mostly local skin irritation and discomfort due to the IM therapy. Pharmacodynamically, pegargiminase suppressed arginine plasma levels (measured on the day of and prior to drug dosing) for 4 weeks before a return to baseline with a reciprocal change in the degradation product, citrulline, a consequence of the production of drug-neutralising antibodies. Partial metabolic responses were documented by FDG-PET in almost 50% of patients by the third week of pegargiminase administration. Thus, while the PFS primary endpoint was modest, the ADAM trial is the first proof of principle study to show a survival benefit using an ASS1 biomarker-directed strategy. More recent efforts in the arginine deprivation field have focused on rational drug combinations. Preclinically, pegargiminase reduces intracellular thymidine pools via inhibition of enzymes involved in de novo synthesis, specifically thymidylate synthetase and dihydrofolate reductase, and pyrimidine salvage via thymidine kinase 1, collectively enhancing pemetrexed cytotoxicity in arginine-auxotrophic tumour cell lines, including mesothelioma. This was tested in the phase 1 TRAP study (NCT02029690) combining pegargiminase with pemetrexed and cisplatin (ADIPemCis) in patients with ASS1-deficient mesothelioma (n=5) and non-squamous non-small cell lung cancer (NSCLC, n=4). The dose-escalation portion of the study revealed ADIPemCis was safe with a 78% (n=7/9) partial response rate and an overall 100% disease control rate. Moreover, partial responses were seen in biphasic and sarcomatoid mesothelioma considered to be largely chemorefractory. The overall PFS and OS in this small study was 7.5 and 13.9 months, respectively. A dose expansion cohort in mesothelioma at the maximum tolerated dose confirmed a similarly high disease control rate of 93.5% (29/31) and, with two-thirds of patients with non-epithelioid mesothelioma (10 biphasic and 10 sarcomatoid), an overall median PFS of 5.6 and OS of 10.1 months was observed. Although, a small series there was a 3 fold-higher survival at 12 months for patients with sarcomatoid mesothelioma compared with historical controls (30% versus 10% survival). These data supported the opening of a randomised double-blind phase 2/3 trial called ATOMIC-meso and the first to focus on the most aggressive subtypes of mesothelioma that is expected to report initial results by 2020 (NCT02709512). Mesothelioma therapeutics are at a crossroads with increasing evidence for a key role of immunotherapy in a subset of patients. Objective responses of 10-30% have been reported in several phase 1-2 studies of PD1/PD-L1 antagonists with or without CTLA4 blockade in patients with mesothelioma. Pegargiminase increases PD-L1 expression on mesothelioma cells and leads to an influx of T cells in immunocompetent murine tumour models. Furthermore, urea cycle dysregulated cancers with increased aspartate flux and pyrimidine synthesis are hypothesized to generate genomic signatures more amenable to immune checkpoint blockade. Preliminary results of a phase 1 study of pegargiminase and pembrolizumab reveal activity in arginine auxotrophic cancers with good safety and tolerability (NCT03254732). Similarly, a first-in-man trial of platinum, pemetrexed combined with pegargiminase and atezolizumab (iTRAP study) is planned to start in 2019 focusing on patients with ASS1-deficient non-squamous NSCLC (NCT03498222). Pending these early data, and further ASS1 and PD-L1 biomarker analyses, additional studies are planned in patients with mesothelioma. Recent preclinical work in our laboratory has revealed that arginine deprivation has a key role in remodulating the tumour microenvironment with an increase in macrophages involved in resistance to pegargiminase. Mesothelioma cells co-cultured with macrophages released several proinflammatory cytokines including IL-1alpha and the CXCR-2 dependent chemokines IL-8, CXCL2 and CXCL8 with a co-ordinate increase in ASS1 and ASL in macrophages and tumour cells, respectively bypassing sensitivity to pegargiminase. Moreover, analysis of blood from the ADAM study revealed an increase in argininosuccinate in the plasma of early metabolic progressors and paired biopsies from the TRAP mesothelioma expansion cohort revealed an influx of macrophages consistent with the preclinical work. Thus, re-education of macrophages with chemokine or "don't' eat me" inhibitors may be a viable strategy in mitigating stromal resistance to pegargiminase. Further optimisation of pegargiminase for the treatment of mesothelioma may come from manipulation of additional resistance pathways. Thus, antimalarial agents such as chloroquine inhibit autophagy, a common escape mechanism to nutrient deprivation, and have enhanced the effect of arginine depletion in various ASS1 negative tumour cell lines including mesothelioma. Lastly, synthetic lethal approaches targeting polyamine metabolism in ASS1-negative mesothelioma cells, also merit clinical investigation in combination with pegargiminase and may lead to deeper and more durable metabolic responses. In summary, bench-to-bedside studies of pegargiminase have progressed to a phase 2/3 trial in mesothelioma. Combinations of pegargiminase with immune checkpoint blockade and modulators of resistance pathways appear promising areas for further development.

ES03.05 INHERITED PREDISPOSITION TO MESOTHELIOMA, BIOLOGICAL AND CLINICAL DIFFERENCES WITH SPORADIC MESOTHELIOMA

J.E. Churpek

The University of Wisconsin Madison, Madison/United States of America

Why less than 5% of those exposed to asbestos develop malignant mesothelioma, [1] has long fueled the hypothesis that inherited genetic factors may contribute to risk. Studies in erionite exposed households in Turkey suggested that inherited genetic factors cooperate with shared exposures in mesothelioma development.[2] In 2011, the discovery of inherited mutations in the gene *BAP1* in families clustering multiple cases of mesothelioma[3] and demonstration of further proof of causation in a mouse model, showing that mice

with one abnormal copy of *Bap1* develop mesothelioma more quickly, with lower asbestos doses, and at a higher proportion than wild-type mice[4, 5] solidified the role of inherited genetics in mesothelioma risk. Failure to detect inherited *BAP1* mutations in a substantial subset of cancer-prone and sporadic mesothelioma cases suggested, however, that *BAP1* was not the only gene involved. A strong family history of many types of cancer has also been observed, suggesting that other broad cancer susceptibility genes were involved.[6, 7] Recently, our group as well as groups at the NCI and in Italy all published results of targeted panel-based genomic sequencing of three unselected series of mesothelioma cases (Table 1).[8-10] We all found a similar overall germline mutation frequency of 10-12%, placing mesothelioma among a growing number of solid tumors, such as metastatic prostate cancer, with mutation frequencies in this range. Clinical predictors of a germline mutation from all three series include: peritoneal compared with pleural disease, younger age, those with a personal history of other cancers, female gender, and lower level of prior asbestos exposure. By gene, *BAP1* accounted for the most mutations, but overall more than half of those carrying a germline mutation carried a mutation in a gene other than *BAP1*. Biologically, most of these genes function predominantly in DNA repair pathways, especially the homologous recombination pathway involved in double strand break repair. These data may explain prior observations of complex cytogenetics and other features of genomic instability in mesothelioma tumors[9-11] and could explain platinum sensitivity, a chemotherapy drug known to have increased efficacy in solid tumors, such as ovarian cancer, in those with germline mutations in genes in the same pathway. To investigate this possibility, we combined our data with data from the NCI series and together, our groups found that a germline mutation in any DNA repair gene was associated with improved OS after platinum based chemotherapy and that this effect was independent of age at diagnosis and gender, two key known prognostic factors.[9] Interestingly, this effect was only present in those with pleural disease, in whom mutation carriers had a median OS of 7.9 vs 2.4 years in non-mutation carriers (p=0.0012). Further, among germline mutation carriers, OS for those with pleural or peritoneal disease was similar suggesting a similar biology is a more important predictor of OS than site in those cases. These data support the investigation of other DNA repair based therapies, such as PARP inhibitors, in patients with mesothelioma, especially among those with a relevant germline mutation. Further investigation of the full spectrum of inherited risk factors in mesothelioma, their interaction with response to various therapies, as well as how patterns of acquired mutations in mesothelioma tumors differ by germline mutation status and whether those without a germline mutation but whose tumors acquire similar gene mutations respond to similar therapies are all yet to be determined.

ES04.01 UPDATE IN SYSTEMIC TREATMENT OF SCLC

S. Thongprasert

Bangkok Chiangmai Hospital, Chiangmai/Thailand

Chemotherapy combination of cisplatin plus etoposide is the standard option for extensive stage Small Cell Lung Cancer (SCLC); though the response rate was very high, however most cases of the extensive stage recurred within one year and there was no good regimen for second line. Several chemotherapeutic agents such as topotecan, irinotecan, amrubicin or combination of cyclophosphamide, doxorubicin and vincristine (CAV) had been used as second line treatment with minimal benefit. Within the past couple years there're the new way of treating lung cancer especially the use of immunotherapy, which several agents had their roles in the treatment of Non-Small Cell Lung Cancer (NSCLC). The study of immunotherapy in SCLC was very slow. The use of T cell immune-checkpoint inhibitors (anti-PD1: nivolumab, pembrolizumab; anti-PD-L1: atezolizumab, durvalumab; anti-CTLA-4: ipilimumab, tremelimumab) have shown promising antitumor activity with the potential to prolong survival in SCLC patients. Nivolumab was the first immunotherapy agent that had approved by The US Food and Drug Administration (FDA) 2018 to be the third line drug according to the outcome in CheckMate-032, which's a multicenter, open-label trial in patients with metastatic solid tumors. This subgroup comprised 109 patients with metastatic SCLC, with disease progression after platinum-based therapy and at least one other prior line of therapy, regardless of tumor PD-L1 status. All patients received nivolumab at3 mg/kg by intravenous infusion over 60 minutes every 2 weeks. The ORR was 12% (95% CI: 6.5, 19.5). Responses were durable for 6 months or longer in 77%, 12 months or longer in 62%, and 18 months or longer in 39% of the 13 responding patients. PD-L1 tumor status did not appear to be predictive of response. Pembrolizumab has been granted a priority review designation by the FDA for the treatment of patients with advanced small cell lung cancer (SCLC) whose disease has progressed following ≥2 prior lines of therapy. Data from the phase II KEYNOTE-158 and phase Ib KEYNOTE-028 studies, pembrolizumab at 200 mg intravenously (IV) every 3 weeks for 2 years or until disease progression, unacceptable toxicity, or study withdrawal elicited 19% and 33% overall response rates (ORRs) in patients with extensive-stage SCLC, respectively. Atezolizumab plus carboplatin and etoposide, was approved by FDA for the first-line treatment of adult patients with extensive-stage small cell lung cancer based on the data from IMpower133 which is a randomized treatment using atezolizumab 1200 mg and carboplatin AUC 5 mg/mL/min on day 1 and etoposide 100 mg/m2 intravenously on days 1, 2 and 3 of each 21-day cycle for a maximum of 4 cycles, followed by atezolizumab 1200 mg once every 3 weeks until disease progression or unacceptable toxicity, or placebo and carboplatin AUC 5 mg/mL/min on day 1 and etoposide 100 mg/m2 intravenously on days 1, 2, and 3 of each 21-day cycle for a maximum of 4 cycles, followed by placebo once every 3 weeks until disease progression or unacceptable toxicity. Overall survival (OS) was 12.3 months for patients receiving atezolizumab with chemotherapy and 10.3 months for those receiving placebo with chemotherapy (hazard ratio 0.70; 95% CI: 0.54, 0.91; p=0.0069). Median PFS was 5.2 months (4.4, 5.6) compared with 4.3 months (4.2, 4.5) in the atezolizumab and placebo arms, respectively (HR 0.77; 0.62, 0.96; p=0.0170). In conclusion, there are several new ways and also new agents that target the immune cell and should be able to improve the outcome and survival of SCLC.

ES04.02 PATHOLOGY OVERVIEW FOR CARCINOID AND NE SPECTRUM

E. Brambilla

CHUGA/Université Grenoble Alpes, La Tronche/France

The spectrum of neuroendocrine (NE) tumors ranges from low grade typical carcinoid (TC) to intermediate grade Atypical carcinoids to high grade small cell lung carcinoma (SCLC) and large cell neuroendocrine carcinoma (LCNEC) Although very different from high grade tumors in their molecular genetics and expression profiling, carcinoid are included in the spectrum of NE tumors since WHO 2015 (1) on the basis of their common NE epithelial differentiation.Carcinoids display many clinical differences with high grade NE tumors being not strongly associated with smoking (only 20-40% smokers), their specific association with Multiple Endocrine Neoplasia type 1 (MEN1) not seen in High grade tumors and their occurrence on the background of NE cell hyperplasia and tumorlets in 60% of TC and AC, very rare in high grade tumors. Whereas carcinoid are never combined with conventional lung cancer, 20 to 25% of SCLC and LCNEC are combined. Since the NE markers are common in the full spectrum, morphology, mitoses and KI 67 (proliferations markers) are useful to differentiate carcinoids from SCLC and LCNEC. The accurate diagnosis of each is critical in view of their eminently different therapeutic management. Small cell lung carcinoma (SCLC SCLC is the most frequent NE lung tumor (15-20% of lung cancer) and has the worse prognosis in the spectrum. Most are proximal, 70% perihilar forming peribronchial growth involving lymph nodes .Less than 5% are solitary primary nodules stage I. SCLC is a high grade malignant epithelial NE tumor with characteristic cytopathologic features recognizable in routine microscopy without use of immunohistochemistry (IHC) in optimal cell preservation. IHC may be used in suboptimal condition (crush artifact) to confirm the diagnosis. SCLC is made of sheets of small cells ,round/oval or spindle shaped forming whorls, with little cytoplasm, nuclei with unconspicuous nucleoli, finely granular dispersed chromatin, and nuclear molding. Mitotic rate is very high more than 50 reaching 100 for 2mm^2 and KI67 exceeds 50% (50-100%).Extensive necrosis is frequent .Most SCLC express NE markers Chromogranine A, Synaptophysin and CD56. 75% express TTF1 (recommended clone 8G7G3 1). Less than 10% remain negative for all 3 NE markers and TTF1. In these cases a P40 staining is mandatory to eliminate a basaloid carcinoma (P40 Positive) with which it may be confused in suboptimal preparations. SCLC can present as pure or combined. Any association of small cells with another NSCLC (Adenocarcinoma, Squamous cell carcinoma, large cell or large cell NE carcinoma, sarcomatoid giant and spindle cells) is diagnosed as combined SCLC (20%). Several studies of their molecular characteristics were recently published and compared with other tumors of the NE spectrum. Theses are specific, closer from a part of LCNEC but distinct from theses of carcinoids (Georges 2016, Georges 2018). Small cell carcinoma in non-smokers should be looked for EGFR mutation (acquired after TKI therapy of an Adenocarcinoma or spontaneous). Large cell neuro endocrine carcinoma (LCNEC) LCNEC is a high grade NE lung tumor accounting for 3% of lung cancers .The diagnosis is based on the necessary association of NE morphology (organoid nesting ,rosettes ,palisading) and expression of NE markers (at least one):chromogranine A, synaptophysin and CD56. Seventy-nine % develop in the lung periphery, 5% show endobronchial growth .They form circonscribed nodular mass intensely necrotic .They lack typical cytology in contrast with SCLC .The mitotic rate is more than 10 per 2mm^{2}to distinguish them from atypical carcinoid (2 -10/2mm ^{2}) ,ranging from 20 to 80-100 with KI67 very high exceeding 50% usually 80-100%. They are composed of large cells with low nuclear to cytoplasmic ratio, a conspicuous nucleoli and vesicular chromatin .A spectrum of morphologies range from SCLC (small cell –like) to non small cell-like or to a few atypical carcinoids-like, showing the need for an accurate diagnosis using objective criteria (proliferation). A constellation of multiple criteria should be used to distinguish them fro SCLC or AC .Combined LCNEC is the association of any LCNEC component with a conventional component (25%). Due to spatial heterogeneity of NE morphology and NE expression the diagnostic may be difficult on small biopsies .However a NSCLC without NE morphology but 1 or 2 NE markers is diagnosed as a NSCLC (with unclear phenotype) since 15 % of NSCLC also express 1 or 2 NE markers.TTF1 is expressed in 41 % of LCNEC specially when combined with adenocarcinoma.Molecular genomics and expression profiling

classify in 2 categories one simiilar to SCLC with biallelic inactivation of P53 and RB genes and another with KEAP 1 or LKB1 mutations looking like NSCLC .LCNEC are very different from Carcinoids (Georges 2018) Carcinoids tumors:Typical and Atypical Carcinoids Carcinoids account for 1-2 % of lung tumors of which 10% are Atypical carcinoid .Typical (low grade) and atypical carcinoids(intermediate grade) are distinquished on objective criteria (mitoses index (table I) and necrosis, but KI67 has no defined cut- off to separate them. They develop centrally as endobronchial growth or in the lung periphery (16-40 %) Cytology allows accurate recognition. NE morphology is well achieved with organoid patterns(glandular, follicular ,trabecular, angiomatoid...) most often multiple .Spindle cell pattern is more frequent in the peripheral carcinoids. All express the 3 NE markers and TTF1 is usually negative (except in a few peripheral carcinoids) References Travis WD, Brambilla E, Burke AP, Marx A, Nicholson AG. ES04.04 ROLE OF STEREOTACTIC BODY RADIATION IN EARLY AND ADVANCED SCLC

R. Decker

Yale School of Medicine, New Haven/United States of America

Stereotactic Body Radiotherapy (SBRT) has been rapidly adopted as the standard of care for patients with early-stage Non-Small Cell Lung Cancer (NSCLC) who are medically inoperable, and more recently for selected patients with oligometastatic cancer. The utilization of SBRT in patients with Small Cell Lung Cancer (SCLC) is markedly lower, reflecting both the lower incidence and the lack of clinical data, but it has been increasing over the past several years. Given the aggressive nature and high metastatic potential of SCLC, the optimal integration of SBRT into the multimodality treatment of early-stage SCLC patients is critical, so that we don't delay or otherwise compromise systemic therapy. In patients with advanced or recurrent SCLC, SBRT offers a valuable treatment option for well selected patients, a group that may be increasing as new therapeutic options emerge. Small Cell Lung Cancer (SCLC) represents less than 20% of all new lung cancer diagnoses. Compared to NSCLC, SCLC is less likely to present with localized disease, carries a higher risk of metastatic failure, and stage for stage is associated with worse overall survival. The majority of limited stage SCLC patients have locally advanced tumors, and the standard of care remains concurrent chemotherapy with fractionated thoracic radiation. Stage I SCLC is diagnosed in less than 5% of incident cases. Given the propensity for nodal metastasis, invasive staging of the mediastinum is indicated in all of these patients. For those who are node negative, there is a limited amount of data to guide decisions about optimal management. Surgery has emerged as a standard of care for operable patients, based on favorable outcomes in population-based studies. Following surgery, adjuvant chemotherapy is recommended regardless of tumor size, based on the high risk of subsequent metastatic failure. For those patients who won't tolerate lobectomy, consensus guidelines now recognize that Stereotactic Body Radiotherapy (SBRT) is a treatment option, and a reasonable alternative to conventional chemoradiotherapy. This is largely justified by the observed increased efficacy of SBRT compared to fractionated radiation in stage I NSCLC, an observation which is now supported by a randomized trial. The published data to date suggests that the utilization of SBRT in stage I SCLC has been increasing. Single- and multi-institutional case series suggest, unsurprisingly, that this approach appears to be safe, and the efficacy in terms of local control appears to be similar to that seen in NSCLC patients. In the US, the use of SBRT in SCLC appears to be more common in elderly patients, and the utilization seems to be driven by large institutions. Chemotherapy is an essential part of multimodality care of SCLC in all stages of disease. The addition of adjuvant chemotherapy sequentially after SBRT in early stage patients is associated with improved survival in retrospective studies, similar to the better outcomes seen with surgery and chemotherapy in operable SCLC patients. Recent and ongoing prospective efforts are evaluating concurrent chemotherapy with SBRT, including both traditional short-course and more extended hypo-fractionated radiation schedules. ES04.05 ADVANCES IN RADIONUCLIDE TREATMENT FOR NEUROENDOCRINE TUMOURS

A. Lamarca

The Christie NHS Foundation Trust, Manchester/United Kingdom

Lung carcinoids (LC) are rare tumours, however incidence is increasing due to improvement in diagnostic techniques. They account for approximately 2% of all lung malignancies and around 20-30% of all neuroendocrine tumours (NETs). They characteristically have an indolent clinical behaviour with longer survival intervals compared to poorly differentiated lung neuroendocrine malignancies. LC are divided into typical or atypical carcinoid tumours according to pathological characteristics, such as amount of mitosis and necrosis. A significant proportion of LC expresses somatostatin receptors by immunohistochemistry. Nuclear medicine imaging, such as somatostatin receptor scintigraphy, has been employed for staging of LC for years. Development of new nuclear medicine imaging techniques, including Positron Emission Tomography (PET) combined with CT has improved diagnosis, staging and treatment of patients diagnosed with LC. 68-Gallium(^{68}Ga)-radiolabelled PET (^{68}Ga-DOTA-PET) tracers for functional NET imaging have emerged as potentially useful tools for diagnosis and staging. For localised stages of LCs, surgery is the treatment of choice, performed with curative intent. Locally advanced inoperable or metastatic tumours are treated with palliative approaches based on somatostatin analogues (SSAs), temozolomide-based chemotherapy combination and targeted therapies (everolimus). Recently, the use of Peptide Receptor Radionuclide Therapy (PRRT) has revolutionised the treatment of extra-pulmonary neuroendocrine tumours. Based on the results of the NETTER-1 study, PRRT has been approved for the management of small bowel and pancreatic NETs and it is considered a standard of care after progression to SSA for patients with uptake in ^{68}Ga-DOTA-PET (theranostic approach). This lecture will summarise the state of the art of LC with a focus behind the rationale of PRRT and its potential role in the management of LCs.

ES04.06 SYSTEMIC TREATMENT OF LARGE CELL NEUROENDOCRINE CANCER

F. Blackhall

The Christie NHS Foundation Trust, Manchester/United Kingdom

Large cell neuroendocrine cancer (LCNEC) is a rare, aggressive cancer that accounts for approximately 3% of all lung cancer. It is characterised by high-grade features (>10 mitoses/2mm2) and the presence of neuroendocrine morphology and markers (1). The diagnosis of LCNEC is distinct from both non-small cell lung cancer (NSCLC) and other pulmonary neuroendocrine tumours such as carcinoids and small cell lung cancer (SCLC). Survival is poor with only 5% of patients alive at 5 years from diagnosis regardless of stage at presentation. Conventionally treatment has mirrored that of SCLC despite limited evidence for this approach. The recommended standard of care is a combination of platinum with etoposide based on the results of one single arm phase 2 study in which there were only 29 evaluable patients (2). The median progression free survival (PFS) and overall survival (OS) rates were 5 months and 8 months respectively. Of note the observed objective response rate was 34%, lower than reported ORRs in SCLC of ~70%. Similar worse outcomes in the LCNEC population are observed for treatment with irinotecan and cisplatin (3). The explanation for this disparity is provided by emerging evidence that LCNEC can be subcategorised into two major and clinically relevant subsets according to genomic characteristics (4). A 'SCLC-like' genomic profile is estimated to account for about 40% of LCNEC, characterised by RB1 and TP53 that hallmark SCLC and 'SCLC-like' LCNEC has clinical behaviour consistent with SCLC. The other subset is 'NSCLC-like' with wild-type RB1 as the main distinction alongside mutations that also occur recurrently, at various frequencies, in NSCLC such as STK11, KRAS, KEAP1 and NFE2L2. The latter were hypothesised to be relatively more sensitive to chemotherapy approved for NSCLC. Consistent with this, in a carefully conducted retrospective analysis patients with NSCLC-like LCNEC (RB1 wild type) who received platinum with gemcitabine or a taxane had a median OS of 9.6 months whereas those who received platinum and etoposide had a significantly shorter median OS of 5.8 months (p=0.026) (5). These results question the current standard of care for LCNEC and highlight the need for prospective examination of molecular subtyping to direct treatment decision making. The molecular heterogeneity underpinning LCNEC may also have implications for selection of immune checkpoint inhibitors (6) and other precision medicines targeting actionable mutations (7). The advent of specific KRAS inhibitors that appear promising in early phase development (8) generates further impetus to redesign our therapeutic algorithms for LCNEC according to genomic context if we are to improve outcomes for patients with this orphan disease. ES05.01 LUNG CANCER SURVIVAL: PROGRESS AND CHALLENGES

M. Nicolson

Aberdeen University, Aberdeen/United Kingdom

Background Between 1970s and 2011, many tumour 10-year survival rates increased significantly (eg prostate cancer from 25% to 84%) yet lung cancer lags behind with 5-year survival below 20%.1, 2 Most countries have no lung cancer screening programme and >80% of patients are diagnosed with advanced disease. A significant challenge for the United States lung cancer screening programme is poor uptake by low income but high risk candidates.3 To optimise results from potential curative radical radiotherapy and surgery, accurate staging of patients is vital; modern staging can improve patient selection for radical treatment, with stage 1 lung cancer 4-year overall survival (OS) increased in one study by 14.3% between 2001 and 2010, and postoperative survival improved from 51.5% to 66.5%.4 Over 80% of patients diagnosed with lung cancer are active or past cigarette smokers, and the need to maximise prevention remains. Government implemented smoking bans and funding of smoking cessation programmes are important, despite sketchy evidence for the latter being of benefit to lung cancer patients.5 Radiotherapy progress Improved techniques allow accurate targeting with stereotactic ablative radiotherapy (SABR) for patients with a small tumour who are unfit for surgery. In stage III NSCLC, CT simulation results in a smaller tumour target, better dose delivery and fewer side-effects. The immune stimulating effect of radiotherapy may increase effectiveness of immunotherapy (IO) on which further research continues. Radiotherapy ablation of oligometastatic tumours is also under investigation in ongoing attempts to improve survival in advanced disease. Systemic therapies improving survival There has been little improvement in small cell lung cancer (SCLC) outcomes the since 1980s, but progress for the 85% of patients with non-small cell lung cancer (NSCLC) is impressive, resulting from improved understanding of tumour molecular biology. Chemotherapy combinations seemed equivalent in NSCLC until groundbreaking results showed better survival in non-squamous NSCLC who received platinum with pemetrexed over gemcitabine.6 Maintenance pemetrexed improved survival still further in patients with NSCLC stable or responsive to induction chemotherapy. Controversy over patient selection for targeted therapy with tyrosine kinase inhibitors was resolved by the IPASS study which confirmed that testing for a sensitising EGFR mutation status was mandatory to ensure benefit.7 Patients inevitably develop resistance to EGFR TKIs and tumour rebiopsy is encouraged to determine the new molecular profile to optimise subsequent treatment. The new generation TKI osimertinib gave superior survival as first line therapy compared with erlotinib or gefitinib. In patients with ALK translocated NSCLC (approximately 5% of tumours), crizotinib was better than chemotherapy. More recently alectinib or brigatinib superceded as survival improved through their enhanced effectiveness in the CNS.8 Drugs are available to treat lung cancers with less common genetic drivers like ROS1 and BRAF but the commonest NSCLC mutation KRAS - in up to 30% cases - is not yet amenable to specific therapy, although several drugs are in development. Reflex testing by pathologists of non-squamous NSCLC is recommended with squamous tumours tested only in never smokers or mixed adenosquamous lung cancer.9 Identification of EGFR or ALK oncogene addicted lung cancers is vital to ensure delivery first line of appropriate targeted therapy since this increases patients' survival. NSCLC response to IO drugs targeting PD-1 and PD-L1 has revolutionised systemic therapy. Nivolumab was effective in relapsed squamous NSCLC, then first line pembrolizumab superceded chemotherapy in patients with >50% PD-L1 expressing non-squamous tumours. Atezolizumab (second line) and pembrolizumab-chemo (first line) efficacy are independent of PD-L1 expression. In stage III NSCLC, patients with no tumour progression following combination chemoradiotherapy have better OS with maintenance durvalumab.10 An important feature is the durable response to IO seen in some patients, with toxicity usually manageable and less than many chemotherapies. Studies with IO as adjuvant and neoadjuvant treatments are ongoing. Since IO treatment may continue every 2-3 weeks by intravenous infusion for up to two years, there is a significant impact on pharmacy, hospital time for patients and healthcare costs. More research is ongoing to mitigate these burdens. Conclusion Improving survival in lung cancer patients remains a challenge dependent on prevention, screening,

optimal surgery, modern radiotherapy and improved systemic therapies targeted through understanding the molecular biology of these heterogenous tumours. Despite clear progress to date, there is much need for improvement, offering ample opportunity for future research. ES05.02 FROM LIVING LONGER TO ALSO LIVING BETTER – THE ROLE OF COMMUNICATION AND INTERPROFESSIONAL COLLABORATION IN METASTATIC LUNG CANCER

M. Villalobos

University Hospital Heidelberg, Heidelberg/Germany

Despite ongoing progress in diagnostics and treatment, many patients with metastatic lung cancer still harbor a limited prognosis that may lead to existential uncertainty. These patients and their caregivers are confronted with a complex situation as burden comprises physical, psychosocial and spiritual needs [1]. During the illness trajectory they are exposed to different multiprofessional healthcare settings and providers that challenge the continuity and coordination of care. Therefore, the care of these patients and their relatives is often characterized by discontinuity, lack of coordination and insufficient communication [2]. Additionally, shared decision-making between active cancer treatment and end-of-life care constitutes a continuous and challenging balancing act for all who are involved in the process. Several studies have shown that early integration of palliative care (EPC) and adequate advance care planning (ACP) improve quality of life and satisfaction with care. Two studies evaluating EPC have even shown positive results in survival [3,4]. In the recommendation of the American Society of Clinical Oncology concerning the integration of palliative care into standard oncology care, the following were defined as essential components: "rapport and relationship building with patients and family caregivers; symptom, distress, and functional status management; exploration of understanding and education about illness and prognosis; clarification of treatment goals; assessment and support of coping needs; assistance with medical decision making; coordination with other care providers" [5]. This underlines the importance of communication in this setting and defines it as a central element for the effective provision of early palliative care. Another central element is interprofessional collaboration. Studies incorporating interprofessional involvement (notably physicians and nurses) showed more consistent results regarding the positive effects of EPC [6]. Through the different perspectives of the involved professions towards care needs, healthcare delivery may be enriched and become more holistic. Additionally, nurse navigation supports orientation in the healthcare system and provides continuity and coordination of care. For this strategy communication skills of healthcare providers and interprofessional collaboration should be strengthened. Joint communication training may play an important role to overcome interprofessional barriers and sharpen communication skills. Advanced communication techniques are essential for early integration of palliative care, facilitation of prognostic awareness, and by this means introduction or adaptation of advance care planning [7]. An interprofessional, longitudinally structured communication approach should improve the experience and outcomes of patients with advanced lung cancer and their caregivers [8]. Further research should address the feasibility of institutional strategies for implementing this approach. ES05.03 FROM LIVING LONGER TO ALSO LIVING BETTER; MANAGING LUNG CANCER AS A CHRONIC DISEASE - THE PRINCIPLE OF SURVIVORSHIP

M. Rigney

GO2 Foundation for Lung Cancer, Washington/United States of America

With exciting advances in lung cancer screening, diagnosis, and treatment, those diagnosed are living longer than ever before. Around the globe, more and more people are balancing the great hope and vast uncertainty of living with advanced lung cancer as a chronic disease. A chronic disease is one that lasts three months or longer, doesn't disappear, and is not preventable by vaccines nor curable by medicine. (US National Center for Health Statistics). Uncontrolled, any chronic disease can be life threatening. The 2008 IOM report, *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs,* outlined the physical, emotional, social challenges, and financial stressors that result from living with a chronic disease. Cancer as a chronic disease increases anxiety, adds fear of recurrence, causes difficulties in making life plans, affects interpersonal relationships and prompts existential questioning. People diagnosed with lung cancer may additionally experience a myriad of distinct stigma-related challenges, including guilt, shame and increased isolation. Over ten years after the IOM report, cancer as a chronic disease remains a relatively unexamined area of study and, as Dr. Ross Camidge has said, "The rulebook hasn't been written." This presentation seeks to help us, the loved ones, advocates, clinicians, organizations and researchers begin to understand the unique needs of this population as we consider lung cancer as a chronic disease through: -- The lens of the ecological concept of the

ecotone -- Recognizing the effects of months or years of continuous or intermittent treatment on the individual -- A commonly accepted model of chronic disease management and coping -- The lived experiences of those effected, gathered through focus groups and one-to-one conversations

Keywords: Survivorship, Chronic disease

ES05.04 SOCIAL MEDIA AND LUNG CANCER - A GLOBAL PICTURE

C. Sit[1], J. Fox[2], S. Malia[1]

[1]*Lung Cancer Canada, Toronto/Canada,* [2]*Roy Castle Lung Cancer Foundation, Liverpool/United Kingdom*

Social media has transformed the health communication landscape. It is evident in the rise of social media groups that social media is an important communications and connection tool for the community impacted by lung cancer. Individuals across the cancer continuum use social media for a myriad of purposes and there are differences between user profiles. For example, physicians and academics use social media to announce new innovative treatment options, for debate, and to highlight the successes and failures of lung cancer research. The general population utilizes social media to fundraise, garner support, and share their personal experiences with cancer. Social media may now be one of the most common communications vehicles for global campaigns concerning lung cancer, impacting education, fundraising and advocacy. In order to more optimally use social media to further objectives for patient organizations, it is integral to understand global trends in social media usage and what users are saying online. This global research project aims to answer these questions, as possessing more information on user trends will better inform those that are trying to reach and engage with these individuals. This global research project will also provide an opportunity for lung cancer professionals and organizations to refine their social media communications strategies. The research will identify best practices for organizations in engaging their lung cancer communities, as well as content strategies to boost reach, engagement and community size. *Purpose:*The objective of this research project is to evaluate the use of social media platforms, including Twitter, Facebook, and blogs, to understand *how*and *why*individuals are using each platform and *what*is being said. *Methodology:*Through the social listening tool *Brandwatch*this study will analyze social media usage between November 2018 to May 2019 in eleven (11) countries: Canada, United States, United Kingdom, Russia, Brazil, China, India, Israel, Australia, South Africa and Poland. This study utilizes topic analysis to understand the qualitative themes that are currently happening in the online conversation. These eleven (11) countries have been chosen due to high incidents of lung cancer, confidence in government data on lung cancer statistics, and frequency of social media use. In each jurisdiction, *Brandwatch*monitors the use and flux of specific key terms relating to lung cancer. In analyzing the data that *Brandwatch* generates, the team can effectively monitor the conversations (frequency, subject, emotion, and corresponding debate) that happen at a grassroots level. In a parallel research method, the project will gather data from over forty (40) lung cancer organizations' social media accounts across all major platforms including Facebook, Twitter, LinkedIn, Pinterest and YouTube. This data will be analyzed quantitatively and qualitatively to identify which social media strategies work best to engage members of the online lung cancer communities globally. *Analysis:*Preliminary findings indicate that the conversations occurring on social media across jurisdictions are both profoundly different yet have underlying similarities. Data will be extracted from initial findings to target populations with campaigns on issues that matter distinctly to them. As technology continues to drive decision-makers, organizations must adapt to foster the best results. In understanding who and how to target populations, it is expected that global lung cancer campaigns—for awareness, public policy changes or research funding—will reach, and hopefully exceed, their targets.

ES05.05 STILL STRUGGLING FOR TRACTION - FROM PROVING LUNG CANCER SCREENING WORKS TO GLOBAL PRACTICAL IMPLEMENTATION, INCLUDING ENGAGEMENT OF THE TARGET POPULATION

J. Mulshine

Rush University, Chicago/United States of America

Still Struggling for Traction-from Proving Lung Cancer Screening Works to Global Practical Implementation, Including Engagement of the Target Population

James L. Mulshine, Rush University, Chicago, IL 60612 Based on the results of the National Lung Screening Trial, United States Preventive Services Task Force (USPSTF) reviewed and recommended low-dose CT screening for lung cancer. Next the Centers for Medicaid and Medicare reviewed this service and after February 5, 2015 issued a National Coverage Decisions to add coverage under Medicare Part B to allow low-dose CT screening in high-risk populations began (1, 2). A few years on, articles are frequently reporting that screening uptake in the United States is anemic. In a setting where enthusiasm differs about the prospects for lung cancer screening, issues of cost and bandwidth loom large (3, 4). Realistically, cancer screening whether cervical cancer, breast cancer or colon cancer all took extended periods of time to become established and problems of compliance with all three measures still exist. However, the results of the National Lung Screening Trial are now buttressed with the results of Dutch/Belgian trial (NELSON), as well as the 10 year follow up of the Milan randomized cohort experience (MILD) (4-5). Consequently, we are now seeing national screening not only being implemented in the United States but and with similar activity moving forward in Canada, Poland, the United Kingdom, South Korea as well as other nations. It is heartening to see evidence of careful planning to define the optimal screening programs for national implementation ongoing in a number of countries such as the United Kingdom, Canada and Poland. Cautious optimism that lung cancer screening may have turned a corner seems justified. These early adaptor national screening programs will provide an opportunity to evaluate national statistics for the annual distribution of stage frequencies. As it is a critical measure of public health progress to have falling national smoking rates, now we can also look for national level stage shifts to determine if the detection rates of Stage I cases rise along with corresponding drops in Stage III/IV frequencies. Furthermore, critical information about actual experience in these large national settings can inform the discussion about the realities of harms experienced in the screening process and this information would be useful in advancing lung cancer screening participation. Communication disseminated by venues like IASLC and GLCC will be essential to encourage efforts to enhance the process of screening to sustain the brisk pace of research focusing on screening management optimization. The efforts of the American College of Radiology in adapting breast cancer screening process for managing the lung cancer screening process has been important as it creates a much more familiar transition for institutions attempting to launch lung cancer screening services (6). This ACR process, called LungRADS leverages a management approach that is already well established in the radiology community and makes for a smooth transition in defining a systematic screening management approach for lung cancer. This recent development has addressed a major concern relative to the rate of false positive screening cases that was dampening screening enthusiasm for some healthcare professionals. Fortunately, there are even more advanced developments in the offing for more effective and workflow friendly software tools. If best-practice nodule management of I-ELCAP, NELSON, and UKLS using software-driven direct measurement of lung cancer volume become more generally available, these tools can further reduce the rate of false-positive diagnosis and improve the efficiency of the case finding process (7-11). Fortunately, in collaboration with I-ELCAP and the Veterans Administration in the US, activities are underway to address this complex issue. Annual lung cancer screening has also provided an opportunity to re-consider how to best encourage more effective smoking cessation. The National Cancer institute in the United States launched a number of studies to experiment with more intensive approaches to smoking cessation specifically in the setting of screening. These studies will be completed over the next few years and these new approaches can be applied to help more people overcome this dangerous but deeply additive behavior and in a

complementary fashion improve the prospects for more favorable health outcomes. Quietly over the last decade, we have witnesses continuous refinements in the surgical approach to resecting early lung cancer (12). We would expect further evidence to accrue informing the most favorable approach to curative resection. Within this time window, we expect to also start seeing more experimental approaches to managing small, favorably located lung cancers with inter-luminal approaches. In the wake of recent cardiology guidelines revisions to include low-dose thoracic CT as a biomarker for managing coronary calcium deposition, we would expect to see greater awareness of other routine tobacco-related findings seen in the course of a thoracic CT screening (13). Together lung cancer, coronary artery disease and COPD constitute the three most lethal diseases across the world. The pathogenesis of all three of these diseases is greatly accelerated by tobacco-combustion product deposition in the lungs. As the prevalence of lung cancer screening evolves, considerably more cases of coronary artery disease and COPD cases will come to clinical attention than lung cancer, so collaboration across relevant disciplines will increase to provide thoughtfully integrated management of CT screen identified consequences of prolong tobacco exposure (13). The bulk of the preventive managements of these three most lethal diseases detected in high risk but asymptomatic individuals will include more concerted tobacco cessation support, advice to enhance levels of physical activity and to improve the quality of dietary consumption. Through time, CT-informed lung cancer screening will create an annual opportunity for a health check to improve the health of tobacco-exposed individuals. This possibility could great enhance the support of low-dose CT evaluation of thorax in smokers across many communities. In parallel, targeted drug development guided by information derived from systematically examining resected screen-detected cancer looking for signatures of aggressive behaving cancers that will need adjuvant interventions beyond surgery to ensure curative outcomes. In this strategy, lung cancer care may follow breast cancer care and we will see the emergence of neoadjuvant and adjuvant early lung cancer therapies as a critical part of ensuring favorable individual outcomes. In closing, screening is a complex process with many moving parts. Establishing this process with careful attention to quality and then testing to see how to optimize the delivery as outlined in a recent I-ELCAP report, takes time (14). Participation in lung cancer screening is low. Given the recent strong screening results from multiple international sites especially with the NELSON trial as well as contributions such as LungRADS, and process research such as with I-ELCAP, there is a basis for optimism that significantly greater uptake will be occurring in large measure due to mutually beneficial collaborations. ES06 NEW APPROACHES IN SECOND LINE TREATMENT IN NSCLC
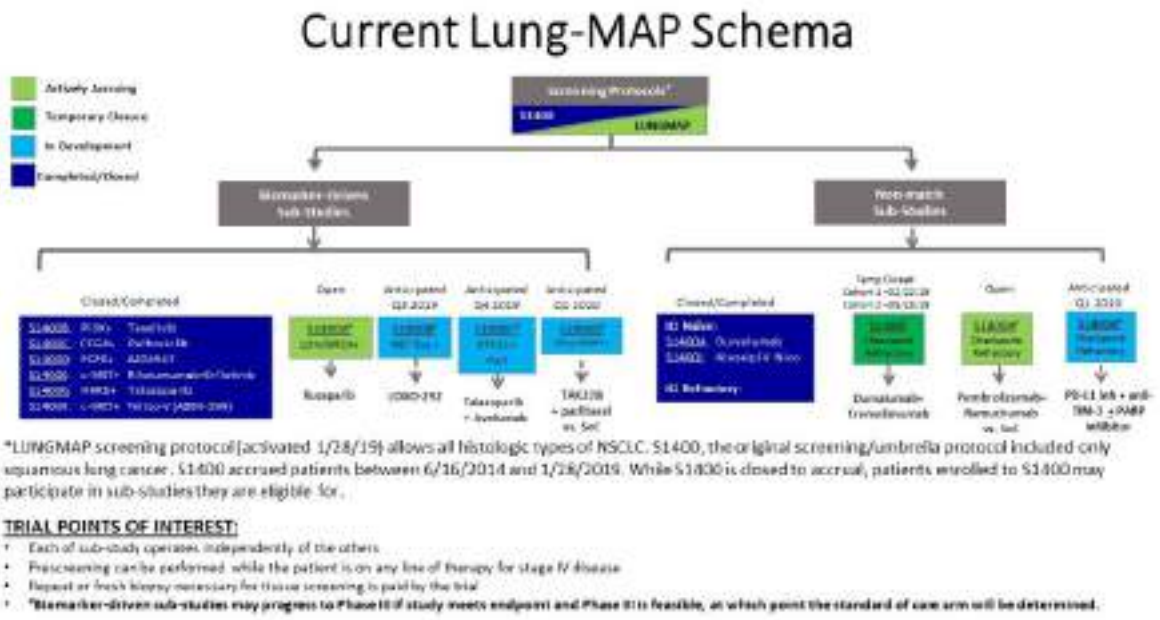
SUNDAY, SEPTEMBER 8 13:30–15:00

ES06.01 RECENT ADVANCES IN SECOND LINE TREATMENT

R. Herbst

Yale University School of Medicine, New Haven/United States of America

Despite advances in the treatment of cancer and reductions in smoking rates, lung cancer continues to be one of the leading causes of cancer death worldwide. Over the past decade, a handful of immune-checkpoint inhibitors (nivolumab, pembrolizumab, atezolizumab) have been shown to improve survival and changes have been made to the standard of care for first-line treatment of patients with non-small cell lung cancer (NSCLC). However, only a minority of patients respond to these treatments and even these patients acquire resistance to the therapy. Continued investigation and research for second-line therapy options are vital to provide treatment options to patients who progress. Master protocols, like LUNGMAP, are efficient trial designs used to quickly and safely investigate new therapies or combinations. LUNGMAP is the first major trial, supported by the National Cancer Institute (U.S.) to simultaneously test multiple treatments under an umbrella design. LUNGMAP was launched in 2014 to investigate new therapies for squamous cell lung cancer, enrolling over 2000 patients. In 2018, the trial underwent a major expansion to include all non-small cell lung cancer patients. Treatments being tested include immunotherapy combinations and targeted therapies that are associated with specific genomic alterations. This allows for the identification of potential biomarkers which can help identify the treatments that would most likely benefit a patient. LUNGMAP is an unprecedented public-private partnership that is more flexible and efficient and will help to speed-up the development process for new lung cancer drugs. References: RS Herbst et al. Clin Cancer Res. 2015 Apr 1;21(7):1514-24 doi: 10.1158/1078-0432.CCR-13-3473. Epub 2015 Feb 13.



ES06 NEW APPROACHES IN SECOND LINE TREATMENT IN NSCLC
SUNDAY, SEPTEMBER 8 13:30–15:00

ES06.02 WHAT IS THE BEST STRATEGY IN PROGRESSIVE DISEASE AFTER CONSOLIDATION WITH DURVALUMANB, OR RAPID PROGRESSORS TO FIRST LINE?

F. Barlesi

Aix Marseille University, CNRS, INSERM, CRCM, APHM, Marseille/France

Immune Check Points Inhibitors (ICIs) have dramatically changed the management of locally advanced and advanced NSCLC patients. While the survival improvement compared to previous standard of care is undoubtable, several patients still progress on or relapse after ICIs. How should these patients be managed? To better understand how to manage these patients, we should probably try to better understand the underlying mechanism(s) of resistance to ICIs. Schematically, we can propose three main categories, with primary resistances, occurring early after ICIs initiation, secondary resistances, occurring after a previous response or disease stabilization on ICIs, and follow-up resistances, occurring after stopping ICIs, either per protocol or severe adverse event(s). Management of primary resistances to ICIs. Although no validated definition is available, primary resistances might include hyperprogressors and progressors within the first 12- (to 18) weeks of treatment with ICIs. It represents approximately 20 to 30% of stage III NSCLC patients receiving durvalumab after concomitant chemo-radiation, 30% of stage IV patients PD-L1 50% or more NSCLC patients treated with pembrolizumab and 20 to 30% of stage IV patients NSCLC patients treated with a combination of chemotherapy and ICIs. Few data are available on the underlying biological mechanisms to explain these primary resistances. Considering clinical data of the PACIFIC trial, 41% of patients in the durvalumab arm (without precise characterization of the time or progression) received a subsequent therapy. For the patients who already received durvalumab as a consolidation treatment, 20 patients received a subsequent ICI. The response rate in this case was 0%. With a longer follow, different patients' profiles will certainly be reported in this setting, with possibly responses to ICIs alone or in combination for patients relapsing a long time after stopping Durvalumab. Considering clinical data for stage IV NSCLC patients treated in the first line setting in monotherapy, a recent long term analysis of the Keynote 024 trial. The management of patients with an early progression on Pembrolizumab was not specifically detailed. Globally, 56 out of 154 patients received a subsequent oncologic treatment, mainly chemotherapy. Considering clinical data for stage IV NSCLC patients treated in the first line setting with combination of chemotherapy and ICIs, few results are available to date on the management of early progressors. Finally, all trials assessing the efficacy of new IO agents or new ICI-based combinations as a rescue treatment after failure of a previous line of ICIs are globally disappointing. A summary of ongoing trials will be presented at the meeting. In summary, the best strategy to date for early progressors on ICIs, alone or in combination, unfortunately remains a standard chemotherapy; a participation in a clinical trials should be also discussed giving the efficacy of rescue treatments in this situation.

ES06 NEW APPROACHES IN SECOND LINE TREATMENT IN NSCLC
SUNDAY, SEPTEMBER 8 13:30–15:00

ES06.03 FUTURE STRATEGIES IN SECOND LINE TREATMENT

G. Riely

Memorial Sloan Kettering Cancer Center, New York/United States of America

With the continued refinement of molecularly targeted therapy and the dramatic changes in initial therapy for patients with newly diagnosed NSCLC without a molecular target, the concept of "second line" therapy has largely become outdated. For the more than one-third of patients who have a targetable oncogenic driver (with aberrations in genes such as EGFR [exon 19 deletion, exon 21 point mutation, or exon 20 insertion], ALK, ROS1, BRAF, RET, MET exon 14, or TRK), multiple lines of targeted therapy are possible prior to receiving a platinum-based combination chemotherapy combination (sometimes with the addition of an anti-PD-1/PD-L1 antibody). In such patients, "second line treatment" could actually be the fifth treatment regimen. Similarly, for patients with PD-L1 that is 50% or greater, the second-line treatment is typically platinum-based doublet chemotherapy. Practically, "second line treatment" is that given after a regimen that contains platinum-based chemotherapy. Despite the difficulties in defining second line treatment, it is an area with critical need for development of new treatments. Some new approaches to development of second line therapies are dependent upon a molecular evaluation of the patient's tumor, typically selecting for targets that are not oncogenic drivers but rather other, non-driver, vulnerabilities found in a patient's tumor. This approach is best exemplified by the Lung MAP (Lung Cancer Master Protocol). This NCI-sponsored trial that began by enrolling only patients with squamous cell lung cancer but now enrolls patients with any NSCLC,

uses the results of a comprehensive genomic profiling platform that looks at over 200 cancer-related genes for genomic alterations to assign patients to a genetically matched sub-study or randomize patients to an immunotherapy treatment. Cohorts have included patients with PI3KCA mutations receiving GDC-0032, patients with FGFR amplifications receiving AZD4547, patients with homologous repair deficiency receiving PARP inhibitors, and patients with STK11 alterations receiving talazoparib + avelumab. Critically, this trial uses staged evaluation of an arm to minimize the number of patients treated with relatively ineffective therapies. There is a great deal of interest in identifying new immunologic approaches for patients with NSCLC who have progressed after initial treatment with anti-PD-1/PD-L1 therapy. These approaches include the exploration of antibodies against such targets as the T-cell inhibitory receptor Tim-3 (T-cell immunoglobulin and mucin-domain containing-3) or small molecule inhibitors of indoleamine 2,3-dioxygenase 1 (IDO1), a principle enzyme in tryptophan catabolism alone or in combination with anti-PD-1 or PD-L1 antibodies. Beyond this, there are attempts to improve the efficacy of single-agent anti-PD-1 antibodies by adding MEK inhibitors. Building off great successes in hematologic malignancies, there are new effort that seek to use cell-based therapies in patients with solid tumors. These include clinical trials of autologous T-cells that have been transduced with vectors expressing T-cell receptors against such targets as NY-ESO-1 and LAGE-1a for patients with NSCLC as well as trials exploring ex vivo expansion of tumor infiltrating lymphocytes. Treatment of patients who have progressed on available targeted therapies as well as platinum-based chemotherapies remains a notable challenge, with current treatments having limited activity. While none have yet proven effective, there are a broad array of treatments under study, whether using targeted therapies, chemotherapy combinations, or immunologic approaches.

ES06 NEW APPROACHES IN SECOND LINE TREATMENT IN NSCLC
SUNDAY, SEPTEMBER 8 13:30–15:00

ES06.04 THE BEST TREATMENT SEQUENCE FOR ADVANCED NSCLC EGFR/ALK/ROS/BRAF WT

J. Wolf[1,2]

[1]*University Hospital of Cologne, Cologne/Germany,* [2]*Center for Integrated Oncology, Cologne/Germany*

Most current guidelines recommend molecular testing of activating alterations in EGFR, ALK, ROS1 and BRAF before first line treatment decision in advanced NSCLC. These recommendations mostly are based on the approval status of the respective targeted therapies. For the remaining patients combinations of immunecheckpoint inhibitor (ICI) therapy and platinum-based chemotherapy (CT) has become standard for patients with a PD-L1 tumor proportion score (TPS) of below 50% and may also be used for patients with a higher score in case of aggressive tumor growth and good performance score (PS). Patients with a TPS of 50% and more may be treated with ICI alone. Tumor mutational burden (TMB) is currently evaluated as new predictive marker for either ICI mono- or combination therapy, the definitive value of this approach in first or second line so far, however, is still unclear. If these (EGFR-, ALK-, ROS1-, BRAF wildtype) patients relapse after ICI monotherapy, platinum-based CT, eventually with the addition of bevacizumab, widely is considered standard treatment. By comparison, for patients with relapse after ICI/CT combination systemic treatment options are quite unsatisfying. Docetaxel monotherapy has only marginal efficacy which may be modestly increased by the addition of antiangiogenic agents. Numerous immunotherapeutic approaches are evaluated In this situation (next generation ICIs and other immunomodulatory drugs), preferably in combinations. However, so far, no convincing results have been reported from these clinical trials. It is therefore particularly important to identify from these patients the subgroup with a possible benefit from driver-mutation directed treatments – either within a clinical trial or a compassionate use program or as off-label treatment. Numerous such approaches are in clinical evaluation. Examples are kinase inhibitors against RET-fusions, TRK-fusions, MET exon 14 skipping mutations, MET amplification, HER2 mutations, EGFR-/HER2 exon 20 mutations, NRG-1 fusions. High response rates and clinical significant duration of responses have already been reported for many of these personalized treatment options, some of them are already in accelerated approval procedures. Many of them will forge ahead towards first line treatment in particulary, since ICI therapy partly seems not to work well here. Until the approval of these new treatment options it is of particular importance to test patients at the latest upon failure of ICI with or without chemotherapy on the presence of driver mutations in their tumors and to try hard to bring them into a clinical trial or to enable off-label treatment. Given the dynamics in the field, this treatment algorithm will change in the near future not only by the approval of several of these new driver-mutation directed treatments, but also by the development of more effective and more tailored immunotherapies as well as by the availability of potent KRAS inhibitors.

ES07 THORACIC ULTRASONOGRAPHY: DIAGNOSIS AND STAGING
SUNDAY, SEPTEMBER 8 13:30–15:00

ES07.01 TRANSTHORACIC ULTRASONOGRAPHY

N. Rahman

University of Oxford, Oxford/United Kingdom

This presentation will review data on the utility of thoracic ultrasound in diagnosis, staging and subsequent management of malignant thoracic and pleural disease.

ES07 THORACIC ULTRASONOGRAPHY: DIAGNOSIS AND STAGING
SUNDAY, SEPTEMBER 8 13:30–15:00

ES07.03 RADIAL ENDOSONOGRAPHY

L. Crombag

Amsterdam UMC, Amsterdam/Netherlands

Flexible bronchoscopy, with its attendant procedures, is a valuable tool for diagnosis and staging of patients with suspected lung cancer. The development of endobronchial ultrasound (EBUS) has extended the view of the bronchoscopist beyond the bronchial wall. Two types of EBUS exist. The curved linear (convex) probe EBUS and the radial probe EBUS. The convex ultrasound transducer is located at the tip of a flexible bronchoscope (linear scanning EBUS) and allows real-time sampling. This technique is mainly used for mediastinal nodal staging and assessment of centrally located lung tumours when lung cancer is known or suspected. The radial EBUS probe houses a rotating ultrasound transducer at the distal end which produces a high-resolution radial (360˚) ultrasound image of the airway wall and surrounding structures. This probe is inserted through the biopsy channel of a standard bronchoscope. In a lung cancer setting, this technique is used for evaluation of the depth of tumour invasion in the central airways enabling differentiation between early and invasive lung cancer and detection of peripheral pulmonary lesions (PPLs). Radial EBUS does not permit sampling in real-time such that sequential sampling with separate equipment is necessary. The current focus of this abstract is the role of radial EBUS for PPLs. With the increased use of chest CT-scans, the frequency of incidentally found PPLs has increased as well. Guidelines advise to evaluate and manage individuals with pulmonary nodules by estimating the probability of malignancy. The goal is to diagnose a malignancy promptly for timely treatment and to avoid invasive procedures and surgery in patients with benign lesions. Approaches to establish a tissue diagnosis include imaging-guided transthoracic and bronchoscopic sampling techniques. The sensitivity of traditional flexible bronchoscopy - with or without fluoroscopic guidance – for peripheral lesions in patients suspected of having lung cancer is suboptimal and is affected most by the size of the lesion (<2cm 34%; >2cm 63%).[(1)] For PPLs, the sensitivity of transthoracic needle aspiration (TTNA) is greater than that of bronchoscopy. In this setting, TTNA has an approximately 90% chance of providing confirmation of a diagnosis. However, CT-guided percutaneous TTNA has a considerable risk of pneumothorax.[(1)] This has led to the development of new modalities as radial EBUS, virtual bronchoscopy, electromagnetic navigation bronchoscopy and ultrathin bronchoscopes. In 2002, radial EBUS was first used to guide transbronchial lung biopsy (TBLB).[(2)] Numerous papers has been published since, reporting varying diagnostic performances of radial EBUS. Three systematic reviews and meta-analyses report

a sensitivity of radial EBUS for diagnosis of peripheral lesions of 70% to 73%. Although there is considerable heterogeneity in lesion size, prevalence of malignancy, variable use of additional image guiding technology and reference standard in included studies.[3-5] The diagnostic yield of radial EBUS is significantly higher for lesion > 2 cm in size, malignant in nature and those associated with a bronchus sign on CT scan.[3-5] The diagnostic yield is also higher when the radial EBUS probe is in the center of the lesion opposed to being adjacent to it.[3] The diagnostic yield of radial EBUS does not exceed CT-guided percutaneous needle biopsy / aspiration. The major advantage of radial EBUS over a transthoracic approach is its safety profile (overall pneumothorax rate of just 1.0%)[4] and the ability to combine with staging procedures. In conclusion, to diagnose PPLs (not visible by bronchoscopy) radial EBUS is a safe and has a reasonably high diagnostic yield. Main limitations of the technique include operator dependence and the need for sequential sampling as radial EBUS does not allow real-time sampling. 1. Rivera MP, Mehta AC, Wahidi MM. SUNDAY, SEPTEMBER 8 13:30–15:00

ES07.04 PREDICTIVE MOLECULAR TESTING ON SMALL BIOPSY SAMPLES

C. Dooms

University Hospitals KU Leuven, Leuven/Belgium

According to international guidelines for molecular testing as updated in 2018, any lung cancer sample (tissue biopsy or cytology) with adenocarcinoma or not-otherwise specified (NOS) histology and adequate tumor cellularity should be tested for routinely treatable mutations with a turnaround time of no more than 10 working days.1,2 Single gene testing or restricted hotspot testing methods were developed to screen for EGFR p.Leu858Arg mutations or deletions with the exon 19 in advanced stage non-small cell lung cancer. Next-generation sequencing (NGS) platforms have facilitated multigene mutational profiling using small amounts of nanograms (ng) of DNA, making the NGS technology attractive for and applicable to small biopsy and cytology specimens. NGS and especially targeted NGS panels were rapidly validated for small biopsy samples and implemented in diagnostic laboratories as they focus on hotspot regions and frequently altered genes with direct and known consequence on therapy.3,4 Compared to sequential single-gene testing, targeted NGS is considerably faster and more cost-effective.5 There are however several barriers to universal broad biomarker testing. Despite most tests can be run on only small biopsy and cytology specimen, in real world testing rates are far from 100% (even for EGFR, ALK and ROS1 testing) and up to 25% of samples lack sufficient tumor material in small biopsies. Molecular testing accuracy depends on multiple factors that include overall tumor cellularity, method of fixation, tumor fraction of the sample, and the analytical sensitivity of the molecular testing platform used for the analysis. Pre-analytical strategies to improve testing success are: (1) work with dedicated interventionalists (e.g. radiology, pulmonology) to get sufficient tissue as one single pass is not enough, (2) work with dedicated pathologists to enhance quality control and reflex testing, and (3) consider ROSE. In a reference center with dedicated interventionalists, a dropout rate of 3.4% was observed either due to quantitatively insufficient tumor material or inadequate nucleic acid quality based on a series of 3,000 consecutive lung cancer cases that were sequenced.6 In a randomized trial comparing two different needle sizes and a turn-around team (interventional pulmonologist, pathologist, molecular biologist) using standard operating procedures, several conclusions could be drawn given a successful NGS testing rate for all clinically relevant genes in 96% of samples.7 Four needle passes were needed to obtain adequate material for molecular analysis. A tissue core was reported present in almost 70% of specimens for both needle types. Less than 3% of samples had tumor cellularity of <10%, and there was no significant difference in tumor cellularity between 19G and 22G needles. Both the tumor surface area measured and the amount of DNA extracted from the selected cell block were larger for the 19G compared to the 22G specimen, with a median tumor surface area of 4.91 mm2 vs 2.35 mm2 and median DNA extracted of 1150 ng vs 818 ng, respectively. There is a paucity of articles outlining best practice guidelines for immunocytochemistry. With proper optimization and rigorous quality control, high-quality staining can be achieved on cellblock and non-cellblock preparations.8 Cytology preparations that are non-formalin-fixed provide the best alternative source of well-preserved DNA. Cytology specimens allow for rapid on-site adequacy assessment (ROSE), which can ensure the collection of adequate and sufficient material for ancillary studies including immunohistochemistry and molecular testing. Although there are no universally accepted criteria for EBUS-TBNA lymph node adequacy, structured semi-quantitative scoring schemes for ROSE and diagnostic category assignments have been proposed. The decision of whether or not to provide ROSE for EBUS-TBNA procedures is largely institution dependent. Validation studies are essential with correct implementation of these pre-analytical factors for any molecular testing in cytologic samples. In conclusion, a single NGS panel test covering all clinical relevant markers is most tissue and cost efficient. Strategies to obtain a higher rate of successful testing, even on only small biopsy and cytology specimens should be considered whenever needed: reflex testing, dedicated interventionalists, and strong communication with all team members. ES08.01 PARTICIPATION OF THE TARGET POPULATION IN LUNG CANCER SCREENING

R. Cornelissen

Erasmus University Medical Center, Rotterdam/Netherlands

Participation of the Target Population in Lung Cancer Screening Robin Cornelissen, MD, PhD. Erasmus MC cancer institute Rotterdam, The Netherlands The two largest randomized controlled trials performed, The National Lung Screening Trial (NLST) and the Nederlands-Leuvens Longkanker ScreeningsONderzoek (NELSON) [1,2], proved that lung cancer screening using low dose CT scan, resulted in a significant reduction in lung cancer mortality. Following the results of the NLST trial, lung cancer screening was initiated in the United States and Canada. However, the uptake of lung cancer screening is poor, with only 3% to 4% of all eligible persons participating in the implemented screening program [3]. Given more recent positive results of the NELSON study that were presented at the World Conference on Lung Cancer last year in Toronto, lung cancer screening is now considered in many countries across the globe. This low uptake of lung cancer screening is however a cause of concern. The reasons for the low participation rate are multi-factorial. The novelty of the lung cancer screening program is such a factor, resulting in lower uptake and might be the easiest one to address. The identification of the target population is more challenging due to the fact that the population to be screened is more defined than just age and sex. In addition, the lower socioeconomic status, which presents a significant portion of the to be screened population, and those who face barriers to care present a major challenge for implementing a successful screening program with a satisfactory uptake rate. Several strategies have been proposed to improve lung cancer screening uptake. In the socioeconomically deprived and heavy smoking communities, lung cancer is perceived as an uncontrollable disease [4], while cure rates in yearly screening programs lead to a cure in the majority of patients when lung cancer is detected [5,6]. Therefore, public awareness of the curability of lung cancer when screening programs are implemented could boost the participation rate. Mobile lung cancer testing in supermarket car parks proved to be a successful pilot [7]. This strategy avoids difficulties relating to the distance of travel, lack of public transport available, and the cost of either the journey itself or hospital parking. This strategy is currently explored in a larger cohort. One potential intervention that is being evaluated in clinical trials to improve the uptake and implementation of lung cancer screening is a patient navigator. A navigator can be a layperson, a medical assistant, or a nurse who will directly contact potential candidates for lung cancer screening for enrollment [3]. The Accelerate, Coordinate, Evaluate (ACE) Programme, initiated in the United Kingdom, is an early diagnosis of cancer initiative focused on testing innovations that either identify individuals at high risk of cancer earlier [8]. This program consists of several individual programs in different regions of the UK, of which The Liverpool Healthy Lung Programme is a participant. Among other goals, this initiative tries to improve uptake in the hard to reach cohort. They used general practitioners' records to invite participants meeting the criteria to a 'Lung Health Check'. This 'Lung Health Check' is a novel approach that may overcome or minimize the emotional barriers associate with the term "lung cancer screening". This method resulted in an uptake level up to 40% [9]. This initiative is an example that a higher uptake rate is indeed possible, even in the hard to reach population. At the IASLC World Conference on Lung Cancer in Barcelona, the issues regarding participation of the target population in lung cancer screening will be addressed and possible strategies will be discussed to overcome these challenges. As lung cancer screening is yet to be implemented in the majority of countries worldwide, we now have a unique opportunity to test and apply these strategies to successfully implement lung cancer screening in order to reduce lung cancer mortality. ES08.02 NODULE GROWTH ASSESSMENT

M. Oudkerk[1,2]

[1]*iDNA-Institute for Diagnostic Accuracy BV, Groningen/Netherlands,*
[2]*University of Groningen, Groningen/Netherlands*

In the past 15 years several lung cancer screening trials have been performed in Europe[1]. Experts involved in these trials recently published a position paper in the Lancet Oncology[2]. Several conclusions and recommendations were drawn to enable a smooth and timely implementation of lung cancer screening in Europe. The experts made a strong and conditional argument on the methodology of lung cancer screening by low-dose computed tomography (CT). Quality control by regular CT phantom testing enabling standardization of CT data acquisition as well as benchmarking of CT software post processing and data analysis are mandatory. It is promoted to execute the CT screening Q/A control through national reference centers similar to the organizational structure of breast screening programs. In this manner the CT screening programs can be implemented in a responsible way avoiding the detrimental side effects of too high false positive CT outcome rates on the one hand and keeping up the most effective lung cancer early detection rate on the other hand. Apart from the acquisition protocol, the CT lung nodule analysis methodology is a critical factor for successful implementation of CT lung cancer screening [3]. The diameter based NLST protocol used a 4 mm threshold (~ 30 mm^3) as significant suspicion for malignancy. This approach yielded a positive rate of approximately 27% in the baseline round with a very low positive predictive value for lung cancer of 3.8%[4]. The NELSON study introduced a nodule volume analysis and a volume doubling time methodology with 2 CT measurements with a 3-month interval to calculate the volume doubling time as a biomarker for growth rate in indeterminate nodules. This approach resulted in a 2.6% positive rate in the baseline round with a high positive predictive value for lung cancer of approximately 36%, which is within the criteria needed for lung cancer screening implementation[3]. In the meantime, a ten times higher threshold of 8 mm (~300 mm^3) was recommended to correct the high false positive rate of the NLST diameter methodology by several international societies[5]. After the publications of the NELSON data on increased lung cancer probability in baseline nodules at a threshold of 100 $mm^3$the US guideline recommendations shifted from 300 $mm^3$to 100 mm^3(~ 6mm)[6]. A direct comparison of diameter and volume protocols cannot be performed through the assumption that all nodules are spherical. While this approach was chosen in a recent publication of the IELCAP investigators[7], even the slightest correction for the assumption of sphericity reveals the substantial inferiority of diameter protocols. At follow-up CT examination at annual incident screen new nodules represent a high lung cancer probability at lower volumes than at baseline screen[8,9]. The upper threshold is at 200 mm^3as indication for further clinical workup while new nodule at incident screen between the 30-200 $mm^3$are classified as indeterminate and need a repeat scan at 3 months to calculate the volume doubling time. Lung cancer screening should be integrated in a defined national program and therefore opportunistic screening is not recommended. Calcium scoring as a *screening method*is not yet established as a validated tool for early detection of coronary

artery disease and the outcomes of the ROBINSCA study (risk or benefit in screening for cardiovascular disease www.robinsca.nl) are being awaited. Thus, so far, it is not indicated as a combined clinical routine screening methodology since ECG triggering is mandatory[10]. Non-triggered CT coronary artery calcium scoring will result in high false negative percentages. A lower CT radiation exposure threshold at a DLP of 50 mGy or 0.6 mSv is defined to assure the calibration of the quantitative imaging biomarkers for lung nodule detection. Lower radiation doses will induce false negative and unreliable growth rate results. ES08.03 THE MAGNITUDE OF THE BENEFIT

D. Yankelevitz

Icahn School of Medicine, NY/United States of America

Why do people get screened? The obvious answer is so that cancer can be detected early with a view towards a higher chance of cure with early treatment. Therefore the critical questions that must be addressed relate to the risk of cancer over time and then, how likely cure will be when screen-detected versus clinically detected. Current approaches to evaluate screening have relied on randomized controlled trials with a view towards demonstrating that a benefit actually exists but are not designed to quantify the magnitude of the benefit. Current trial designs have limited rounds of screening and long-term follow up after screening has stopped. When these parameters change, the results of the trial will also change. Several approaches currently exist to estimate that critical parameter regarding the curability of screen detected lung cancer. This includes modeling approaches which can use data extracted from a variety of sources, they can also be measured directly as was done in the I-ELCAP study which measures directly the reduction in case fatality rate by using long term survival as a measure of cure, and an additional approach would be to screen continuously in the context of a clinical trial and measure the reduction in mortality after several years of screening where the benefit of screening reaches its maximum and becomes equivalent to the reduction in case fatality rate. When applied to lung cancer it can be shown that this benefit is far greater than the 20% so commonly reported and instead is in the 60=80% range for cure. Were this to be fully understood the entire rationale behind requiring shared decision making would be called into question as it was thought that the balance between benefits and harms was so tenuous that shared decision making was necessary. When considering whether a particular type of screening is to be considered beneficial there is also a tendency to compare different types of screening and seeing how many screens are necessary to save a life. Here to, this approach suffers from the same mistake. Each of those screening exams estimates this number based on their own randomized trial and each of these differ in terms of the design parameters, therefore the comparisons are essentially meaningless.

ES08.04 MANAGEMENT ALGORITHMS

C. Henschke[1], R. Yip[1], T. Ma[2], S. Aguayo[3], J. Zulueta[4], D. Yankelevitz[1]

[1]*Icahn School of Medicine at Mt. Sinai, New York/United States of America,* [2]*Tong Ren Hospital, Capital Medical University, Beijing/China,* [3]*Phoenix VA Health Care System, Phoenix/United States of America,* [4]*Clinica Universidad de Navarra, Pamplona/Spain*

Introduction Clinical management decisions arising from the first, baseline round of screening for lung cancer are most challenging, as nodules that are seen for the first time may have accumulated over a lifetime and almost all of them are of no clinical concern [1]. In contrast, new or changing findings on subsequent annual repeat low-dose CT scans (LDCTs) have much greater clinical significance. Efficiency is particularly important in the baseline round in order to minimize unnecessary harms caused by work-up within the 12 months after the baseline LDCT. Potential workup includes surgery, biopsies, and diagnostic tests requiring intravenous injection (e.g., PET scans, contrast CT). Biopsies and surgery have greater risks than LDCT, and thus the management protocols should aim to minimize these higher risk procedures as much as possible [2]. It is also important not to discourage participants undergoing the baseline round from future participation in annual rounds as these provide the real benefit of annual LDCT screening. Methods We compared the efficiency of three published baseline LDCT screening protocols [2], the International Early Lung Cancer Action Program (I-ELCAP) [3], American College of Radiology (ACR)-LungRADS [4], and the European Consortium protocols [5] for participants 50 years of age or older with at least 20 pack-years of smoking. The three protocols provide recommendations for immediate workup, 3-month and 6-month LDCT as shown in Table 1 [1]. The three protocols use the diameter of the entire solid and nonsolid non-calcified nodule (NCN), but differ for part-solid NCNs. For part-solid NCNs, I-ELCAP uses the diameter of the solid component [6], while ACR-LungRADS uses both the entire diameter of the part-solid NCN as well as the diameter of its solid component. The European Consortium protocol determines the volume of a solid NCN using their software [5], but also specifies the equivalent diameter values for the entire part-solid and nonsolid NCNs as volumetric measurements for these are problematic as was recognized [5]. Measurement error and rounding of measurements are also an important consideration [7,8]. Efficiency was defined as an efficiency ratio (ER): the number of participants recommended for a particular workup divided by the resulting number of participants diagnosed with lung cancer [2]. An ER of 1 would mean that each recommended workup resulted in a diagnosis of lung cancer. An optimum ER has not been established for lung cancer, but it has been suggested that for lung surgery, a rate of 10% for non-malignant resections is desirable (9), this would be an ER of 1.1. In breast cancer biopsies which have a much lower risk than lung biopsies, it is recommended that 40% of biopsies should be negative to ensure sufficient workup to diagnose breast cancers early enough this would represent an ER of 1.4 Results Table 1 provides the frequency of following the recommendations, the number of cancers diagnosed and the ER for each protocol. In summary, I-ELCAP recommendations had the lowest ER values for overall, immediate and delayed workup, and for potential biopsies. Discussion All three protocols used LDCT to guide evaluation of NCNs, particularly for the smaller NCNs. LDCT is a very low risk test as it requires no injection of contrast, the radiation dose is deemed “small” and “hypothetical” by the American Association of Physicists in Medicine [10], and the charge for a LDCT is 10-20 times lower than for a PET scan. This underscores the recognition that LDCT is a very useful tool for identifying growth at a malignant rate prior to further invasive testing. The main point is that the definition of a “positive result” needs to be continually reevaluated and updated in light of emerging technology and evidence from ongoing screening programs with the goal of reducing unnecessary invasive procedures for non-malignant pulmonary NCNs, which will markedly reduce the concerns about potential harms and increase the benefit by early diagnosis and treatment of small, early *curable* lung cancers. ES08.05 ADVANCES IN ARTIFICIAL INTELLIGENCE - HOW LUNG CANCER CT SCREENING WILL PROGRESS?

D. Gil[1], A. Rosell[2]

[1]*Computer Vision Center, Bellaterra/Spain,* [2]*Hospital Universitari Germans Trias i Pujol, Barcelona/Spain*

Predictive models for personalized medicine (also known as radiomics) is a recent discipline that uses sophisticated image analysis and artificial intelligence (AI) methods to obtain quantitative image-based features that correlate to final diagnosis and treatment outcome [1]. The application of radiomics in lung cancer screening can represent a critical shift in this field. Some recent studies, like [2-3], show that radiomic features (including tumor shape descriptors and texture analysis) extracted from CT scans have significantly better predictive value than volumetry alone (AUC= 0.9 vs 0.74). Texture analysis reflects tumour heterogeneity and has recently introduced in PET images. In fact, PET texture analysis has demonstrated its value in establishing survival [4], predicting distant metastasis [5], detecting mutations and establishing radiotherapy doses [6]. However, and despite the promising results, there are some limitations like the low reliability of heterogeneity parameters in tumours with small volume, the low repeatability and reproducibility of textural features in the clinical setting and the limitation of the analytic methods. A multi-radiomic model that could integrate morphological features from the CT together with biological characteristics from the PET and clinical risk factors (age, smoking history, contact with asbestos or family cancer background), would become a highly accurate diagnostic and prognostic method and, thus, make lung cancer screening programs cost-effective. However, in order that radiomics become the cornerstone for clinical decision-making, new machine learning and statistical strategies adapted to the specific requirements of clinical applications should be formulated. A main pitfall in current state of the art AI methods is the use of generic machine learning and statistical tools borrowed from other fields of application which fall short under clinical conditions [7]. Predictive radiomic models for personalized medicine should address several specific challenges different from the ones common to other application areas of artificial intelligence. First, models should collect and integrate diverse multimodal data sources in a quantitative manner that delivers unambiguous clinical predictions. Second, models should also be easily interpreted from a clinical point of view to allow the analysis of the clinical factors that have an impact on the clinical decision. Third, predictions should be robust concerning data uncertainties due to the impact of collection conditions (like acquisition parameters or variability in manual annotations) and the presence of rare and/or outlying cases, which become highly influential for minority classes lead to overfitting. This work reviews state-of-the-art AI methods for radiomics, the specific

challenges that they must face in medical imaging applications and the latest advances for reliable personalized early diagnosis of lung cancer. ES08.06 COST EFFECTIVENESS OF COMPREHENSIVE SCREENING AND SMOKING CESSATION PROGRAMMES

B. Pyenson

Milliman, Inc., New York City/United States of America

There is broad consensus that lung cancer screening with low-dose CT is cost-effective. However, there has been slow take-up in the US where it is covered by commercial insurance and by the federal Medicare program. One way to optimize LC screening is to consider screening as part of an integrated program that specializes in population health for the cluster of smoking-related illness. There are four components of this, LC screening centers can provide high-quality screening and systematic follow-up and appropriate referrals Imaging for LC screening can quantify cardiac calcification, COPD, and osteoporosis, all of which may be associated with smoking LC screening centers can operate as a center for smoking cessation, exercise counseling, and adherence support For the 1.5 million annual indeterminant pulmonary nodules in the US, LC screening centers can provide appropriate follow-up. The vast majority of such cases receive no follow-up. There are both economic and financial consequences for integrated screening. The economic consequences are measured in cost-effectiveness. The financial consequences are attracting high-utilizing people away from lower-quality providers, which can offset the loss of income from treating late stage lung cancers.

ES08.07 SYSTEM APPROACH TO SCREENING MANAGEMENT

A. Reeves

Cornell University, Ithaca/United States of America

Screening seeks to identify a specific disease or set of diseases at an early stage where therapy can be most effective. It involves application of a medical test or tests to a group of asymptomatic individuals at-risk for the disease. Only a very small fraction of the tested population will be expected to have the target disease. Thus, a system for managing the screening process focuses on a single complex protocol and differs significantly from the more traditional medical practice that has a focus on symptomatic diseases and medical conditions. Very high compliance with the protocol and timeliness in follow up actions are critical to extract the maximum benefit of the screening process and avoid unnecessary actions on the majority of the participants that do not have the disease. System requirements for Lung Cancer Screening Screening involves detection of early stage asymptomatic disease and timely follow-up to provide the maximum therapeutic benefit of early stage detection. This requires a system to track participants throughout the screening process, from initial contact to documentation of screening results to follow-up. To maintain the highest degree of quality and timeliness, the screening management system should be comprehensive for all the digital data in the screening program and incorporate the screening protocol in its design. For lung cancer screening (LCS), the web-based I-ELCAP management system was implemented in 2000 [1] with integration of all screening functions into a single system, including: scheduling, data collection, follow-up, patient reports and QA reports. This system includes structured reports for all patient interactions and medical events. The screening protocol is built in to the system; hence, there are real-time checks on adherence to the screening protocol. Any deviations from the protocol, such as a missing report or appointment schedule are flagged for attention. In addition, the management system includes all acquired digital images linked to the patient records; physicians may review images from within the system. Finally, the system includes computer image analysis methods for automated pulmonary nodule detection and for nodule growth rate assessment. Additional findings and Computer Aided Diagnosis Since that early system implementation in 2000, the importance of additional findings for other organs visible in the chest CT scans have become apparent. The radiological structured reporting requirements have been increased to include findings of the heart, and the lungs (emphysema, COPD) which, with lung cancer, covers the three main causes of death for the high-risk screening population. The detailed reporting of the CT scan reading, especially once the initial baseline scan has been read, places an increased burden on the radiologist. To improve the program quality and to address the reading issues a number of additional automated computer analysis functions have been integrated into the system, Reeves et. al. (2017) [2]. These include measures for: coronary calcium, heart size, the aorta, pulmonary hypertension, emphysema, major airways, bone mineral density from thoracic vertebra, breast density, and liver density. In addition, an automated quality assessment of the CT scan itself is reported. The role for AI in screening management Recent advances in AI technology, including deep learning with convolutional neural networks, have increased the capabilities of computer aided diagnostics. A landmark paper by Gulshan et. al. (2016) [3] showed that an automated end-to-end review of eye fundus images for diabetic retinopathy to determine if a follow-up action was indicated could be effectively accomplished without requiring a human read of the images. Following this work a commercial product for this task is now available. A recent paper by Ardila et. al. (2019) [4] showed that, for LCS CT scans, a similar approach with a more complex system could be used for predicting cancer events in a manner similar to LungRADS. A challenge with this LCS study, compared to Gulshan diabetic retinopathy study, is the cost and reporting complexity of the former for training data. While the Gulshan study was prospective and trained on over 120,000 cases, the Ardila study was retrospective with a subset of the NLST data of around 10,000 cases and only considered lung cancer. These methods employ the natural advantage of computer analysis with respect to human readers in attention to detail and lack of fatigue. Further, modern AI methods when appropriately designed, can assimilate data from millions of cases, far beyond human capacity. Efficient large-scale documentation methods have been developed to address the data issue for LCS [2] in which over 25,000 cases have been documented for multiple diseases. These studies move us closer to the point where the majority of the CT image report for LCS could be automatically completed and the role of the physician focused to reviewing a small number of the most significant findings. ES09 HOW I DO IT - REAL WORLD ISSUES IN THE DIAGNOSIS AND TREATMENT OF METASTATIC NSCLC
SUNDAY, SEPTEMBER 8 13:30–15:00

ES09.01 HOW I OPTIMIZE TISSUE SPECIMEN PROCESSING FOR HISTOPATHOLOGICAL AND MOLECULAR PROFILING

A. Bal

PGIMER, Chandigarh/India

Lung cancer is the most common cancer in males worldwide, and the most common cause of cancer related mortality in both sexes. There have been significant advances in the treatment of non-small cell lung cancer (NSCLC) in the last several years, which require careful biopsy sample acquisition and processing. Approximately 70% lung cancer patients present in advanced stage, thus most diagnosis of lung cancer are offered on cytology specimens and small biopsies. Specimens for diagnosing lung cancer For diagnosis of lung cancer, the specimens received in pathology laboratory includes; Effusions and FNAC samples from which cell blocks can be prepared, endobronchial biopsies, transbronchial lung biopsies, CT/PET guided core biopsies and biopsies from metastatic sites like lymph nodes, bone etc. Since tissue is an issue in diagnosis and management of lung cancer, thus strategies to manage limited tissues have been developed: The pre-analytical steps involved in handling, fixing and processing these precious tissue samples are critically controlled to obtain accurate and meaningful biomarker tests. For molecular testing two block setting is used: One block for diagnostic immunostains and second block is reserved for molecular workup. Pathological analysis of NSCLC on small biopsies: *Histological Sub-typing of NSCLC:*The subtyping of NSCLC on small biopsies has poor inter-observer agreement. WHO 2015 classification recommends use of ancillary techniques like mucin histochemsitry and immunohistochemistry for cases that cannot be classified based on light microscopy and minimize the use of term NSCLC-NOS.[1]To refine separation of squamous from adenocarcinoma; use of one adenocarcinoma marker and one squamous marker is suggested to preserve tissue for further molecular testing.For adenocarcinoma, TTF-1, Keratin 7 and napsin and for squamous, P40, p63 and keratin5/6 are used. Cocktails of nuclear and cytoplasmic antibodies like, TTF1/CK5/6 and napsin/p63 are also available. For neuroendocrine tumours, the specific markers include; neuron-specific enolase, chromogranin, synaptophysin, and CD56. With the use of immunohistochemistry the NSCLC-NOS category has been reduced from 10% to 5% in our setup.[2] *Morphological Patterns of Adenocarcinoma:*The histologic patterns of adenocarcinoma described in WHO 2015 classification include; lepidic predominant, acinar predominant, papillary predominant, solid predominant and micropapillary predominant pattern. These histological patterns though described for resection specimens, should be reported on small biopsies as they provide prognostic information; Lepidic pattern is associated with favorable prognosis, acinar and papillary with intermediate prognosis whereas the solid and micropapillary patterns have poor prognosis.[3] Genetics for personalized medicine in lung cancer *Epidermal Growth Factor Receptor gene (EGFR) mutation:*Most common mutations in young Asian females and/or never smokers and involves exons 18-21 of EGFR gene, the encoding a portion of the tyrosine kinase domain. Ninety percent of EGFR mutations are exon 19 deletions or missense point mutation in L858P in exon 21. Additional mutations in EGFR (T790M in exon 20) as well as mutations in other genes such as MET have been responsible for resistance to EGFR inhibitors. *Anaplastic Lymphoma Kinase (ALK) rearrangement:*EML4-ALK translocation of the transcription activation domain of ALK and the dimerization domain of EML4, leads to interstitial inversion in the short arm of chromosome 2. EML4-ALK translocation is seen in 5-8% of adenocarcinomas and is detected by break apart FISH or by IHC (D5F3 clone on Ventana system). *Overall incidence of EGFR mutations in our set up is 22.3% and for ALK re-arrangement is 9.5%.*[3,4] *ROS1 re-arrangement:* Similar to ALK mutations, ROS1 re-arranged tumours respond to tyrosine kinase inhibitor therapyandaccounts for 1-2% of pulmonary adenocarcinomas. ROS1 expression is screened by immunohistochemistry (D4D6 clone from Cell signaling) and break-apart FISH confirms the positive cases. *Rare genetic changes:*Other rare mutations reported in lung cancer includes; HER2 mutations (1%); BRAF mutations (2%); RET and NTRK rearrangements reported in 1.9% and 0.9%, respectively Immunotherapy In addition to targetable mutations, immune checkpoint inhibitors have revolutionized the treatment of lung cancer. The programmed death 1 (PD-1) and programmed death ligand 1 (PD-L1) have monoclonal antibodies directed towards them, which have shown promise with regards to overall survival in advanced NSCLC. PD-L1 expression status as assessed by immunohistochemistry is important in predicting response to PD-1/PD-L1 inhibitors. However, there are challenges in PD-L1 testing that includes; four different IHC clones on different staining platforms, due to limited tissue all assays cannot be performed, heterogeneity of staining and the need for standardization of interpretation and scoring criteria. Recent advances Since tissue is an issue in molecular testing of lung cancer, targeted next generation sequencing panels are available for testing all relevant molecular changes in one go. Oncomine Dx is one such panel for lung cancer that has got FDA approval. In absence of available tissue especially in setting of relapse, cell free DNA is an alternative for detecting molecular alterations. Conclusions The exact histological subtyping of NSCLC, thus reducing the 'NOS' rate, analysis of genetic alterations for targeted therapy and evaluation of targets for immune checkpoint inhibitors has significantly impacted the treatment and prognosis of lung cancer patients. Thus procurement of adequate tissue and its judicious use is of utmost importance. As the number of clinically significant targetable mutations and chromosomal rearrangements continues to grow, the next generation sequencing becomes the need of the day. ES09.02 HOW I REPORT IMAGING FOR ASSESSMENT OF RESPONSES TO TARGETED THERAPIES VS. IMMUNE CHECKPOINT INHIBITORS VS. CHEMOTHERAPY

R. Gill

Beth Israel Deaconess Medical Center, Boston/United States of America

Response assessment is an integral part of radiological reporting in tumor imaging. Our daily workflow includes diagnostic evalaution, determining resectability and response assessment. The radiology template and format is determined by the indication of the exam, and the clinical report may not include detail of all the lesions, but is a synopsis of the findings and an overview of the disease state and longitudinal change on the current therapy. In general our clinical reports do not have details related to detailed response categories and criteria. Response assessment is reported through a separate portal, which is generally overseen by the clinical trials office. Response to therapy is the primary endpoint in most Phase I and II clinical trials. The response criteria to be used and primary and secondary endpoints are detailed in the study protocols based on the type of drug being used. In the era of precision medicine, the traditional response criteria have been evaluated and modified to assess response in targeted and immune therapies. The immune response criteria were developed to follow delayed healing and pseudoprogression. This presentation will discuss details on how I assess response in the context of chemotherapy, targeted therapy and immunotherapy. Assessment of response to chemotherapy was performed using RECIST initially published in 2000 and revised in 2009(1,2). In the current practice RECIST 1.1 is used unless specified by the study protocol. The study protocol will detail the modality technique, duration and reporting criteria. In general the detailed protocol will prove information on the modality of choice. In traditional chemotherapy, the effect of cytotoxic drugs results in gross rumor reduction in most cases. Most trials require more than I independent reviewers, and may have an onsite review and a central review for confirmation of response. Targeted therapies require matching the right gene mutation to the right pharmaceutical

agent, which improves the efficacy and the effectiveness of therapy. Response assessment is on similar lines as chemotherapy. However, response beyond RECIST progression may be allowed on investigator discretion, if the tumor is progressing very slowly and the subject is asymptomatic. In patients with EGFR-mutant NSCLC treated with EGFRTKI, continued EGFR-TKI therapy may be indicated in those patients with progressive disease as these tumors grow slowly over many months and some tumor cells may remain sensitive to EGFR-TKI (3). Erlotinib and crizotinib are commonly continued beyond RECIST progression, because of an initial dramatic response followed by slow progression over many months in relatively asymptomatic patients. Immunotherapy trials are assessed using immune response criteria (iRECIST), the main difference between iRECIST and RECIST, is that the patients are allowed to continue on therapy once disease progresses (PD) for another cycle is continued PD, to ensure it is not pseudoprogression(4). Response assessment in immune therapy trials, allows an extra cycle at 4 to 5 weeks after progression is documented before a decision is made to change therapy. Progression is confirmed at the following cycle or with pathology confirmation. Additional criteria from PETCT and MRI and CT using volumetric assessment is used in the research arena, but not yet used universally for clinical trials. Modified RECIST(5) is more appropriate for pleural tumors as it improves reproducibility of measurements across reviewers and time points. Volumetric assessment is thought to more representative of the morphological changes but definite cut offs as surrogate of the response need validation(6). MRI can assess both size and cellularity and function and hence MR based response assessment derived from apparent diffusion coefficient and pharmacokinetic parameters such as area under the curve, permeability coefficient and elimination coefficient can provide anatomical and functional response to therapy(7,8). It is vital to make a note of any atypical findings and also to recognize adverse events related to the drug and help with timely management. The presentation will detail how I assess response in the real world with case specific examples and illustration of some atypical responses and lesions that can mimic progression.

ES09.03 HOW I DECIDE 1ST LINE TREATMENT OPTIONS FOR METASTATIC NSCLC WITHOUT DRIVER MUTATIONS - BALANCING EFFICACY, TOXICITY AND COST

M. Frueh

Kantonsspital St. Gallen, St. Gallen/Switzerland

Chemotherapy alone has been the accepted standard treatment for patients with stage IV non-small cell lung cancer (NSCLC) for more than two decades based on trials demonstrating a survival benefit and improved quality of life. In the first line setting, the addition of the anti-VEGF antibody (AB) bevacizumab and anti-EGFR ABs cetuximab and necitumumab resulted in modest improvement of survival. Recently, immune-checkpoint inhibitors (ICI) have revolutionized systemic treatment approaches of patients with EGFR/ALK wild type NSCLC in the first and further line setting, mainly due to their ability to achieve long-term tumor control in a subset of patients. Although a considerable proportion of patients doesn`t respond to ICI, immunotherapy is now widely used in combination with chemotherapy as first line treatment in an increasing number of patients as a result of the absence of a reliable predictive biomarker. This situation leaves physicians in the dilemma of balancing the benefit of potential long term disease control in a limited number of patients with the harms which include not only toxicities but also costs. The implementation of novel ICI treatment options in the first line treatment of metastatic NSCLC into current clinical practise will be discussed.

ES09 HOW I DO IT - REAL WORLD ISSUES IN THE DIAGNOSIS AND TREATMENT OF METASTATIC NSCLC
SUNDAY, SEPTEMBER 8 13:30–15:00

ES09.04 HOW I DECIDE 2ND LINE TREATMENT OPTIONS FOR RELAPSED/REFRACTORY METASTATIC NSCLC

N. Singh

Postgraduate Institute of Medical Education & Research (PGIMER), Chandigarh/India

Management of advanced and metastatic non-small cell lung cancer (NSCLC) has been revolutionized in the past decade with the advent of testing for 'druggable' molecular driver alterations and availability of therapies for the same. More recently, immunotherapy (in particular PD-1/PD-L1 immune check point inhibitors) have opened up a fifth frontier for the treatment of this disease. However, barring exceptions, patients with advanced/metastatic NSCLC relapse irrespective of whether they received a targeted therapy or chemotherapy (with/without immunotherapy) or immuno(mono) therapy in the front line setting. This is understandable as cures are uncommon in metastatic disease although sustained and durable responses to immunotherapy and targeted therapies are well known. Treatment of relapsed disease presents a greater challenge as performance status, ability to bear cost of treatment and finally wishes of patients and caregivers often change as opposed to the treatment naïve state. Additional factors also come into play in low and middle income group countries (LMICs) and resource constrained settings. Practicing precision medicine remains the goal even for the relapsed setting. However, finding additional targets or drugs for identified secondary targets mandates rebiopsy which may be limited by ease of access to the desired site for rebiopsy as well as patients' willingness to undergo the same. Liquid biopsy (typically blood and less commonly other body fluids) appears to be an increasingly promising alternative to conventional tissue biopsy with the availability of highly sensitive testing platforms (especially NGS) and the ability of the former to provide 'global' assessment of biomarker status as opposed to the latter. Tissue heterogeneity is more pronounced in the setting of relapsed disease as compared to treatment naïve settings. In case of EGFR mutated NSCLC,

the advent of T790M inhibitors (osimertinib) was the preferred treatment approach for patients progressing on 1st/2nd generation EGFR TKIs and with a demonstrable exon 20 T790M mutation on either tissue or liquid biopsy (AURA trial). However, the FLAURA trial led to osimertinib moving to the frontline setting and therefore relapses on osimertinib is typically followed by chemotherapy unless specific mechanisms of resistance can be demonstrated which can be further targeted by available drugs. It is likely that 4th generation TKIs will be available for patients in the coming few years thus providing an opportunity to use another TKI following progression on osimertinib. For ALK rearranged NSCLC, there is a similar story. 2nd generation ALK inhibitors (alectinib, ceritinib and brigatinib) were developed and initially approved for patients intolerant to or having progressed on the 1st generation ALK inhibitor crizotinib. The ALEX/J-ALEX trials (for alectinib) and ASCEND-4 trial (for ceritinib) meant that these drugs moved to the front-line setting. In particular data from ASCEND-8 trial showed that 450 mg of ceritinib with a low-fat meal was as effective and better tolerated than the conventional 750 mg taken empty stomach. For resource constrained settings, this has an additional implication of lower cost of treatment. Lorlatinib, a 3rd generation ALK inhibitor, approved for use following progression on the 1st/2nd generation ALK inhibitors described above is also attempting to move to the frontline setting pending results of ongoing trials for this purpose. For both EGFR and ALK, the debate on using the best and most effective drug first vs. sequencing lower followed by higher generation drugs continues to be hotly debated as treatment options for progressors on 3rd generation TKIs given upfront are mostly limited to chemotherapy or experimental therapies as part of ongoing clinical trials. Platinum based doublet chemotherapy (pemetrexed based for non-squamous histology and gemcitabine/paclitaxel/nab-paclitaxel for squamous histology) was the cornerstone of treatment for patients without a targetable genetic alteration. Docetaxel single agent was the standard 2nd line treatment option and attempts were made to enhance its efficacy by combining it with VEGF inhibitors like ramucirumab (REVEL trial) or nintedanib (non-squamous only; LUME LUNG-1). Simultaneous time period saw the results of PD-1 inhibitors (nivolumab; CheckMate 017 and 057 and pembrolizumab; KEYNOTE 001 & 010) as well as PD-L1 inhibitor (atezolizumab; OAK) and thus these drugs become the preferred and standard 2nd line treatment. However, a similar story as for EGFR and ALK happened herein as well with the KEYNOTE 024 trial (pembrolizumab monotherapy for PD-L1 expression of 50% or higher) and KEYNOTE 189 and 407 trials (pembrolizumab combined with chemotherapy irrespective of PD-L1 expression) leading this drug to be part of front line treatment. Atezolizumab as part of a 4 drug regiment (paclitaxel-carboplatin-bevacizumab-atezolizumab) also appeared to provide similar efficacy in the front line setting (IMPOWER 150) for non-squamous NSCLC although concerns about toxicity remain. The effect of immunotherapy coming to the front line treatment setting (alone or in combination with chemotherapy) also implies that these drugs have no proven role in relapse as there is no data currently that patients treated initially with immune check point inhibitors benefit from the same class of drugs on relapse. Patients in LMICs and resource constrained settings tend to get treatment in more conventional ways than listed above as newer drugs and regimens are either not available or are not approved as fast as in the US/Europe or are very expensive. Hence it is fairly common for EGFR mutated patients to receive 1st generation EGFR TKIs, for ALK rearranged patients to receive crizotinib and for those without any driver mutations/rearrangements to receive only platinum doublet chemotherapy in the first line setting. This sort of represents a time lag compared to what is applicable in the US/Europe. The need to provide affordable yet effective treatment remains the primary aim of clinical oncologists in LMICs and precision medicine is therefore informally and practically adapted to the available resources. ES09.05 LIMITATIONS IN THE AVAILABILITY OF RADIOTHERAPY

J. Khader

King Hussein Cancer Center, Amman/Jordan

Limitations in the Availability of Radiotherapy Abstract The annual global incidence of cancer, according to Globocan 2018 report is 18 million new cancer cases, and the number is projected to rise in 2035 to 25 million cases (13 million deaths), with 70% occurring in low- and middle -income countries (LMICs), where there is a severe shortfall in the availability of radiotherapy (1). Radiotherapy is an essential component of overall curative and palliative cancer care. It is estimated that about half of cancer patients would benefit from radiotherapy for treatment of localized disease, local control, and palliation (2). Yet, this crucial component of the response to cancer has been largely absent from global health discourse, and has received limited domestic and international funding. As a result, there is a worldwide shortfall of radiotherapy services; with more than 90% of the population in low-income countries, lacking access to radiotherapy(2). The growing burden of cancer will place increased demand on the already-scarce radiotherapy services worldwide. A 2015 report by the Global Task Force on Radiotherapy for Cancer Control estimated that by 2035 at least 5000 additional megavolt treatment machines would be needed to meet LMIC demands, together with about 30 000 radiation oncologists, 22 000 medical physicists and 80 000 radiation therapy technologists(3). Many of the challenges in delivering radiotherapy in LMICs that were identified including: (a) a shortage of good-quality radiotherapy equipment capable of both simple and more complex radiotherapy treatment delivery, (b) the challenge of servicing the linacs, both for preventative maintenance and upon equipment breakdown and (c) the chronic shortage of adequately trained personnel(3). In LMICs, the costs of equipment, building and salaries are 81, 9 and 10% of the total cost of the facility, respectively, compared with 30, 6 and 64% in high-income countries. Some of the challenges facing LMICs are also related radiofrequency power systems, linac beam production and control, durable and sustainable power supplies, computer applications in radiation therapy & linac safety and operability(4). Investment in radiotherapy is crucial and an imperative in low-income and middle-income countries, if unnecessary cancer deaths and suffering are to be avoided. Investment in radiotherapy is timely for many reasons, including evidence from The Lancet Commission on Investing in Health (5) showing the benefits of investing in health to achieve convergence in health outcomes between low-income countries and upper-middle-income countries, the momentum for investing in low-income and middle-income countries to expand surgery,(6) and the UN resolution on sustainable development, which recognises that "universal health coverage is a key instrument to enhancing health, social cohesion and sustainable human and economic development".(7) Conclusion It is a call for action to enhance population-based cancer control plans, expansion of access to radiotherapy, human resources for radiotherapy, sustainable financing to expand access to radiotherapy and align radiotherapy access with universal health coverage. ES10 ONCOLOGY DRUG APPROVAL: CHALLENGES AND OPPORTUNITIES
SUNDAY, SEPTEMBER 8 13:30–15:00

ES10.01 US FOOD AND DRUG ADMINISTRATION

G. Blumenthal

FDA, Silver Spring/United States of America

Dr Blumenthal will provide the US FDA Oncology Center of Excellence perspective on Oncology Drug Approval: Challenges and Opportunity. With the recent influx of novel targeted therapies, immunotherapy and chemotherapy to treat patients with lung cancers, there are increased challenges to ensuring that safe and effective therapies are available to patients as efficiently as possible while ensuring that the evidence generated is robust and reliable. This talk will discuss FDA's perspective on global drug development.

Keywords: regulation, development, access

ES10 ONCOLOGY DRUG APPROVAL: CHALLENGES AND OPPORTUNITIES
SUNDAY, SEPTEMBER 8 13:30–15:00

ES10.02 JAPAN PHARMACEUTICALS AND MEDICAL DEVICES AGENCY

S. Nagai

The University of Tokyo Hospital, Tokyo/Japan

The Pharmaceuticals and Medical Devices Agency (PMDA) and the Ministry of Health, Labour and Welfare (MHLW) are responsible for reviewing applications and approving the marketing authorization of drugs, medical devices, and regenerative medicines in Japan. All applications for marketing authorization in Japan are submitted to the PMDA. The PMDA conducts scientific review. Review reports prepared by the PMDA are then submitted to MHLW. The MHLW approves the marketing authorization. Japanese regulation has two categories of regulatory review: standard review and priority review. Priority review is applied to orphan drugs and products designated by the MHLW. Other than orphan drugs, the MHLW designates medical products as priority review products based on the following criteria described: 1. Seriousness of the target disease and 2. Clinical usefulness of the drug: no standard therapy exists, and clinical usefulness is superior to the existing products in terms of efficacy, safety, or the patient's quality of life. The target total review time for standard review products and priority review products is 12 months and 9 months, respectively. The conditional and term-limited approval system has been first introduced for regenerative medical products since November, 2014. Regenerative medical products may be granted conditional and term-limited approval if their efficacy can be assumed and safety is confirmed in early-phase (phase I and/or II) registration trials. In the approval system, sponsors of the products must confirm their efficacy and safety after marketing authorization in postmarketing clinical studies etc and by resubmitting applications for regular approval within a predetermined period (not more than 7 years). The conditional and term-limited approval for regenerative medical products is similar to the accelerated approval in the US. In addition, the conditional approval system for drugs has been newly instituted since October, 2017 in Japan. This may be granted if all of the following requirements are met: 1. seriousness of the target disease, 2. clinical usefulness of the drug: no standard therapy exists, and clinical usefulness is superior to the existing products in terms of efficacy, safety, or quality of life, 3. it is difficult or it takes too long time to conduct a confirmatory study, 4. exploratory clinical studies can show efficacy and safety, and 5. surveillance or clinical studies must be conducted as post-marketing requirement. Because these requirements include the requirements for priority review (seriousness of the target disease and clinical usefulness of the drug), drugs granted conditional approval can automatically enjoy priority review. Moreover, the requirement for conditional approval "it is difficult or it takes too long time to conduct a confirmatory study" in Japan is totally different from accelerated approval based on surrogate endpoint in the US. The requirement is similar to the requirement for marketing authorization under exceptional circumstances "companies cannot provide comprehensive clinical data because of the rarity of the disease" in the EU. Although the requirements for conditional approval for drugs in Japan include "surveillance or clinical studies must be conducted as post-marketing requirement", the term of validity for conditional approval of drugs in Japan is not established, which is different from the conditional and term-limited approval for regenerative medical products in Japan. As of May 31, 2019, only lorlatinib for ALK fusion-positive non-small cell lung cancer and pembrolizumab for MSI-high solid cancer have been granted conditional approval for drugs in Japan. Conducting confirmatory comparative studies is not included in postmarketing requirements for the both drugs. The MHLW instituted in 2015 the SAKIGAKE (meaning pioneer or forerunner in Japanese) designation system for medical products for diseases in urgent medical need of innovative therapy and that may satisfying the following two conditions: 1. The medical product has been first developed in Japan, and a sponsor is planning to submit a marketing authorization application; and 2. Prominent effectiveness can be expected based on data from the mechanism of action, non-clinical studies, and early-phase clinical studies. Advantages of sponsors who have medical products granted SAKIGAKE designation are as follows: prioritized consultation (reduced waiting time), substantial pre-application consultation, prioritized review (target total review time of 6 months only for drugs, devices, and IVDs), assigning a PMDA manager as a concierge, and an extension of the reexamination period. Total review time for SAKIGAKE-designated regenerative medical products is not established. Although the SAKIGAKE designation is similar to a breakthrough therapy designation in the US and PRIME in the EU, the requirement "the medical product has been first developed in Japan" and the advantage of specific shortened total review time are unique to the SAKIGAKE. Companion diagnostics (CDx) are important for oncology drug development. Current regulatory considerations regarding CDx and tumor profiling test in Japan are similar to those in the US. As of May 31, 2019, three next generation sequencing-based oncology panel tests have been approved as CDx and/or tumor profiling test in Japan. However, more flexible regulations regarding CDx are necessary for efficient clinical practice and drug development. I will give an overview of regulatory frameworks and challenges regarding oncology drugs and companion diagnostics in Japan. References: •Nagai S, Ozawa K. ES10.04 EUROPEAN MEDICINES AGENCY

J. Camarero

Spanish Medicines Agency, Madrid/Spain

Oncology Drugs Approval: Challenges and Opportunities In recent years, the development of new drugs in the oncology field has notably increased. This growth in oncology clinical trials appears to be mainly associated with the increasing knowledge in pathophysiology and molecular medicine in oncology. Targeted therapies have been approved, overall, on the basis of its ability to prolong progression free survival and/or life expectancy of patients. In addition, immunotherapy has arisen as a turning point in the treatment of cancer, opening a new era and setting up a milestone in the current armamentarium. However, the regulatory decision making process behind some of the approvals for these products have proven difficult and lead to important uncertainties still to be addressed. Such unanswered questions relate, among others, to the target population, subgroups of patients partially covered by authorized indications and limitations on important aspects such as duration and combination of treatments. Likewise, this increase in new molecules development poses a remarkable pressure on regulators, clinicians and payers, who albeit from different perspectives, face the very same problem of how to ensure (timely) access to patients of new authorized products. From a regulatory perspective, randomized clinical trials remain the gold standard for

adequate assessment of both efficacy and safety. Nevertheless, conducting single arm studies is becoming a commonly approach for companies to speed up regulatory approval in those situations where there is an unmet medical need. The latter cast important doubts on when, where and how this strategy can be accepted. Last but not least, new clinical trials designs and the proposal of using Real Word Evidence/Real World Data to complement non-compelling clinical development, are creating a new parading when it comes to making a decision upon the benefit-risk balance

ES10.05 BRAZILIAN HEALTH REGULATORY AGENCY - AGÊNCIA NACIONAL DE VIGILÂNCIA SANITÁRIA

C.G. Ferreira

Oncoclinicas Institute For Research and Education, Rio Janeiro/Brazil

Brazil, the largest country in South America, has become the second largest pharmaceutical market in the emerging world. The Brazilian Health Surveillance Agency (Agencia Nacional de Vigilancia Sanitaria - ANVISA) was created in 1999 with the primary goal to protect and promote public health surveillance over products and services in Brazil. Its hallmarks are administrative independence, financial autonomy, and the stability of its directors. Within the federal public regulatory structure, the agency is linked to the Ministry of Health [1]. Despite major advances in the regulatory process in Brazil, it is important to highlight that a major delay in cancer drugs approval over the last decade has had a negative impact on patient access to novel medications in Brazil. According to Barrios et al., [2] well-established and adequately functional drug approval legislation is indispensable to guarantee a country's population health. Any malfunctions or delay in such a crucial process have serious consequences. As an example, the drug Crizotinib (Xalcori®Pfizer, NY, USA), which had its approval denied by ANVISA in June 2014 may be seen as a landmark. Assuming different premises, Barrios et al. [2] calculated 1.367 years of life lost over 34 months due to lack of access to Crizotinib between August 2011 (FDA approval) to June 2014 (refusal by ANVISA). Of note, Crizotinib was not approved in Brazil until Feb 2016, what may have added additional 804 years of life lost to final numbers due to this delay. Other example of unexplained delay in drug approval in lenalidomide. The gap between the drug approval in the US and Brazil was 12 years. Regarding drugs that do require a companion diagnostic, the situation may become more complicated since, unlike the US Food and Drug Administration, no clear mechanism is in place with ANVISA for the simultaneous linking of most companion diagnostic tests with their respective targeted therapeutic drug [3]. In trying to understand the reasons behind this delayed drug approval process, methodological, cultural, political and ideologic reasons may account. At odds with other regulatory agencies such the FDA that allow conditioned approval based on non randomized data for drugs addressing unmet medical needs. For many years ANVISA authorities mandated randomized phase 3 data for a definitive approval, since no conditioned approval was allowed. In this context, having a specific oncology area or committee, such as the FDA Oncology Drug Advisory Committee [4], may be crucial. Fast track approval, breakthrough designation, companion diagnostics, different surrogate endpoints, integration of real world evidence (RWE) into the regulatory process are very specific topics from the oncology field and do require to be analyzed under the perspective of cancer specialists. From a political, cultural and ideologic perspective, althoughit is notorious that Brazil has invested substantially in expanding access to health care for all of its citizens, the country has, essentially, two clear distinct and dissimilar health systems [3]. The public system allows drugs to become commercially available through processes that are different from those in place in the private health-care system. Although difficult to measure those disparities and difficulties to reimburse expensive drugs in the public system, may have influenced the delayed process during the last decade. Over the last decade, delays at ANVISA's approval process have been considered the only reason for the inequitable access to oncology care between the USA and Brazil. Yet, this may be a biased conclusion and a more comprehensive analysis in needed. By analyzinga basket of twenty-three oncology products approved by ANVISA after 2002 Bustamante et al. [5] identified that on average there was a difference of 8.6 months (449 X 186 days). However on average, a delay in the manufacturers' submission for regulatory approval of 1.1 years (393 days between Brazil and the USA) was also identified. More recently, a trend toward improvements in the drug approval process has been identified (ex. Osimertinib and Durvalumab). Osimertinib was firstly approved by ANVISA in 2017 as a second line treatment in patients who did not respond well to the initial drug. With the new determination, in 2018 ANVISA approved its use as a first therapy to treat locally advanced non-small cell lung cancer. Durvalumab was approved by ANVISA in 2017. Nevertheless there is clear room for a continuous improvement. Increase in the number of ANVISA technicians, continuous training and collaboration with academic institutions and other regulatory agencies elsewhere are mandatory. Close scientific collaboration and open and transparent dialogue between ANVISA and pharmaceutical companies are required. In sum, if we are to have a continuous improvement in the oncology drug approval process, all the stakeholders (ANVISA, drug manufactures, patient advocacy, players at the private and public health systems) must act together. ES11.01 LUNG ADENOCARCINOMA TO SQUAMOUS CELL CARCINOMA TRANSDIFFERENTIATION AND DRUG RESISTANCE

H. Ji

Institute of Biochemistry and Cell Biology Shanghai Institutes for Biological Sciences Chinese Academy of Sciences, Shanghai/China

Lung cancer is notorious for high heterogeneity and strong plasticity, which might contribute to the development of drug resistance. Lineage transition from lung adenocarcinoma (ADC) to squamous cell carcinoma (SCC), as implicated by clinical observation of mixed ADC and SCC pathologies in adenosquamous cell carcinoma (Ad-SCC), reflects strong cancer plasticity and potentially links to drug resistance. Using Genetically Engineered Murine Model (GEMM), we have provided *in vivo* evidence in supporting the ADC to SCC transdifferentiation (AST): *Lkb1*-deficient mouse lung ADC transdifferentiates into SCC progressively via pathologically mixed Ad-SCC. Mechanistically, we find that down-regulation of reactive oxygen species (ROS) level through N-acetyl cysteine (NAC) treatment or NRF2 expression inhibits this transition, highlighting the functional importance of ROS in regulating cancer plasticity. Pentose phosphate pathway deregulation and impaired fatty acid oxidation collectively contribute to the redox imbalance and functionally affect the AST process. Importantly, similar tumor and redox heterogeneity are also found in human LKB1-inactivated lung cancer. In preclinical trials toward metabolic stress, Lkb1-inactivated ADC can develop drug resistance through squamous transdifferentiation. Recent observations in clinic further suggest that such pathological transition might be responsible for resistance to tyrosine kinase inhibitor (TKI) therapy and chemotherapy in relapsed EGFR-mutant lung ADC patients. These findings demonstrate that lung cancer plasticity potentially affects therapeutic response and precision medicine through histological transition.

ES11.02 SCLC LINEAGE TRANSFORMATION IN LUNG ADENOCARCINOMA AND RESISTANCE TO TARGETED THERAPIES

W. Lockwood, Y. Inoue

British Columbia Cancer Research Centre, Vancouver/Canada

Lung cancers are typically divided into two main histological types: small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). NSCLC accounts for approximately 85% of all cases and lung adenocarcinoma (LUAD) is the most frequent subtype. Current treatments of LUAD aim to inhibit driver oncogene alterations and have shown unprecedented success. Among the oncogenic alterations in LUAD, EGFR kinase domain mutations are found in ~40-50% of patients in east-Asian countries and 20% of patients in western countries1. EGFR tyrosine kinase inhibitor (TKIs) are highly effective for tumors with EGFR mutations and resistance mechanisms to these compounds have been well documented: the most frequent being the acquisition of a secondary mutation in EGFR (T790M)2, followed by amplification of the hepatocyte growth factor receptor (MET) gene3 and mutations in BRAF and PIK3CA genes4,5. Histological transformation from LUAD to SCLC occurs in up to 15% of cases with acquired resistance to first and second generation EGFR TKIs5. Histological plasticity as a mechanism of resistance is becoming increasingly prominent as other resistant mechanisms can now be successfully targeted: MET-inhibitors are employed for MET-amplified tumours and 3rd generation EGFR TKIs are used to overcome resistance driven by the EGFR T790M muation6. Importantly, the 3rd generation EGFR TKI osimertinib was approved by the FDA in 2018 and thus, cases of treatment-induced SCLC transformation may increase in prominence as other mechanisms are targeted. Currently, conventional platinum doublet chemotherapy is the standard of care for patients with treatment-induced SCLC as well as de novo SCLC. Unfortunately, this treatment often produces an incomplete and non-durable response followed by inevitable relapse within months, leading to poor patient outcomes7. Thus, this mechanism of resistance will represent a major barrier towards the success of 3rd generation TKIs and new strategies to prevent this lineage shift or to treat SCLC transformed tumors are urgently needed. Despite the increasing clinical importance of LUAD to SCLC transformation, the biological pathways regulating this process are poorly understood. Since the first description in 20068, numerous studies have aimed to characterize the molecular changes that drive transformation in the context of drug resistance. Assessment of clinical samples has revealed that EGFR-mutant tumors universally lose EGFR protein expression upon SCLC transformation, despite still harboring EGFR mutations that confirms their clonal origin9. Furthermore, the mutation spectrum of these transformed cases often resemble de novo SCLC, containing inactivation of the tumor suppressors RB and p53 in nearly all cases9. This mirrors neuroendocrine transformation that occurs in prostate adenocarcinoma, where loss of RB/p53 are known to upregulate the reprogramming transcription factor SOX2, driving lineage plasticity and resistance upon anti-androgen therapy10. Furthermore, loss of RB and inactivation of p53 are required to reprogram a normal cell of epithelial lineage to a neuroendocrine lineage, and when combined with expression of myristoylated AKT1 and overexpression of MYC and BCL2, leads to the development of lethal SCLC in vivo11. Inactivation of p53 and RB also leads to the development of SCLC in transgenic mouse models, even when targeted in specifically to type-II airway epithelial cells, the putative cell of origin for EGFR-mutant LUAD12. Together, these studies highlight the essential role for these tumor suppressor genes in reprograming transcriptional profiles and chromatin accessibility in facilitating neuroendocrine lineage transformation. However, accumulating experimental evidence has demonstrated that while necessary, dual inactivation of RB and p53 is not sufficient to cause SCLC lineage transformation in EGFR-mutated LUAD, suggesting that additional factors are required9. MYC amplification and PIK3CA mutation have been proposed to potentially cooperate with RB/p53 loss to facilitate transformation13, and specific epigenetic regulators may also provide the appropriate context for lineage reprograming to occur. Despite this, no *in vitro* or in vivo models of SCLC transformation in EGFR TKI resistance have been developed, making it difficult to comprehensively explore the molecular events driving this lineage shift. Interestingly, there are clear differences between LUAD and SCLC regarding EGFR expression and gene alterations in MAPK pathway including EGFR/KRAS mutations: EGFR is usually not expressed14 and EGFR/KRAS mutations are extremely rare in SCLC15; in contrast, EGFR/KRAS play crucial roles in LUAD biology, including regulating differentiation in addition to prolferation16. To date, however, no clear explanation has been given for these differences. We have recently shown that activation of MAPK signaling in SCLC leads to suppression of the neuroendocrine phenotype - including downregulation of the transcription factors NEUROD1, INSM1, BRN2 and ASCL1 - and transformation to a NSCLC-like state17. Using this model system, we have begun to elucidate the key transcription factors and epigenetic changes that drive SCLC to NSCLC transformation in the hope that the same processes will also be involved in the clinically relevant scenario: SCLC transformation from EGFR mutant LUAD during TKI resistance. We suggest that only EGFR-mutant LUADs that do not reactivate MAPK signaling through secondary EGFR mutations or alterations in parallel kinase pathways (ie. MET) during development of TKI resistance will be able to undergo SCLC lineage transformation, and that RB/p53 loss and epigenetic plasticity provide the permissive context for which this transformation can occur. Greater understanding of lineage transformation in LUAD will provide important insights in terms of managing outcomes of patients undergoing targeted therapy and offer new avenues towards treatment of TKI resistant tumors. ES11.03 IMMUNOTHERAPY AND ENDOGENOUS RETROVIRUSES IN SMALL-CELL LUNG CANCER

I. Canadas

Dana-Farber Cancer Institute, Boston/United States of America

Introduction: Tumor cell heterogeneity is a key determinant of cancer progression and drug resistance, which is often mediated by mesenchymal cell subpopulations. While these subclones can secrete growth factors, chemokines and cytokines, the immune signaling networks that fuel this pro-tumorigenic state remain incompletely defined. Elucidating what underlies this state would provide insights into tumor biology and inform clinical strategies to improve anti-cancer therapies. Methods: Because of their well-defined nature, we used the phenotypically distinct H69M and H69AR Small Cell Lung Cancer (SCLC) mesenchymal subclones to uncover a novel mechanism of dysregulated innate immune signaling as compared with parental neuroendocrine H69 cells. Analysis of gene signatures across TCGA and CCLE databases, functional studies in additional cell lines, and ex vivo testing of patient-derived organotypic tumor spheroids (PDOTS) were conducted to determine the broader relevance across human cancers. Results: We discovered a novel epigenetically regulated subclass of endogenous retroviruses (ERVs) that engages innate immune signaling in mesenchymal cancer subpopulations. Stimulated 3 Prime Antisense Retroviral Coding Sequences (SPARCS) are oriented inversely in 3'UTRs of certain interferon-inducible genes and silenced by EZH2. De-repression of these loci resulted in dsRNA generation following IFNγ exposure due to bi-directional transcription from the STAT1-activated gene promoter and the 5' LTR of the antisense ERV. We found that dsRNA sensing preferentially by MAVS fuels activation of TBK1, IRF3, and STAT1 signaling, sustaining a positive feedback loop. SPARCS induction across specific human tumors and cell lines is tightly associated with downregulation of chromatin modifying enzymes, including EZH2, a mesenchymal AXL positive cell state, and B2M and MHC class 1 antigen expression. SPARCS high tumors were marked by immune infiltration, but also exhibited multiple features of tumor immune suppression. IFNγ treatment of PDOTS with de-repressed SPARCS markedly enhanced CXCL10 production and sensitized them to PD-1 blockade. Conclusions: Together, these data unveil a novel

subclass of ERVs whose de-repression triggers pathologic innate immune signaling in cancer, with potentially important implications for cancer immunotherapy.

ES11.04 MECHANISMS FOR RESISTANCE TO TKI AND ICI

K. Politi

Yale School of Medicine, New Haven/United States of America

Targeted therapies and immunotherapies have transformed the treatment landscape for lung cancer over the past 15 years. These therapies are effective in subsets of patients, however, acquired resistance is an impediment to cures. In the case of targeted therapies, acquired resistance occurs in all cases although new generations of targeted therapies delay inevitable relapse. Upon treatment with immune checkpoint inhibitors, data suggest that acquired resistance occurs in ~50% of cases following an initial response to the therapies. However, studies of acquired resistance to these immunotherapies are limited and the exact frequency remains to be determined. Therefore understanding the mechanisms of acquired resistance to targeted therapies and immunotherapies is of critical importance to developing new therapeutic strategies to overcome and prevent the emergence of drug resistance. EGFR mutant lung cancer is a paradigm for the use of targeted therapies in this disease. Tyrosine kinase inhibitors (TKIs) are the first line of treatment for EGFR mutant lung cancer and are effective in 70-80% of cases. Acquired resistance to first and second generation inhibitors, like erlotinib, gefitinib and afatinib, most frequently is the result of a secondary mutation in EGFR, EGFR T790M. Third generation TKIs that can inhibit the activity of EGFR T790M-containing mutants were recently developed and one of these, osimertinib, is now approved for the first- and second-line treatment of EGFR mutant lung cancer and is increasingly used in the clinic. Even with osimertinib, acquired resistance occurs and there is a need to understand the mechanisms of resistance to this TKI. We will review current knowledge of acquired resistance to osimertinib and discuss new findings from studies in genetically engineered mouse models, patient-derived xenografts, patient specimens and cell line models. In contrast to the extensive knowledge of the mechanisms of acquired resistance to TKIs, very little is known about acquired resistance to immune checkpoint inhibitors. In melanoma, lung cancer and colon cancer, defects in antigen processing and presentation have emerged as a mechanism of acquired resistance to these agents. Defects in this pathway can occur in different ways including loss of specific neoantigens and genetic loss or downregulation of essential components of the pathway like b2-microglobulin. In the presentation, we will discuss known mechanisms of acquired resistance to immune checkpoint inhibitors and new approaches and models that we and others are developing to study this problem.

ES11.05 MSK-IMPACT, A HOSPITAL BASED GENETIC SCREENING USING FDA-APPROVED NGS SYSTEM

A. Drilon

Memorial Sloan Kettering Cancer Center, New York/United States of America

A variety of actionable genomic signatures are found across different cancer types. These signatures have been associated with clinical benefit from a variety of therapeutics, including targeted therapy and immunotherapy. MSK-IMPACT is a broad, hybrid capture-based next-genereation sequencing platform that is capable of detecting sequence mutations, small insertions and deletions, copy number alterations, and select structural rearrangements. The assay has been validated and approved for clinical use by the New York State Department of Health Clinical Laboratory Evaluation Program. Furthermore, the assay has received authorization by the United States Food and Drug Authority. Comprehensive profiling of various cancers with assays such as MSK-IMPACT has advanced genomic medicine by increasing the identification of patients for whom matched therapies may be appropriate, elucidating putative resistance mechanisms, and identifying novel, potentiallly actionable signatures.

ES11.06 TOXICOLOGY OF TOBACCO AND METABOLITES, AND IMPACT ON CANCER

M. Goniewicz

Roswell Park Comprehensive Cancer Center, Buffalo/United States of America

Tobacco smoke is a significant source of exposure to toxic compounds among active smokers and those exposed to secondhand smoke (SHS). Over 7000 chemicals have been identified in tobacco smoke, including 69 known carcinogens. Characterizing human exposure to tobacco smoke constituents is important for public health efforts aimed at reducing exposure to these chemicals. Tobacco smoke exposure can be assessed through biomonitoring, i.e., by measuring the concentration of a toxicant or its metabolites in human physiological fluids. Biomarkers, ideally unique to a toxic mixture such as tobacco smoke, are useful for exposure assessment and for source apportionment. Nicotine, its metabolites, and the tobacco-specific nitrosamine (TSNA) metabolite 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) are the most specific of the commonly used biomarkers for tobacco smoke exposure. Carbon monoxide, metabolites of volatile organic compounds (VOCs), and polycyclic aromatic hydrocarbons (PAHs) metabolites, are also useful biomarkers, but they have sources other than tobacco smoke. Levels of these biomarkers are generally elevated in smokers as compared to nonsmokers, but specificity may be inadequate to measure SHS exposure. In general, biomarker studies can demonstrate internal exposure to toxic constituents due to tobacco product use and can be used to assess relative harm of modified-risk tobacco products. Epidemiologic studies directly support a link between exposure to tobacco-specific toxicants and subsequent risk for cancer in smokers of conventional cigarettes as well as lifelong never-smokers. Nicotine metabolites and total nicotine equivalents (sum of nicotine, cotinine, 3'-hydroxycotinine, and their glucuronides), which can be measured in urine, blood or saliva, represent approximately 73%–96% of the nicotine dose and provide a superb indicator of nicotine uptake. Although nicotine was one of the first biomarkers to be used for assessing exposure to cigarette smoke, its short half-life ($t_{1/2}$=~2 h) and variable rate of metabolism led to the use of cotinine and other nicotine metabolites as biomarkers of nicotine exposure. Cotinine is the major metabolite of nicotine, and its longer elimination half-time ($t_{1/2}$=16–18 h) makes it a good biomarker for nicotine uptake in various biological fluids and tissues. The nicotine metabolite ratio (ratio of 3'-hydroxycotinine to cotinine) in plasma is an excellent phenotypic indicator of hepatic CYP2A6 activity in smokers and can be used as a measure of individual risk for addiction. Tobacco-specific nitrosamines (TSNAs) include the potent lung carcinogen NNK and the oral cavity and esophageal carcinogen N'-nitrosonornicotine (NNN) and are—as indicated by their common name—regarded as completely specific to tobacco. Consequently, these compounds and their metabolites are among the most important biomarkers for monitoring tobacco exposure and evaluating cancer risk in tobacco users. NNAL is a metabolite of NNK and itself is a carcinogen. A key benefit of NNAL assays is the compound's elimination half-time ($t_{1/2}$ of 10–18 days), which is longer than other tobacco biomarkers. The main disadvantage is that the urinary concentration of NNAL is many times lower than that of cotinine, so the assay is more technically challenging and expensive to perform. Measurements of NNAL typically require extensive sample preparation and fewer laboratories can reliably measure NNAL than cotinine or nicotine. Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental pollutants formed from incomplete combustion of organic matter and use of combustible tobacco products results in substantial exposure to those chemicals. Over 500 PAHs and their alkyl derivatives have been identified in tobacco smoke. Some PAHs induce tumors in animals and are carcinogenic to humans. For example, benzo[a]pyrene induces malignant lesions in animal studies. Urinary concentrations of PAH metabolites, specifically monohydroxylated PAHs, have been used as biomarkers of human exposure to PAHs including naphthalene, fluorene, phenanthrene and pyrene. The PAH exposure profiles for tobacco smoke may differ from other sources, and it may be possible to identify PAH

biomarkers that are more selective for tobacco smoke than others. Volatile organic compounds (VOCs) are a diverse group of chemicals that are abundant in tobacco product emissions and in the polluted atmosphere. Many VOCs are formed by incomplete combustion of organic materials, and tobacco is not the only source of exposure. Although VOCs are also present in foods and beverages, the levels of many VOCs and VOC metabolites are elevated in smokers' urine compared with nonsmokers. Several VOCs in tobacco smoke, including acrolein, benzene, and 1,3-butadiene, can cause cardiovascular and lung damage. 1,3-butadiene is also a human carcinogen and benzene is a human carcinogen known to cause leukemia. A number of harmful VOCs and their metabolites can be measured in human blood, urine, and breath and those biomarkers serve as a surrogate measure for tobacco smoke exposure. While tobacco-specific biomarkers are useful for interim assessments of exposure, there are several sources of variation to consider when interpreting such data. These include frequency and intensity of tobacco use product type, inter- and intra-individual variability, biomarker/chemical half-life, and variability in lab methods. Differences in carcinogen exposure from different cigarette products could contribute to differences in smoking-associated cancer incidence. Due to the introduction of new tobacco-derived products and the development of novel ways to modify and use conventional tobacco products, biomarker studies can be used to assess relative harm of modified-risk tobacco products. For example, short-term observational studies have shown reduction in biomarker levels for VOCs, TSNAs, and PAHs in cigarette smokers who switched to e-cigarettes, smokeless or heated tobacco products. This suite of biomarkers has the potential to provide objective data on levels of nicotine as well as selected important carcinogens and toxicants that may be associated with use of novel tobacco products.

Selected Biomarkers of Exposure to Tobacco Products			
Toxicant Group	**Tobacco Constituents**	**Biomarkers**	**Clinical Relevance**
Nicotine Metabolites	Nicotine	Cotinine	Addictive chemical
Tobacco Specific Nitrosamines (TSNAs)	4-methyl-nitrosamino)-4-(3-pyridyl)-1-butanon (NNK)	4-methylnitrosamino-l)-4-(3-pyridyl)-1-butanol (NNAL)	Carcinogen
Polycyclic Aromatic Hydrocarbons (PAHs)	Naphthalene and Pyrene	2-Napthol and 1-Hydroxypyrene	Possible human carcinogens
Volatile Organic Compounds (VOCs)	Acrylonitrile, acrolein, acrylamide	CYMA, CEMA, AAMA	Probable human carcinogens

ES12.01 MULTIPLE LUNG NODULES

S. Dacic

UPMC, PITTSBURGH/United States of America

Advanced imaging techniques resulted in increased detection of multiple tumors of the lung. Distinguishing synchronous primary lung cancers from intrapulmonary metastases (separate nodules) is important because treatments are very different. In addition, patients with independent primary tumors are expected to have better prognosis. Staging of such tumors as independent primary tumors or intrapulmonary metastases is often challenging, particularly in squamous cell carcinomas. Martini and Melamed modified criteria were used as the main approach for many decades with the idea that morphology of metastases should match the primary tumor, while different morphology supports classification of tumors as unrelated separate primaries. The 8th edition of the AJCC staging of the lung cancer pretty much has replaced this classification by establishing a multidisciplinary approach to these tumors as a standard of care and by promoting the tools such as comprehensive histologic assessment, imaging studies and molecular characterization either by CGH or biomarker testing. Comprehensive histologic assessment is based on the 2015 WHO classification of lung cancers and includes determination of the main histologic tumor type, quantitative subtyping particularly of lung adenocarcinomas, and assessment of cytologic and stromal characteristics. This approach can be relatively easily applied in lung adenocarcinomas, while squamous cell carcinoma remains a great challenge. A recent study conducted by the IASLC Pathology committee showed a good agreement (κ score 0.60) among thoracic pathologists in the histologic assessment of independent primary tumors from intrapulmonary metastasis. Despite a good agreement, there were cases with split opinions supporting a need for ancillary studies. Over the past decade many studies reported different molecular approaches to analysis of multiple lung tumor nodules including DNA microsatellite analysis, CGH/aCHG and most recently next generation sequencing. The data from published reports indicate a highly variable percentage of multifocal tumors identified as clonally related (up to 70%). Discrepancy between clinical and molecular classification of originally presumed cases of multiple primary lung cancers ranged in different series from 18% to 30%. Recent recommendations for routine molecular profiling of lung adenocarcinoma resulted in a widespread use of targeted mutational profiling for oncogenic mutations (i.e. EGFR, KRAS, BRAF etc) and gene rearrangements (i.e.ALK, ROS1) which results can be used in staging of multiple lung cancers. A different mutation profile in oncogenic mutations strongly indicates two separate primary tumors. However, the presence of a common driver mutation does not necessarily indicate tumors of similar origin. Therefore, limited molecular panels may not be sufficient in some cases. The detection of shared identical breakpoints by whole genome sequencing has been recently proposed as potentially more accurate and specific for lineage determination than the analysis of driver mutations alone. Also whole exome and whole genome sequencing approaches have been reported, but these assays may be technically challenging and turnaround time may not be suitable for routine clinical use.

ES12.02 INVASIVE MUCINOUS ADENOCARCINOMA

Y. Yatabe

National Cancer Center Hospital, Tokyo/Japan

Invasive mucinous adenocarcinoma (IMA) is a variant of adenocarcinoma defined by the current WHO classification of lung tumors.[1] Although IMA used to be categorized into mucinous bronchioloalveolar carcinoma in most cases with the previous classification scheme,[2] separation of this variant was based on unique clinical, radiological, pathological, and genetic characteristics as shown in the following table. Morphologically, IMAs consist of goblet and/or columnar tumor cells, which resemble normal intestinal and/or primitive gut epithelium. This subtype adenocarcinoma develops not only in the lung but also in every organ system, such as the ovary, pancreas, colorectum, and stomach, which are associated with the primitive gut tube in development. Interesting, all mucinous carcinomas have frequent KRAS mutations and quite similar immunohistochemical phenotype, including expression of CK20,

CDX2, HNF4a, and villin. The strong correlation between KRAS mutations and heavy smokers is known, but IMA is not such a case. Indeed, TP53 mutations, which is also associated more with smokers, are quite rare in IMAs. IMA commonly develops in the peripheral lung parenchyma, but there are no normal counterpart cells. Recently, inactivating mutations of TTF1/NKX2.1 have been reported in IMA.[3,4] This alteration can repress TTF1 function, resulting in gastrointestinal differentiation. TTF1-depletion using KRASG12D-transgenic mice induced mucinous tumors, which shared a morphological and phenotypical resemblance to IMA, including columnar tumor cells with goblet cell features and HNF4a expression.[5,6] Because the other mechanisms of TTF1 impairment, the molecular pathway of IMA could be summarized in figure 1. However, it remains unclear why KRAS is selectively mutated in this subtype, and what induce TTF1 mutations. References 1. Travis WD, Brambilla E, Burke A, et al. Table 1 Difference between IMA and AIS/MIA/LPA

	Invasive Mucinous ADC	AIS/MIA/LPA
Female	~60%	~70%
Smoker	~45%	~46%
Clinical symptoms	Mucinous sputa	Mostly no symptom
Radiographic appearance	Majority consolidation; Air-bronchogram	Majority ground-glass attenuation
	Frequent multifocal & multi-lobar presentation	
Cell type	Mucin-filled, columnar and/or goblet	Type II pneumocyte &/or Clara cell
Phenotype		
CK7	Mostly positive (90%)	Positive (~95%)
CK20	Positive (~54%)	Negative (<5%)
TTF1	Mostly negative (<10%)	Positive (~65%)
CDX2	Possible to be positive	Negative
Genotype		
KRAS	Frequent (~75%)	Some (~15%)
EGFR	Almost none (<5%)	Frequent (~45%)

AIS, adenocarcinoma in situ; MIA, minimally invasive adenocarcinoma; LPA, lepidic predominant adenocarcinoma

ES12.03 TUMOR HETEROGENEITY

W. Cooper

Royal Prince Alfred Hospital, Camperdown/Australia

While intertumoral heterogeneity is well recognised in many solid tumours including NSCLC, intratumoral heterogeneity has only recently gained attention. Heterogeneity of tumor morphology, protein expression, gene expression, epigenetic or genetic alterations has the potential to impact optimal biopsy strategies, diagnostic assessment, treatment decisions and clinical outcome. Sequencing of NSCLC from multiple sites of disease shows frequent evidence of intratumoral heterogeneity in terms of genetic mutations, translocations and copy number alterations, although not to the same extent as seen in other tumor types, such as clear cell renal cell carcinoma. NSCLC studies have demonstrated a common pattern of intratumoral heterogeneity with main clonal driver mutations and branched evolutionary acquired mutations. Of clinical relevance, mutations in known lung cancer driver oncogenes (such as *EGFR*, *BRAF* and *MET*) are generally present in all tumor regions in keeping with early evolutionary events. This finding is consistent with the high response rates to tyrosine kinase inhibitors that target these genetic alterations, across multiple sites of disease. Later subclonal driver mutations are found commonly in NSCLC and include alterations in genes such as *PIK3CA* and *NF1*. Metastatic sites can exhibit mutational profiles closely related to specific spatial regions of the primary tumor demonstrating that subclones can determine the course of systemic disease resulting in subclonal diversification. Clonal evolution is driven by multiple factors including selective pressure from targeted therapies and adaptive mechanisms due to interaction with immune cells and the microenvironment. Treatment resistance can occur due to acquisition and/or selection of clones and contributes to temporal heterogeneity. The hierarchy of genetic alterations can be used to trace clonal intratumoral heterogeneity although adequate sequencing depth is required to accurately assess for subclonal mutations. Reassuringly, sequencing of a single region of a tumor should be sufficient to identify known targetable driver mutations as they generally occur early in the evolutionary course of the disease. The exact clinical significance of various subclonal mutations is less well understood. Intratumoral heterogeneity can potentially lead to sampling errors when single sites of disease are sampled for mutational events that may only exist in another metastatic site. For this reason, testing for genetic markers of treatment resistance may be more appropriately performed on circulating tumour DNA as the ctDNA may derive from multiple metastatic deposits, although lower sensitivity limits the effectiveness of this approach. Liquid biopsy approaches also have the advantage of providing a contemporaneous sample, more likely to reflect impact of most recent therapy. Further investigation of spatial and temporal tumoral heterogeneity by comprehensive deep sequencing of multiple spatially discrete sites of disease at different time points may assist in understanding the complexity

of intratumoral heterogeneity and could potentially impact optimal biopsy and treatment strategies, particularly when assessing for drug resistance.

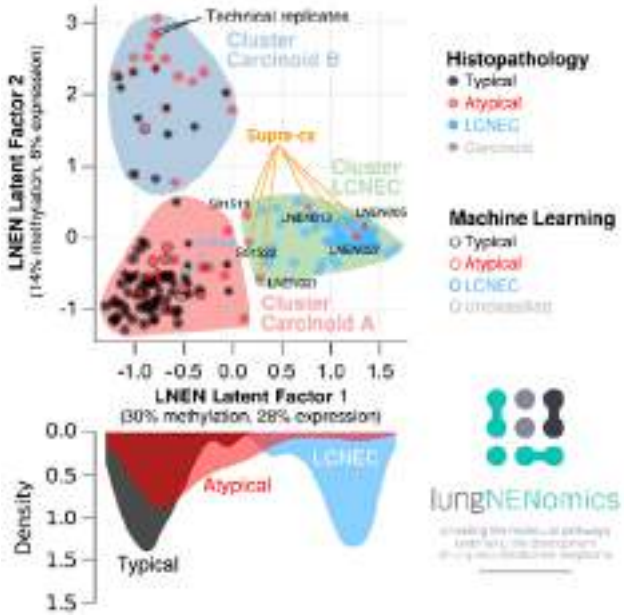
ES12.04 MACHINE LEARNING AND INTEGRATIVE MULTI-OMICS ANALYSIS IDENTIFY NOVEL MOLECULAR GROUPS OF LUNG NEUROENDOCRINE TUMORS

L. Fernandez-Cuesta

IARC, Lyon/France



This work is part of the lungNENomics project, a large multi-omic and multidisciplinary effort, built up on our previous published work (1-4). The lungNENomics project aims at the molecular characterization of rare lung neuroendocrine neoplasms through the integration of whole-genome sequencing, transcriptome sequencing and methylation data, as well as the correlation with epidemiological and clinical information, and taking advantage of unique biorepositories, advanced computational approaches, and state-of-the-art *in vitro* models. The talk would provide an overview of the global lungNENomics project, as well as presenting the identification of a novel molecular entity. The worldwide incidence of pulmonary carcinoids is increasing, but little is known about their molecular characteristics. Through machine learning and multi-omics factor analysis, we compared and contrasted the genomic profiles of 116 pulmonary carcinoids (including 35 atypical), 75 large-cell neuroendocrine carcinomas (LCNEC), and 66 small-cell lung cancers. Integrative analyses on 257 lung neuroendocrine neoplasms stratified atypical carcinoids into two prognostic groups with a 10-year overall survival of 88% and 27%, respectively. We identified therapeutically relevant molecular groups of pulmonary carcinoids, suggesting DLL3 and the immune system as candidate therapeutic targets; we confirmed the value of *OTP* expression levels for the prognosis and diagnosis of these diseases, and we unveiled the group of supra-carcinoids. This group comprises samples with carcinoid-like morphology yet the molecular and clinical features of the deadly LCNEC, further supporting the previously proposed molecular link between the low- and high-grade lung neuroendocrine neoplasms. ES12.05 IMPACT OF STAS IN LUNG CANCER STAGING

W. Travis[1], R. Aly[2], T. Eguchi[1], N. Rekhtman[1], Y. Yagi[1], P. Adusumilli[1]

[1]*Memorial Sloan Kettering Cancer Center, New York/United States of America,* [2]*Alexandria University, Alexandria/Egypt*

Spread through air spaces (STAS) is an established histologic marker of poor prognosis found in 15-60% of lung cancers. The association with poor prognosis is supported by data from over 3500 patients from multiple multidisciplinary investigative groups worldwide. This prognostic significance has been demonstrated in all major types of lung cancer including adenocarcinoma, [1] squamous cell carcinoma, [2] small cell carcinoma, [3] large cell neuroendocrine carcinoma, [3], atypical carcinoid[3] and pleomorphic carcinoma.[4, 5] As this large volume of clinical data has accumulated some important issues that have arisen. 1) Importance of processing, 2) Role in Staging? 3) Limited resection vs lobectomy and 4) Frozen section. Criteria for STAS The original definition of STAS by Kadota et al and the 2015 WHO consisted of tumor cells within the first alveolar air spaces in the lung parenchyma beyond the edge of the main tumor. In adenocarcinoma it can occur as one of three morphologic patterns including 1) micropapillary structures within air spaces; 2) solid nests or tumor islands and 3) scattered discohesive single cells.[1, 6] In a recent paper we also proposed to require the presence of more than a single STAS cluster.[3] The solid nest pattern is characteristic in other lung cancer histologies such as squamous cell carcinoma and neuroendocrine tumors. 3-dimensional studies with serial histologic sectioning and microCT whole block imaging suggest that there may be two mechanisms of spread into the adjacent lung: 1) detachment, migration through air spaces and reattachment with vessel co-option and 2) tumor islands of continuous tumor spread into adjacent air spaces. An important component of the diagnostic criteria is the distinction from artifacts: 1) mechanically induced tumor floaters that are randomly situated often at the edge of the tissue section or out of the plane of section; 2) jagged edges of tumor cell clusters suggesting fragmentation or edges of a knife cut during specimen processing; 3) isolated tumor clusters at a distance from the tumor rather than spreading in a continuous manner from the tumor edge and 4) linear strips of cells lifted off alveolar walls. Importance of

Processing To assess for STAS histologic sections need to be taken in such a way to maximize the interface between the tumor and adjacent non-neoplastic lung parenchyma. For example, sections of subpleural tumors that maximize assessment of the visceral pleura or the interface with dense fibrotic scars or post-obstructive organizing are not well suited for assessment of STAS. This applies to both frozen and permanent sections. Role of STAS in Staging? Although the prognostic significance of STAS, has led some to suggest it might be included as a factor in staging,[7,8] there is insufficient data at this time to make such a recommendation. Tumor size should continue to be measured according to the gross and/or microscopically recognized edge of lung cancers rather than according to the maximum distance of furthest STAS. Although vascular (V) and lymphatic (L) invasion are recognized in TNM staging, only visceral pleural invasion (VPI) is officially incorporated as a T-factor in the 8th Edition. STAS is regarded as a sign of invasion similar to V, L and VPI, however, more data is needed before introducing this as a T-factor for staging. Limited resection vs lobectomy Evidence is accumulating that indicates an increased risk of recurrence and worse survival associated with STAS positive tumors treated by limited resection compared to lobectomy.[5,9] Role of Frozen Sections in Assessing STAS There is limited data evaluating pathologist's ability to recognize STAS in frozen section. Eguchi et al found the sensitivity and specificity of frozen section for prediction of STAS were 71% and 92%. respectively and interrater reliability across 5 pathologists was 0.67.[9] Walts AE et al studied frozen section for evaluation of STAS and recommended that current evidence did not warrant frozen section evaluation for STAS.[10] However, frozen section sensitivity to detect STAS positivity was 50%, with a 100% positive predictive value and an 8% negative predictive value. These studies suggest if a pathologist sees STAS on a frozen section there is a 92-100% likelihood it will be present on permanent sections. Both studies were retrospective so attention was not always given to including the tumor edge and adjacent lung. More studies are needed to evaluate the potential role of frozen section in detecting STAS and guiding intraoperative decisions by surgeons. REFERENCES 1. Kadota K, et al. ES13 GLOBAL POLITICAL, LEGAL, AND FINANCIAL STRATEGIES FOR TOBACCO CONTROL
SUNDAY, SEPTEMBER 8 15:15–16:45

ES13.01 TOBACCO CESSATION AND CANCER PATIENTS

E. Fernandez, C. Martínez

Institut Català d'Oncologia (ICO) / Institut d'Investigació Biomèdica de Bellvitge (IDIBELL), Barcelona/Spain

Smoking among cancer patients reduces the effectiveness of treatment, increases the risk of recurrence, and reduces survival time. One third of cancer patients continue smoking after diagnosis or during their treatment. Smoking is also common in patients with a cancer for which there is limited evidence for carcinogenicity of tobacco smoking. Cancer patients who smoke have greater risks, not only of the well known tobacco-related health problems, such as cardiovascular and respiratory diseases and further cancers, but also unfavourable cancer treatment outcomes. There is sufficient evidence to infer a causal relationship between cigarette smoking and adverse health outcomes, including all-cause mortality, cancer-specific mortality and further primary tobacco-related cancers among cancer patients. Poorer cancer treatment outcomes linked to tobacco use by cancer patients re related to altered cancer biology, altered drug metabolism, increased treatment-related complications, and increased tobacco-related comorbidity. Although smoking cessation is associated with better outcomes, this key and cost-effective preventive strategy is rarely addressed in health care services. Barriers to incorporating tobacco cessation interventions into hospitals include lack of knowledge, expertise, time, and organizational constraints. In addition, many cancer patients show higher rates of nicotine dependence, low self-efficacy, and higher levels of depression. The existing data support the conclusion that continued smoking negatively affects cancer treatment outcomes including survival, recurrence and quality of life and that, by quitting smoking, patients with cancer have the potential to improve their cancer treatment outcomes. At the population-level, there is a need to establish a basic infrastructure to provide tobacco cessation services to cancer patients who smoke, sustainable funding should be identified and allocated to dedicated tobacco cessation services (e.g. quitlines, available treatment for tobacco cessation) as well as tobacco treatment training programmes for health-care providers. At the individual-level, motivational interventions addressed to recognize the cancer-specific risks of smoking do increase patients' self-efficacy in quitting. Morover, cessation using the "5 A's model" provides good abstinence rates, and about 80% of smokers could be reached using this approach.

ES13.02 PURSUING CRIMINAL CHARGES AGAINST BIG TOBACCO

W. De Kanter

Netherlands Cancer Institute, Amsterdam/Netherlands

ABSTRACT 1

Court of appeal rejects charges made against tobacco industry- The Court of Appeal in The Hague has declined to instruct the Netherlands Public Prosecution Service to bring criminal charges against cigarette manufacturers. The court concluded that it is up to the government, not the judiciary, to tackle the rigging of cigarettes. In other words, it's the government's move. On December 6th, 2018 the Court of Appeal in The Hague delivered its verdict in the proceedings brought by criminal lawyer Bénédicte Ficq on behalf of various individual complainants and a large number of legal entities who previously lodged complaints against cigarette manufacturers. Last February the Public Prosecution Service (OM) decided not to instigate legal proceedings, prompting the complainants to instigate an Article 12 procedure in an effort to force the OM to prosecute. In its verdict, the court writes that "the products of cigarette manufacturers are made and tested in accordance with stringent Dutch and European legislation and regulations. As long as the cigarette manufacturers respect these European and national rules, the member states must respect these rules and cannot prohibit the sale of cigarettes. Radical measures

against cigarette manufacturers can only be taken by the European regulator." In her reaction, lawyer Bénédicte Ficq draw attention to the significance of the court's comment, in its detailed motivation, that cigarette manufacturers deliberately market a deadly and harmful product with the sole objective of making money. The court writes: "The fact that smoking is harmful to your health, is a serious health risk, can cause serious illness and even death, and is moreover highly addictive, can in the opinion of the court be considered general knowledge and is not disputed by the defendants. The defendants supply cigarettes that they know are or can be addictive and harmful to the health of active and passive smokers. The court assumes that the defendants act with the aim of making a profit Here the lawyers note the similarities with verdicts reached against cocaine and heroin dealers. Ficq: "The court could have avoided making these remarks, but has instead chosen to make clear that there is a social evil that the court is powerless to address. In other words, the ball is in the government's court." Legislator must intervene In its conclusion the court expresses it very clearly once again: "Complainants have chosen to address a social problem concerning public health within a criminal framework. However, the court agrees with the Public Prosecution Service that criminal law offers no solution. Radical measures such as banning the production and sale of tobacco, which is produced in accordance with the legal directives, can only be taken by the legislator. The ultimate goal of the complainants, to ban cigarettes cannot be achieved through criminal law. It will instead have to involve an appeal to the European legislator." Conclusion:. "The court recognizes the scale of the social problem and the fact that cigarettes are extremely addictive and deadly, and should actually be banned, but it's up to the government to take action. That strengthens us in our demand that the Netherlands Food and Consumer Product Safety Authority and the government must take measures to tackle the phenomenon of 'rigged cigarettes' We feel as if we have ended up in a Kafkaesque situation in which it is patently obvious that cigarettes with holes in their filters release more toxic substances than legally allowed. But the legally prescribed smoking machines measure different levels, so cigarettes in their present form are permitted. Those responsible for passing legislation must now change this situation, especially since we've know that 'rigged cigarettes' cause more lung cancer. Time for government action!"

ABSTRACT 2

Tobacco Industry: first we fix the law, then we abide by it A little-known issue is the way that the tobacco industry has succeeded, over the years, in bending the implementation of anti-smoking laws to its own will. After all, in violation of all international laws, it exerts a strong influence on how the State determines emission values for cigarette smoke. As a result of that interference, the margins for enforcing the law are far too wide. According to Dutch law, every three years cigarette manufacturers must show the government how much tar, nicotine and carbon monoxide (TNCO) their cigarettes contain. These levels are controlled by the National Institute for Public Health and the Environment (RIVM). The RIVM then sends the results to the Dutch Food and Consumer Product Safety Authority (NVWA). If the legally set limits are exceeded, the NVWA must act. It must enforce the law. Those legal norms are unequivocally determined in the Law on Tobacco and Smoking Products. A cigarette may emit a maximum of 10 mg tar, 1 mg nicotine and 10 mg carbon monoxide. A smoker may not inhale more poison than that. The law also determines how levels are measured and the margins within which the legal norms must be met. However, the margins determined by law are very wide: 20% for tar and nicotine and 25% for carbon monoxide. This means that a cigarette with 12 mg tar (instead of 10), 1.2 mg nicotine (instead of 1) and 12.5 mg carbon monoxide (instead of 10) is still permissible. The NVWA will only intervene above those levels. The literature tells us that maximum margins of 10% are more than enough to conceal variations in measured levels. In developing and determining the measurements, the government has — following the example of the European lawmaker — used the services of two private organizations: the Netherlands Normalization Institute (NEN) and the *International Organization for Standardization* (ISO). These organizations consist entirely of representatives from the cigarette industry. The chairperson himself comes from Philip Morris. If you examine the explanation that accompanies the legal article, it turns out that the legal emission margins are statistically baseless. *"The conclusions within the report are based on practical experience of verifying these measurements in a number of different marketplaces underpinned by a theoretical consideration of the sources of statistical variation." (NEN-ISO 8243.2013, IDT)*

ES13.03 FOUNDATION FOR A SMOKE FREE FUTURE: FUNDING OPPORTUNITIES OR SMOKE SCREEN FOR THE TOBACCO INDUSTRY?

E. Stone

Department of Thoracic Medicine, St. Vincent's Hospital, Sydney/Australia

The tobacco industry has long sought interactions with the health and medical communities that will enhance its legitimacy and augment profits. In the early 20thcentury, advertising involved the medical community emphasizing doctors who recommended cigarette smoking. From the mid 20thcentury, as scientific evidence developed, the tobacco industry contested restrictions vigorously as tobacco regulation intensified. The advent of ENDS products opened a new phase in marketing which stretched the limits of conventional tobacco control. The PMI Foundation, launched in 2017, targets the health and medical communities, promising research funding, the "Smoke-Free" aim and its interactions with high profile researchers. In the first few decades of the 20thcentury, tobacco companies involved physicians in advertising campaigns to promote health benefits and minimisation strategies for particular brands. Analysis of 1930s and 40s tobacco advertising in medical journals identified a number of strategies employed to involve doctors in promoting cigarettes including flattery, tobacco 'science', the advisory role to patients, less "irritating" brands and promotion of specific brands[1]. Analysis of tobacco advertising from the 1920s to the 1950s identified a focus on throat irritation, strategies to protect from harmful symptoms and portrayal of otorhinolaryngologists as promoters of cigarette-related benefits[2]. The "More Doctors smoke Camels" campaign[3]launched in the late 1940s by RJ Reynolds made a number of zealous health benefit claims, although landmark publications linking tobacco cigarettes to lung cancer led to scepticism from the health community and eventual banning of cigarette advertising and promotion in medical journals and at medical conventions[3]. From the mid-1960s, the paradigm for tobacco regulation shifted as evidence accumulated for the harmful effects. Additional key papers include a 1912 monograph, one of the first publications to link lung cancer with tobacco, early writings on lung cancer surgery and the 1964 US Surgeon General Report on Smoking and Health. Legislative efforts to control tobacco accelerated with, in the United States, the pivotal 1998 Master Settlement Agreement by which tobacco companies were obliged to pay compensation to 46 states to offset costs of smoking-induced illnesses[4]. In the early 21stcentury the WHO FCTC came in to force in 2005 with the launch of the MPOWER measures in 2008, setting up the tobacco framework that has characterised the last decade and a half and to which 181 countries are signatories. The emergence of e-cigarettes and other ENDS products has shifted tobacco control outside the current purview of the FCTC and opened up new areas of controversy as these products evade conventional regulation. E-cigarettes first appeared in the 20thcentury including designs from the 1960s from BAT and from the 1990s from PMI with the contemporary model attributed to an individual inventor[5]. The early designs were abandoned at least in part due to concerns about commercial viability[6,7]and it was not until the last decade or so that e-cigarettes have reached prominence. The emergence of highly appealing and commercially successful ENDS products such as the Juul device has stimulated concern at the level of the FDA and review of e-cigarette regulation. Companies such as Juul Labs (now owned by a tobacco corporation) and PMI advocate harm-minimization through their ENDS products while parent companies continue to sell conventional tobacco cigarettes in less tightly regulated markets. The Phillip Morris Foundation for a Smoke-Free World[8]was launched in 2017 and immediately prompted controversy. The stated aims of the Foundation include the funding of research, a focus on smoking cessation and harm reduction and the search for solutions to "unique challenges"[8]. Its launch prompted immediate debate and discussion, including a Lancet Viewpoint by the Foundation's director, advocating the benefits of reduced-harm products and expressing concern that full implementation of the FCTC would take many years. An editorial in the same Lancet issue raised strong concerns about involving the tobacco industry in tobacco control while acknowledging that (at the time of writing) the Foundation had yet to begin work[9]. An accompanying commentary piece questions the credibility of the Foundation and points out that the funding of research is used by the tobacco industry as a deliberate strategy that in fact acts as a "public relations" exercise while PMI, in this instance, continues to sell cigarettes as its core

product[10]. More recently, a review of the published tax returns from the Foundation suggest that it is having trouble both raising and spending funds, perhaps indicating some trouble engaging with the research community and multiple publications raise questions about its ethical robustness, the risks of long-term nicotine dependence and its commercial integrity. While the stated aims of the Foundation may appeal, concerns remain about engaging with the tobacco industry, about persistent global cigarette sales, about the use of the Foundation to divert attention from PMI's efforts to build its market for ENDs products and about the prioritisation of harm-minimisation (with accompanying profits) over genuine efforts to make the world free from tobacco. ES13.04 COMPARING ENDS TO NRT FOR SMOKING CESSATION

H. Mcrobbie

University of New South Wales, Sydney/Australia

For people who smoke, quitting completely is associated with numerous benefits for current and future health. There are a range of effective stop smoking medicines that can increase long-term abstinence rates, compared with unassisted quitting. However, these rates remain low (eg. < 25%), with most people relapsing within 3-6 months. Over the past decade electronic nicotine delivery systems (ENDS), more commonly known as e-cigarettes or vaporisers, have become increasing popular among smokers, and in some countries are now the most commonly used tool to aid smoking cessation. Until recently the evidence for the effectiveness of ENDS in helping people stop smoking has been limited, with only two published randomised controlled trials (RCTs). There are now four RCTs; three show the superiority of nicotine containing ENDS, compared to those without nicotine, in helping smokers quit for at least six months and one found vaping to be associated with higher 12-month quit rates than nicotine replacement therapy (NRT; 18% vs. 10%; RR=1.83; 95% CI: 1.30-2.58). The difference in quit rates may have been due to ENDS providing greater withdrawal relief, providing better subjective effects, and smokers being able to self-titrate their nicotine intake. Among 12-month ex-smokers, rates of ongoing ENDS use were significantly higher than ongoing NRT use. This could raise concern if long-term ENDS use is associated with health risk. Alternatively, this could be beneficial if it prevents relapse and so risk-benefit analysis is required. Health professionals are often asked by their patients if ENDS can help aid quitting smoking and if they are safe. There are data to show that ENDS are an effective smoking cessation aid, and some evidence to support their superiority over NRT. Current data suggest that health risks associated with ENDS use are substantially less, overall, than risks associated with smoking tobacco. However, the health risks associated with long-term ENDS use remain unknown, and long-term cohort studies, especially regarding lung health in vapers, are needed. To mitigate concern over unknown health risks associated with long-term vaping ex-smokers can be advices to stop vaping as soon as they feel they are safe from relapse to smoking. This presentation will summarise the evidence of effectiveness of ENDS for smoking cessation, and provide an overview of possible health risks, to enable health professionals to better advise their patients who ask about using ENDS.

ES13.05 STIGMA AND IMPACT OF TOBACCO CONTROL POLICY

A. Borondy Kitts

Lahey Hospital & Medical Center, USA/United States of America

Figure 1 A - Breast Cancer People

Figure 1 B – Lung Cancer People

A simple quick google search on breast cancer people and lung cancer people is enough to show the impact of stigmatizing smoking on people with lung cancer (Figure 1). Breast cancer people are perceived as pink, young, healthy, cheerful, supportive and happy although that is not an accurate depiction of the breast cancer journey. In contrast, lung cancer people are seen as diseased and dying, sad, concerned, bleak, and alone with little support. The stigma associated with smoking stops people from going to the doctor because they are afraid the doctor will think they are stupid for continuing to smoke, it stops people from getting screened for lung cancer because they blame themselves for smoking and feel they deserve the disease or because they are afraid their loved ones will blame them for getting sick. The stigma reduces the funding available for lung cancer research. In the US, federal funding for lung cancer research per lung cancer death is only 15% of the funding amount for breast cancer per breast cancer death. People with lung cancer, regardless of their smoking status, encounter stigma on a regular basis.(1) Often after disclosing a lung cancer diagnosis for themselves or for a loved one the first comment is not, I'm so sorry you have this awful disease. The first comment is invariably "I didn't know you smoked" or "Was he a smoker" or "He smoked a lot. It's not surprising he got lung cancer" or "It's to be expected since you are a smoker" In a Global Lung Cancer Coalition survey, one in five people (21%) agreed with the statement that they have less sympathy for people with lung cancer than for people with other types of

cancer. Studies have shown that the stigma encountered by people with lung cancer reduces quality of life, increases depression and negatively impacts outcomes.(2) Probably most disturbing is that stigmatization of smokers has the greatest impact on the socioeconomically deprived, the disadvantaged populations.(3) These populations have the highest prevalence of smokers and encounter the stigma of their race or disadvantage (poverty, disability, sexual preference, behavioral health etc.) in addition to the stigma associated with smoking.(4) One could argue that tobacco control (tobacco denormalization efforts) may be tolerable if they resulted in short term stigma but increase tobacco cessation for these disadvantaged populations resulting in an overall public health benefit. Unfortunately, studies show that tobacco control efforts have the least impact on socioeconomically deprived populations thus actually increasing the health inequity (and stigma) for this already marginalized population. Smoking related stigma may actually help reinforce smoking in this population by being perceived as resistance to the norms of society. In other words, tobacco control efforts may not work and may actually have the opposite effect. (5,6,7) This stigmatization leads people who smoke to be less likely to seek medical care when they have symptoms, more likely to lie about their smoking, more likely to be refused access to care including curative surgery for early stage lung cancer unless they quit smoking, less likely to be offered smoking cessation help if they are uncomfortable disclosing their smoking status due to stigma and bias from their healthcare professional.(5,6) Tobacco control and stigmatization of smokers has resulted in stigmatizing all people with lung cancer regardless of smoking history or socioeconomic status. It's time to stop stigmatizing people who smoke and people with lung cancer but rather to promote and implement policies that have been shown to work in deterring tobacco use and helping people quit.(8) These include increased age limits for tobacco purchase and use, increased taxes on tobacco sales, free access to tobacco cessation counseling, nicotine replacement products and prescription smoking cessation medications. 1. ES14 WHAT FIRST LINE IN ONCOGENE ADDICTED NSCLC
SUNDAY, SEPTEMBER 8 15:15–16:45

ES14.01 FIRST LINE IN EGFR MUTATED PATIENTS

T. Reungwetwattana

Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok/ Thailand

Precision medicine is currently applied for almost all cancer types, especially, in NSCLC which is the prototype of successful targeted therapy. Epidermal growth factor receptor tyrosine kinase inhibitor (EGFR-TKI) is the first effective targeted drug found in NSCLC for treatment in *EGFR*-mutation positive patients. *EGFR* (also termed human epidermal growth factor receptor 1 [HER1] or ErbB1) is a member of the ErbB family of cell surface receptor tyrosine kinase1. It is a 170 kDa RTK with an extracellular ligand binding domain, a transmembrane region and an intracellular tyrosine kinase. The RTKs form homodimers and heterodimers after binding to specific ligands, leading to autophosphorylation of tyrosine residues on the intracellular TK domain. This interaction recruits a diverse set of signal transduction cascades including the phosphoinositide 3 kinase (PI3K)/protein kinase B (AKT)/ mammalian target of rapamycin (mTOR), signal transduction and transcription (STAT) transcription and RAS/RAF/ mitogen activated protein kinase (MAPK) proliferation pathway1. In 2004, somatic mutations in the TK domain of EGFR, found most frequently in adenocarcinomas from patients in Asia who were never or former smokers, were strongly correlated with sensitivity to EGFR-TKIs[1]. The prevalence of *EGFR* mutation in NSCLC patients is higher in Asian population compared to the other population (50-55% vs. < 20%). These mutations are mostly distributed in four exons (exon18 to exon21)[2]. In frame deletions of exon19 (44%; *E746 A750deletion*) and *L858R* substitutions in exon21 (41%) are the most prevalent mutations associated with sensitivity to EGFR-TKIs. The point mutations in exon18 (G719C, G719S and G719A) and exon20 (V765A and T783A) are less frequent; 5% and 1%, respectively1. Presence of the "classical" mutations in exon19 and 21 are the best predictive biomarker for the efficacy of EGFR-TKIs with superior response rate (RR) of 60-70%, progression free survival (PFS) of 9-18.9 months, and overall survival (OS) more than 2 years compared with conventional chemotherapy in patients with tumors harboring EGFR sensitive mutations making EGFR-TKI is the first-line treatment[3]. Currently, there are 3 generations of EGFR-TKIs approved in the market. The strategy of first-line treatment in *EGFR*-positive patients can be categorized into 2 strategies. The first one is treating by the single agent EGFR-TKIs. The first and second-generation EGFR-TKIs have the efficacy in term of PFS of 9-14.7 months in first-line treatment, but if starting with third generation EGFR-TKI, the PFS is longer (18.9 months)[3-4]. The ORR is similar either starting with 1st, 2nd, or 3rd generation EGFR-TKIs (60-70%). The acquired resistance could be occurred after 9-14 months of treatment by 1stand 2nd-generation EGFR-TKIs and the majority of resistance mechanism is *T790M* (50-60%) which is now we have the 3rd-generation EGFR-TKI for overcoming this resistance. Moreover, the other bypass tracts (*MET* amplification, *BRAF, HER2* mutation etc.)[5] could be the mechanism of resistance as well and we have the potential targeted drugs in the clinical studies which some of them will be approved in the near future. The mechanism of resistance if we start the 1st-line treatment with 3rd-generation EGFR-TKI is different from the previous one. Recently, exploratory data from FLAURA study was reported. They found no T790M detected in the patients whom had progressive disease after 1st-line treatment with 3rd-generation EGFR-TKI. The most common detected acquired resistance genes in the blood were C797S and MET amplification. The other mechanism included HER2 amplification, PIK3CA and RAS mutations. Furthermore, the 3rd-generation EGFR-TKI has the significant strong evidence of better in survival outcome and CNS response in patient whom had the CNS metastases disease[6]. The second strategy is starting 1st-line treatment with the combination therapy. The recent studies reported in ASCO2018 and ASCO2019 showed the longer PFS (16-19 months) in combination of 1st-generation EGFR-TKI and anti-angiogenesis agents and also longer PFS (16-20 months) in combination of 1st-generation EGFR-TKI with doublet platinum-based chemotherapy compared to single agent 1st-generation EGFR-TKI.[7-9] Definitely, there were more adverse events for the combination treatment. The rate of occurring *T790M* as the acquired resistance and the CNS efficacy are the issues to concern for the combination treatment (Figure 1). The most proper sequence of the treatment in EGFR-positive NSCLC is needed to explore more in the clinical studies. It has pros and cons in each approach and it depends on several factors such as; the patients' performance status,

the location of tumor (CNS metastases?), types of *EGFR* mutations, acquired resistance, toxicities, treatment after progression, cost of treatment and the reimbursement issue in each country. In summary, *EGFR* mutation is the crucial oncogenic-driven mutation in NSCLC with effective EGFR-TKI treatment making the patient has good quality of life (QOL) even though they have the advanced-stage disease. The journey of treatment in this group of patients is still underway of development and it is the good prototype for the other targeted drugs development in the clinical studies. I believe that there will be the other effective novel targeted treatments for NSCLC approved in the near future which would improve the long-term survival and QOL for patients. References: 1. ES14.02 FIRST LINE IN ALK TRANSLOCATED PATIENTS

A. Shaw

Massachusetts General Hospital, Boston/United States of America

Chromosomal rearrangement of ALK defines a distinct subset of non-small cell lung cancer (NSCLC) with marked sensitivity to small molecule ALK tyrosine kinase inhibitors (TKIs). Currently, five ALK TKIs are approved as standard therapies for advanced ALK-positive NSCLC, including the first generation ALK/ROS1/MET inhibitor crizotinib, the second generation ALK inhibitors ceritinib, alectinib and brigatinib, and most recently the third generation ALK/ROS1 inhibitor lorlatinib. In three randomized phase 3 studies (J-ALEX, global ALEX, and ALESIA), alectinib has demonstrated superior efficacy compared to crizotinib, and has replaced crizotinib as the standard first-line therapy for advanced ALK-positive NSCLC. Recently, in a planned interim analysis of the ALTA-1L phase 3 study, brigatinib has also shown superior efficacy to crizotinib as first ALK TKI in advanced ALK-positive NSCLC. In this talk, we will review all the available first-line data with ALK TKIs, with a focus on next-generation ALK inhibitors. In addition to discussing second-generation ALK TKIs, we will also highlight available data with lorlatinib in the first-line setting. The phase 3 study of lorlatinib vs crizotinib as first-line therapy (CROWN) has completed accrual, with results expected within the next year. Finally, we will discuss the potential role of investigational combinations as first-line therapy in advanced ALK-positive NSCLC. These investigational strategies hold the promise of further extending front-line progression-free survival as well as overall survival for this molecular subgroup of patients.

ES14.04 FIRST LINE FOR RARE MUTATIONS (RET, BRAF, HER2)

D. Planchard

Institut Gustave Roussy, Villejuif/France

Systemic therapy for non-small cell lung cancer (NSCLC) has undergone a dramatic paradigm shift over the past decade. In the recent years a number of other oncogenic drivers beyond EGFR, ALK, and ROS1 inhibition have emerged as novel molecular targets with potential therapeutic implications, including mutations in the genes BRAF, HER2, as well as RET rearrangements. A great number of clinical trials are currently underway, evaluating agents specifically designed to target these alterations. Here, we discuss both established and emerging targeted therapy approaches, as well as ongoing challenges for the treatment of NSCLC patients harboring these oncogenic alterations.

ES14.05 PATIENTS HARBOURING A DRIVEN-MUTATION: PRO AND PATIENT'S PERSPECTIVE

K. Reckamp

City of Hope Comprehensive Cancer Center, Duarte/United States of America

Genomic alterations in non-small cell lung cancer (NSCLC) define distinct subtypes with specific mechanisms leading to constitutive activity of a gene pathway, and tumor growth and metastasis. Targeted therapy for NSCLC with oncogenic driver mutations or alterations, usually with small molecule tyrosine kinase inhibitors (TKIs), has changed the paradigm for treatment of patients. New genetic alterations continue to be described with potential therapeutic interventions, and over 60% of patients with the adenocarcinoma subtype of NSCLC have a defined molecular alteration[1]. The perspective of the clinician and patient merges on the ideal that treatment for NSCLC should provide a long duration of cancer control (ideally tumor shrinkage) with limited side effects, and improvement in quality of life. Some aspects of treatment with targeted therapy may be more important to the treating physician, while patients may have a differing viewpoint during care. This will be explored. From a clinician's lens, the treatment for patients with NSCLC harbouring an alteration that can be treated with a targeted therapy involves an algorithm that includes the ideal sequencing of therapy. This requires determining the best front line therapy based on progression free survival (PFS) and overall survival while including the toxicity profile into the algorithm, and also assessing possible mechanism of resistance and options for subsequent therapy. A front line option should not be withheld based on second line options, but sequencing of therapy to increase survival and quality of life becomes an important part of the treatment decision (Table 1). This may be best exemplified in the case of *EGFR* mutant NSCLC, in which osimertinib demonstrated clear PFS benefit over erlotinib or gefitinib.[2] In this case, mechanisms of resistance are still being elucidated and subsequent therapy becomes chemotherapy combinations. Recent studies have shown PFS benefit with first generation EGFR TKIs in combination with ramucirumab or chemotherapy, but were not directly compared to osimertinib. Furthermore, the toxicity with the combination therapy was also increased. Therefore, the choice of osimertinib as front line therapy is optimal for most patients. Another important aspect in the physician choice of front line therapy is brain penetration, which most TKI therapy is able to achieve, but some are better than others. Importantly, patients will not be treated with novel targeted therapies if they are not tested. Testing can include single gene testing by PCR and FISH, NGS testing and hotspot analysis either on blood or tissue. The utility of liquid biopsies to identify alterations in the metastatic front line setting has been shown, [3] and detection has led to actionable therapy.[4] Patients expect their physicians to be advocates for their therapy and their lives, and want a reason to hope. Most would like to avoid chemotherapy if possible in the course of treatment. They want the most current, and extensive testing done to determine the right therapy, but also encounter the economic

impact of diagnosis and treatment of oncogene-driven NSCLC. Untangling the clinical trial data to provide the therapy most likely to prolong quality of life and survival is essential. Inadequate testing up front can lead to inappropriate treatments, and increased anxiety associated with additional tests and time required to find the right treatment. A NSCLC patient who is also a physician provides valuable insight into the patient perspective, "Everyone with lung cancer needs to have their cancer tissue tested for genetic mutations... That biopsy may lead to identifying mutations that can be successfully targeted. All therapies, whether conventional or targeted, provide bridges to keep you alive for the next therapy, to get to the next bridge. My ultimate goal is not necessarily to cure the disease, but to successfully manage the disease. Very much like the way HIV/AIDS and diabetic patients manage their disease for many, many years....to convert a death sentence to a chronic illness."[5] References

ES15.01 MANAGEMENT OF COGNITIVE CHANGES IN ONCOLOGY PATIENTS

N. Duma

University of Wisconsin, Madison/United States of America

Over the past two decades, we have seen significant advances in the treatment of thoracic malignancies, from targeted therapy to the introduction to immune checkpoint inhibitors. Secondary to these advances, we have the fortune of observing an increasing number of cancer survivors, something that may have been unthinkable in the past. Cancer survivorship starts the day of cancer diagnosis and entitles many aspects of our patients' lives with cognitive changes being one of them. Cognitive deficits can be secondary to the treatment effects of cytotoxic therapy/immunotherapy and also secondary to the changes our patients experience in their daily lives, living with a chronic disease and for many of our survivors changing to a new way of life with frequent doctors' visits, medication side effects and the fear of early mortality. Often called "chemobrain" or "chemofog" are the cognitive changes that persist long after treatment has ended. The mechanisms by which cancer and cancer treatment impact cognitive function have not been well described. Some investigators have proposed that cancer treatment can either shift the trajectory of normal cognitive aging or accelerate the aging process [1]. Many factors likely contribute to the cognitive decline in our patients with cancer, including inflammation, diffuse decrease in the gray and white matter, direct toxic effects from chemotherapy, and psychosocial challenges related to survivorship [2,3]. Our patients may bring issues related to cognitive decline in several ways, like reporting short term memory loss, difficulty multi-tasking, or living with a "fog" over their heads. Cognitive evaluation of our patients with thoracic malignancies is not standard practice; due to this, it is difficult to quantify the cognitive decline after completion of therapy. Since the etiology of potential cognitive inefficiencies post-cancer treatment is not well established, it is difficult to identify possible modifiers. Interventions are focused on behavioral strategies and psychopharmacological approaches. Most of the data come from studies in breast cancer or hematologic malignancies. Behavioral strategies vary, but all of them have the same goal, compensate for the cognitive deficits. Examples include relaxation techniques with a focus on mindfulness; some studies have reported improvement on patients' quality of life with these techniques [4]. Other alternatives include brain-training programs in combination with occupational therapy, more cancer centers across the United States are offering these programs to our patients surviving with thoracic malignancies. These are usually composed of a standard cognitive rehabilitation program with mental exercises using online tools or devices, the challenges with this type of interventions include insurance coverage, the repetitive visits to the rehabilitation center and the lack of data supporting these interventions in our patients with thoracic malignancies. Exercise has been linked with cognitive improvement in several studies [5]. Physical exercise interventions have been reported to improve quality of life and other adverse events secondary to chemotherapy [6]. Support groups are also an essential resource of our patients with cancer and cognitive changes due to therapy; they provide the sense of community and the opportunity to learn from other survivors about coping strategies and behaviors [7]. Other behavioral interventions also include electroencephalography biofeedback and cognitive behavioral therapy [3]. Pharmacologic interventions can be included in the treatment approach for our patients with cognitive deficits due to cancer therapy. However, the data supporting this is limited. Central nervous stimulants like Modafinil and methylphenidate have been evaluated in this patient population with some data suggesting improvement in cognitive function, including speed of memory, mean continuity of attention and quality of episodic memory, indicating a potential benefit of modafinil for the alleviation of attention and memory problems for survivors [8]. Donepezil is a reversible acetylcholinesterase inhibitor that was studied in a phase II study in patients with primary central nervous system malignancies; the study reported patients experienced improvement in their attention/concentration verbal and figural memory after taking the medication for 24 weeks compared to their baseline [9]. Paroxetine hydrochloride has also been studied in this setting in a study of 781 patients with cognitive deficits secondary to chemotherapy; authors reported statistically significant differences in alleviating some of the cognitive challenges experienced by the patients in the study. Further studies, including double-blinded randomized trials, are necessary to examine the benefits of these and other psychotropic agents, especially in combination with behavioral interventions. It is crucial to notice and act on the adverse cognitive effects that cancer-directed therapy can have on our patients with thoracic malignancies. Awareness and education remain the cobblestone to the problem; patients should be informed of the possible cognitive deficits secondary to systemic and radiation therapy and be educated about compensating mechanisms and to bring up the challenges they are experiencing during their doctors' visits. Our survivors need us; cancer treatment does not end with the last dose of chemotherapy. 1. Ahles TA. Brain vulnerability to chemotherapy toxicities. *Psycho-Oncology.* 2012;21(11):1141-1148. 2. ES15.02 TOXICITIES OF RADIATION AND IMMUNOTHERAPY: WHAT WE KNOW

B. Lok

Princess Margaret Cancer Centre, Toronto/Canada

Radiotherapy is one of the longstanding pillars of cancer treatment. Immunotherapy is being established a new cancer treatment pillar and represents a momentous advance in the armamentarium of the cancer care health professional. As such, how these two modalities interact with each other is important to understand to allow the healthcare team to identify and manage the accompanying side effects. The objectives of this session are to cover a brief overview of basic radiotherapy, basic tumor immunology, followed by a more extensive review on the current status of radiotherapy and immunotherapy in clinical practice with a significant focus on reviewing the toxicities of radiotherapy, immunotherapy and their combination. The goal is to equip all members of the healthcare team to delivery optimal care for patients that receive these treatment modalities.

ES15.03 MANAGING SLEEP DIFFICULTIES AND CANCER

M. Ftanou

Peter MacCallum Cancer Centre, Melbourne/Australia

This paper discusses evidence-based interventions for managing sleep difficulties in people with cancer. Insomnia is a common sleep problem in people with cancer. Insomnia refers to the difficulty of falling asleep, staying asleep and early morning awakenings. It causes distress or impairment in important areas of functioning, such as relationships and employment. It is estimated that between 30-60% of cancer survivors experience significant sleep disturbances that can persist for up to five years post treatment. Aside from greatly impacting on quality of life, poor sleep is associated with anxiety, depression, concentration and memory difficulties, higher rates of pain, increased use of sedatives and poorer work performance [1-3]. People with lung cancer are at an increased risk of experiencing sleep difficulties because of their generally older age, compromised respiratory function, increased disease burden and the impact of treatments [4]. Sleep difficulties also have economic and social impacts on the broader community, due to increased health system costs, productivity losses and wellbeing costs [5]. Cognitive Behaviour Therapy (CBT) is considered to be the first-line treatment for insomnia [6]. CBT targets dysfunctional attitudes, beliefs and habits that interfere with sleep. CBT for insomnia commences with a comprehensive assessment about the nature and duration of sleep complaints, the impact on daytime functioning, compensatory behaviours, the person's beliefs about sleep and any other biopsychosocial factors that might be impacting on sleep. Common screening tools used to assess the impact of sleep difficulties include the Insomnia Severity Index (ISI), the Epworth Sleepiness Scale (ESS) and the Pittsburgh Insomnia Rating Scale (PIRS). These tools are self-reporting and easy to administer. CBT for insomnia is a multi-component intervention and includes psychoeducation, sleep hygiene, stimulus control, sleep restriction, relaxation, cognitive strategies and relapse prevention strategies. It is usually delivered between four to eight session modules. CBT is effective in improving sleep disturbance, fatigue, pain and quality of life. The effects of CBT are durable, with benefits lasting up to three years post-treatment [7, 8]. CBT is suitable for most adults with insomnia, however, it works best with people who are motivated and have the cognitive capacity to learn and adopt CBT strategies. CBT can be effectively provided in group settings, individually, via telephone, video or online methods. Over three quarters of patients achieve remission or significant reduction of sleep disturbance after CBT treatment [9]. CBT has been found to be more effective than mindfulness, massage, exercise and acupuncture intervention. CBT has been found to be as effective as pharmacological intervention in the short-term and more beneficial than medication in the longer term. CBT is also more cost-effective than pharmacological or non-treatment of sleep difficulties [10]. Despite the benefits of CBT, access for people with cancer is limited due to lack specialist availability, cost and awareness of the benefit of CBT. To improve access to evidence-based interventions for people with cancer, stepped-care approaches (where face-to-face CBT is reserved for the most complex cases while less burdensome and less costly self-managed interventions are available for less complex cases) could help translate evidence into clinical practice. Conclusion Sleep difficulties are highly prevalent in people with cancer, however, access to evidenced-based interventions are limited. Embedding evidence based-screening and CBT into routine care is essential to improving quality of life and care for people with cancer. Savard, J., Simard, S., Blanchet, J., Ivers, H. & Morin, C.M. ES15.04 NURSING ROLE IN MANAGING TOXICITY AND EXPECTATIONS OF TREATMENT

J. Mcphelim

NHS Lanarkshire, Glasgow/United Kingdom

This presentation will discuss the clinical patient care and management of patients receiving immunotherapies. A team approach to patient management including patient education, pre asessment, toxicity management and follow up will be presented. This team consists of Oncologists, specialist nurses and cancer care pharmacists, who work together in a dedicated clinic. The benefits to patients will be presented as well as demonstrating efficient use of clinical time.

ES15.05 THE ROLE OF MICROBIOME RESTORATION IN CHEMOTHERAPY AND IMMUNOTHERAPY

A. Chan

National Cancer Centre Singapore, Singapore/Singapore

Microbiomes are composed of bacteria, viruses, fungi, protozoa and archaea that reside on the surface of our body's epithelial barrier. There is increasing evidence to suggest microbiomes' role in carcinogenesis as well as cancer treatment efficacy and toxicity. In this presentation, we will focus on the impact of gut microbiome on efficacy of chemotherapy and immunotherapy. We will also discuss strategies to restore gut microbiome, with the potential on improving the delivery of chemotherapy and immunotherapy.

ES16.01 PROTON THERAPY

C. Faivre-Finn

The Christie-University of Manchester, Manchester/United Kingdom

Proton therapy is an attractive option for the treatment of lung cancer patients due to the physical properties of proton beams. Proton therapy allows a focused delivery of radiation at the Bragg peak, with very steep decline of the radiation dose beyond the target volume. These properties offer the possibility to 1) reduce toxicity by reducing the integral dose and the dose to adjacent normal tissues and 2) escalate the dose to the target in some patients. In this talk, I will summarise briefly the physics/radiobiology of protons and the need for adaptation. I will also discuss the rationale for the use of protons in patients with lung cancer, including reduction in integral dose, cardiac toxicity and reduction in haematological toxicity. The clinical trial evidence supporting the use of protons will be presented in early stage and locally advanced non-small cell lung cancer as well as in small-cell lung cancer. Finally I will discuss future research directions, including preclinical and drug-proton combination research, ongoing clinical trials, the model based-approach and the need for biomarkers. ES16.02 MRI-BASED RADIOTHERAPY

F. Mcdonald

Insitute of Cancer Research, London/United Kingdom

One key potential advance for radical radiotherapy indications in lung cancer is the integration of magnetic resonance imaging (MRI) in the treatment pathway, giving anatomical and functional detail without additional radiation exposure to the patient. Incorporating anatomical MRI into the treatment planning may improve target volume and organs at risk delineation reproducibility. Functional MRI may facilitate heterogeneous dosing of target volumes and assessment of normal tissue toxicity to assist adaptive strategies. Four-dimensional MRI has the potential to complement 4D CT and 4D F-18-FDG PET with superior spatial resolution. MR-guided radiotherapy delivery machines are increasing in number internationally, providing novel hybrid technology that continues to evolve with various technical challenges to overcome. It is anticipated that the clinical benefits of MR-guided radiotherapy will lie the ability to adapt treatment in real-time. Research is ongoing to develop trials of MR-guided adaptive treatment schedules in lung cancer patients.

ES16.03 OPTIMAL INTEGRATION OF RADIOTHERAPY, TKIS AND I/O

U. Ricardi

University of Turin, Turin/Italy

Umberto Ricardi, Serena Badellino, Cristina Mantovani, Donatella Caivano, Stefania Martini, Marzia Cerrato, Giuseppe Carlo Iorio Department of Oncology, University of Turin, Italy Approximately one third of patients affected by non-small cell lung cancer (NSCLC) present with 'locally advanced' disease at diagnosis. Most patients are considered inoperable due to disease extension, and chemo-radiotherapy (CT-RT) still represents the standard therapeutic option, with unsatisfactory results in terms of overall survival (OS) despite advances in staging and technological evolution in radiation therapy planning and delivery. Besides radiation dose escalation, a logical step for improving survival in inoperable stage III patients was to evaluate the combination of concurrent/sequential RT-CT with targeted agents (tyrosine kinase inhibitors, TKI; mono-clonal antibody against EGFR; ALK/ROS1 inhibitors) and/or anti- angiogenic therapies, following the positive results obtained in stage IV disease (1, 2). Since the early 2000s, when first-generation TKIs were first approved for clinical use, several studies have been conducted in an attempt to demonstrate the efficacy of targeted therapies combined with radiotherapy (3, 4, Table 1). These studies were testing mainly the feasibility and the tolerability of this combination, with not statistical significant benefit in terms of outcomes (4, Table 1). Mature results of an international trial testing the contribution of TKIs with chemoradiotherapy in patients affected with stage III NSCLC harboring sensitive mutations are still waited. Immunotherapy, and in particular immune-checkpoint inhibitors targeting the PD-1/PD-L1 axis, gained wide popularity for NSCLC in light of the positive findings of several trials in metastatic disease (1, 5). Radiation therapy combined with immunotherapy represent a new therapeutic opportunity, given the role of RT in reversing immunosuppressive barriers within the tumor microenvironment (6). The growing enthusiasm for immune-oncology and its possible applications in radiation oncology led to a remarkable expansion of pre-clinical and clinical studies testing various combinations of immunotherapeutic agents and radiation. Stage III unresectable NSCLC is an interesting setting for the combined use of chemo-radiation and immunotherapy, also considering the multiple experimental evidences in favor of a synergistic effect between radiation and immune checkpoint inhibitors, with the potential of enhancing immuno-modulating

effects and overcoming resistance. The PACIFIC trial (PD-L1 inhibitor Durvalumab vs placebo, unresectable stage III NSCLC who did not progress following concurrent platinum-based chemo-radiotherapy) showed a major improvement in 2-year PFS and OS, which holds promise for an improved cure rate (7). Even the use of Pembrolizumab (anti-PD-1 agent) is under investigation in a series of trials. A number of studies (e.g. INSPIRE study) investigated the role of Tecemotide (anti-tumor vaccine inducing a specific immune response against MUC-1, glycoprotein overexpressed in NSCLC) (8) in Stage III NSCLC. More evidence is awaited regarding the optimal timing when combining immunotherapy and CT-RT, considering the possibility to improve this synergism even further. Several ongoing trials are testing multiple schedules (5). A predominance of the consolidation/adjuvant/maintenance setting is evident, however many studies also integrated immunotherapy at the beginning of chemo-radiation. The latter schedule should be one of the most efficient ways to fully harness the synergistic effects of chemo-radiation and immunotherapy in terms of boosting the immune-stimulating effects, particularly when using anti-PD-L1 agents, given that enhanced expression of PD-L1 during RT may be one of the main causes of radioresistance. Some attention should also be paid to those trials introducing anti-PD-1 agents before chemo-radiation, as neo-adjuvant: this innovative approach could be promising, by integrating radio-chemotherapy in a tumor micro-environment already modified by immunomodulators, and with a subsequent consolidation phase. When using anti-PD-L1 agents in this setting, PD-L1 expression levels would probably be necessary to stratify patients as highlighted in the PACIFIC trial post-hoc analysis (9). ES16.04 MOLECULAR BIOLOGY OF RADIATION TOXICITY

F. Hegi-Johnson

Peter MacCallum Cancer Centre, Melbourne/Australia

Molecular Biology of Radiation Toxicity Radiotherapy causes damage to normal and malignant cells, resulting in the cell death of tumour cells and radiation toxicity. Historically, the damage caused by radiotherapy has been described by the linear quadratic(LQ) model; a model of cellular survival derived by observing the effects of fractionated radiotherapy on cell cultures. However, it is increasingly understood that radiation toxicity is a complex event mediated by both the DNA damage modelled in the LQ model, and contributory factors such as immune and inflammatory upregulation and vascular dysfunction (see Figure 1). In this talk we will review the role of DNA damage immune and inflammatory mediated reactions on the development of radiation toxicity. DNA damage and cell death Radiotherapy effects damage on normal cells by both direct and indirect means. Direct damage to DNA by either secondary electrons or reactive oxygen species (ROS) causes the initiation of DNA damage responses (DDR). This can result in varying effects depending on individual variation in the efficiency of the DDR pathways, the severity of the insult, and the type of normal cell (2). For example, haematological cell death is usually mediated through primary apoptosis within a few hours of exposure; the majority of non-haematological cells die when they enter mitosis inappropriately (mitotic catastrophe). Several key mediators of DDR have been identified. The 2 most important genetic modulators of DDR appear to be TP53, which mediates cell cycle arrest, facilitating both apoptosis and mitotic catastrophe, and ATM, which encodes the main kinase responsible for repairing double-strand DNA breaks (3). P53 works through downstream targets such as PUMA and p21, with evidence suggesting that different pathways are significant in different systems. In murine models of GI induced radiation toxicity, loss of PUMA is protective, whilst p53 and p21 loss increases toxicity (4). In contrast, in slowly replicative systems, such as the CNS and salivary glands, non-lethal radiation dose induced p53 activation may result in cell cycle arrest and altered differentiation (1); the survival of these damaged cells may lead to stem cell ageing and second malignancies. Immune and Inflammatory system upregulation during radiotherapy and the impact on radiation toxicity Radiotherapy exposure results in global upregulation of the immune system, increasing immune activity by increasing tumour cell-surface expression of major histocompatibility complex (MHC) class 1, increasing expression of tumour-associated antigens, activating dendritic cells, and changing the T cell repertoire, with a consequent reduction in the immune suppressive regulatory T-cells and an increase in active CD8 populations (5). These responses underpin the positive outcomes seen in immunoradiotherapy trials, but the relationship between radiotherapy and the immune system is likely to have complex effects both on tumour control and radiation toxicity. Under normal circumstances dying cells are phagocytosed by macrophages and an anti-inflammatory pathway mediated by IL-10, TGF-b, platelet-activating factor, and prostaglandin E2 (PGE2) suppresses inflammation (6). During radiation the high levels of DNA damage results in the release of a high concentration of pro-inflammatory “damage-associated molecular patterns”(DAMPS) including oxidized DNA, adenosine triphosphate (ATP) heat shock proteins (HSPs) and high -mobility group box 1 (HMGB1)(7), leading to upregulation of inflammatory pathways through activation of

TLR's and triggering of pro-inflammatory cytokine cascades (8). This acute inflammatory reaction contributes to several of the hallmarks of acute radiation toxicity, including erythema, ulceration and oedema (9). Finally, chronic inflammatory responses induced by radiotherapy contribute to radiation fibrosis; a result of imbalance in the creation and destruction of extracellular matrix components mediated by the upregulation of pro-inflammatory cytokines (TNFα, IL1, IL-4, IL6) and fibrogenic cytokines (TNFβ) (10). Summary Our understanding of the molecular biology of radiation toxicity continues to evolve, but is increasingly seen to be the result of the complex interplay of dysregulated DDR, immune and inflammatory responses. These pathways will provide a rich source of future therapies to increase both the efficacy and safety of radiotherapy treatment. ES17.01 MESOTHELIOMA EVOLUTION

E. Hollox

University of Leicester, Leicester/United Kingdom

Malignant pleural mesothelioma (MPM) is mostly caused by prior exposure to asbestos fibres. It has a long but variable latency period following exposure, with a median of around 40 years but a range between 20-70 years, possibly reflecting the length and level of asbestos exposure as well as other environmental and genetic causes. Upon diagnosis, there are limited treatment options, and median survival time is a year, although, again, this is highly variable. Understanding the genetic events in the mesothelium between asbestos exposure and diagnosis of MPM is important for two reasons. Firstly, it will inform the biology of MPM tumour growth and potentially highlight different environmental and genetic factors that cause the variation in latency. Secondly, it will help identify key early driver mutations in MPM informing biology and candidate changes for developing approaches for early detection of the cancer. Evolutionary genetics is based on inferring past events from current genetic/genomic sequences. It has long been recognised that the development of cancer is an evolutionary process, and the availability of large amounts of DNA sequence data have facilitated an understanding of evolution of tumours using methods mostly borrowed from evolutionary genetics. One powerful approach compares a matched tumour and normal genome, infers the somatic mutations in the tumour, and uses the ratio of mutations that change an amino acid to mutations that don't change an amino acid (dN/dS ratio) across all genes to identify particular genes that have been positively selected during tumour evolution. This approach can also shed light on overall evolutionary processes that have occurred in the tumour. Genomic sequences from multiple regions of the same tumour not only emphasise the molecular heterogeneity of tumours but allow an explicit phylogenetic tree of the evolution of the tumour for each patient, distinguishing somatic mutations that happened early in the tumour's evolution (and are therefore present throughout the tumour) from those that happened late in the tumour evolution. Here, I report preliminary findings from a British Lung Foundation/Mesothelioma UK-funded project entitled MEDUSA - Mesothelioma Evolution: Deciphering drUgable Somatic Alterations as potential targets for synthetic lethal therapy. This project uses multiregional sampling of MPMs, together with matched whole blood, to infer a phylogenetic tree of MPMs. The preliminary data presented focuses on the first 20 patients, with between 4 and 5 regions of the tumour analysed per patient. Using whole exome sequencing, the project aims to identify truncal changes, that is, mutations that happened early in the tumour and are present throughout the tumour that can be potential targets for drugs, with the aim of developing personalised, effective tumour treatment for each patient. We focus on copy number changes (deletions and duplications of genes) and confirm that MPM is highly heterogeneous with extensive copy number changes in the genome. We focus on truncal copy number changes in ~20-25% of patients affecting the known mesothelioma tumour suppressor genes *BAP1*, *MTOR*, *CDKN2A* and *SETD1*. Distinguishing patients that have truncal copy number changes in these genes, in contrast to those patients with copy number changes in the terminal branches of the evolution of the tumour, helps to tailor individualised drug therapies. Our approach emphasises the importance of multiregional sampling of tumours to account for MPM heterogeneity. For example, by sampling the posterior costophenic angle of these MPM from these 20 patients, we would find 10 deletions of *CDKN2A*, of which only 5 are truncal, with the other five localised to only part of the tumour. Multiregional genomic analysis and evolutionary genetics approaches can illuminate the history of a tumour and have the potential to guide therapy. They also provide the framework for follow-on studies in a patient, such as analysing the origin of metastases and identifying the effects on the tumour of treatment. The extra information provided by multiregional sampling supports the idea that this approach should become routine in tailoring the treatment to the tumour in MPM.

ES17.02 MOLECULAR HETEROGENEITY

D. Jean

Centre de Recherche des Cordeliers - Inserm UMRS 1138, Paris/France

Molecular heterogeneity in Malignant Pleural Mesothelioma Malignant Pleural Mesothelioma (MPM), a rare thoracic tumor strongly linked to asbestos exposure, is one of the most aggressive cancer with a very poor prognosis. Clinical trials have highlighted MPM diversity in terms of prognosis and patients' response to anti-cancer agents, suggesting an underlying tumor heterogeneity. As current treatment options are rarely curative, a better characterization of inter and intra-tumor heterogeneity is essential for the identification of new therapeutic strategies, and for the implementation of precision medicine with the aim to improve the cure to this dreadful cancer. The first level of inter-tumor heterogeneity in MPM is histologic with three main histologic types i.e. epithelioid, sarcomatoid and biphasic. The latter is also an evidence of intra-tumor heterogeneity as the biphasic histologic

type is a mix of variable proportion of epithelioid and sarcomatoid tumor cells. The histologic heterogeneity is even more complex with the characterization of several histologic subtypes (1). Large-scale omics and NGS (Next Generation Sequencing) studies also highlighted MPM heterogeneity at the molecular level. MPM show a complex pattern of chromosomal abnormalities and mutations, so it is difficult to take into account this molecular heterogeneity of MPM solely on the basis of chromosomal or genetic alterations. We and others, using unsupervised hierarchical clustering based on transcriptomic or integrated multi-omics data, defined molecular classification in 2 and 4 tumor subtypes (2-4). These molecular subtypes are related to histology and associated to prognosis, to specific mutations in genes such as *BAP1* and to the deregulation of specific signal pathways such as epithelial-mesenchymal transition (EMT). Smaller and highly homogeneous subtypes were also defined by taking into account molecular subtypes and mutation profiles such as the one characterized by a double inactivation in the two tumor suppressor genes related to Hippo signal pathway, *NF2* and *LATS2* (5). Interestingly, based on preclinical studies, a potential target therapy has been proposed for this subtype illustrating the interest to define homogenous tumor subtypes in order to develop new therapeutic approaches. However, these molecular classifications in subtypes have some limitations. First, they take into account only inter-tumor heterogeneity but not intra-tumor heterogeneity, which is poorly described at the molecular level in MPM (6). Second, a meta-analysis comparing all molecular subtypes obtained by unsupervised hierarchical clustering of several different transcriptomic dataset highlighted only two main subtypes, which are highly correlated in all datasets. Apart from these two opposite subtypes corresponding to pure epithelioid and sarcomatoid phenotypes, intermediate subtypes could simply reflect various cut-offs of a continuum combining epithelioid and sarcomatoid entities, which could be better defined using molecular gradients (7). For these reasons with the aim to better characterize MPM molecular heterogeneity, we used a deconvolution method that decomposes the MPM transcriptomic profile of each tumor as a combination of epithelioid and sarcomatoid components. We determined the proportion of these epithelioid and sarcomatoid components (E.score and S.score, respectively) in large series of tumors. These two opposite histo-molecular gradients were related to histology types and to subtypes of MPM molecular classification (7). The underlying oncogenic pathways driving the establishment of the epithelioid and sarcomatoid related cell entities were specified. Integration of transcriptome, methylome and miRNome data showed the strong contribution of epigenetic regulation. We also highlighted the link between the histo-molecular gradients and the tumor microenvironment and the immune contexts. A strong positive correlation was observed between the S.score and the infiltration of T lymphocytes, monocytes, fibroblasts and endothelial cells, while the E.score was linked to natural killer cells infiltration and complement pathway. These results suggested the presence of an adaptive immune response in tumors with a high S-score and of an innate immune response in tumors with a high E-score. The S.score was also strongly correlated with high expression of most immune checkpoint inhibitors, including *CD274* (*PDL1*) and *CTLA4* (7). More importantly, we highlighted the potent clinical impact of histo-molecular gradients on prognosis and on personalized therapeutic strategies in MPM. First, we showed that the S.score has a strong prognostic value, higher than histologic and molecular classifications. Second, our data supported that these histo-molecular gradients might be used to guide therapeutic strategies such as targeted therapies by performing preclinical studies. Third, the strong correlation of the S.score with T lymphocytes infiltration and immune checkpoint inhibitors expression supports that a high S.score could be predictive of immunotherapy based on anti-PDL1 and anti-CTLA4 inhibitors (7). Prediction of patients responding to these inhibitors is particularly important given the recent promising results of this immunotherapy for some MPM patients (8). More recently, we have performed a genetic profiling, focusing on the main key genes altered in mesothelial carcinogenesis, of a large collection of MPM with complete clinical annotations and well-characterized for heterogeneity using current available tumor classifications. The unpublished results provided a comprehensive overview of the genetic landscape of MPM taking into account the histologic and molecular heterogeneities. References: 1. Husain A. MONDAY, SEPTEMBER 9 11:00–12:30

ES17.03 HETEROGENEITY & IMMUNE CHECKPOINT EXPRESSION

A. Mansfield

Mayo Clinic, Rochester/United States of America

Mesothelioma is a spatially complex malignancy. Morphologic heterogeneity is commonly identified, especially with surgical resection that can unmask distinct histologic components across sites of disease. Molecular analyses of *HUMARA* methylation patterns on the X-chromosome, *CDKN2A* deletions, and single nucleotide variants from multiple tumor sites all suggest that mesothelioma is polyclonal with multiple genetic subclones within each tumor. Temporal histologic heterogeneity has also been reported with sarcomatoid differentiation during progression of disease. The selective pressures of the microenvironment and therapies may further drive tumor heterogeneity. With the application of immune checkpoint inhibitors for the treatment of this disease, the expression of immune checkpoints and the immunologic milieu of mesothelioma has been increasingly investigated. Whereas most studies report immune checkpoint expression from a single site of disease obtained from a single time point, distinct immunologic patterns have been observed within tumors from different sites. The molecular and immunologic heterogeneity of mesothelioma may have prognostic and therapeutic implications.

ES17.04 NEW INSIGHTS INTO THE MOLECULAR CHARACTERISTICS AND INTRA-TUMOR HETEROGENEITY OF MALIGNANT PLEURAL MESOTHELIOMA FROM THE MESOMICS PROJECT

L. Fernandez-Cuesta

International Agency for Research on Cancer (IARC-WHO), Lyon/France

Malignant pleural mesothelioma (MPM) is a rare but deadly disease, which molecular characteristics have only recently been uncovered through large-scale genomic studies (Bueno Nat Genet 2016; Hmeljak Cancer Discov 2018). Although insightful and important, many questions are still unanswered, which could be addressed with additional comprehensive and integrative genomic analyses. In addition, we have recently performed a reanalysis of the transcriptome data of the two aforementioned cohorts with no assumption of discretness, in which we have uncovered the importance of angiogenesis and the immune system for understanding the diversity of MPM molecular phenotypes (Alcala et al. under review). Intra-tumour heterogeneity (ITH) is commonly reported in MPM at the histopathological level; however, the question of the molecular ITH of this disease has not been comprehensively addressed so far. Only one recent study has highlighted the

enormous ITH at the microenvironment level (Thapa et al. JTO 2017), suggesting that MPM experience spatially heterogeneous selective pressures, or possibly that there exist MPM clones that differentially alter their micro-environment. In close collaboration with the French MESOBANK/MESOPATH, we have started the MESOMICS project aiming at performing a molecular characterization of a large series of MPM through the integration of muti-omic data and detailed epidemiological and clinical information in order to better understand this understudied and deadly disease. For this we have collected 130 fresh frozen tumors and their matched-normals from all the three MPM types (epithelioid, biphasic, sarcomatoid) and the main morphological subtypes of the epithelioid MPM. We have performed whole-genome sequencing, transcriptome sequencing and 850K methylation arrays in all these samples. For 12 of them we had access to several regions of the tumor, which allowed us to perform ITH analyses. The preliminary analyses of these data will be presented and discussed. ES18 ACQUIRED RESISTANCE TO TKIS: THE REBIOPSY CASE AND THE FUTURE OPTIONSES
MONDAY, SEPTEMBER 9 11:00–12:30

ES18.01 REBIOPSY IN ONCOGENE ADDICTED NSCLC AT PROGRESSION

D.R. Camidge

University of Colorado Cancer Center, Aurora/United States of America

As we have defined piecharts of different oncogenes at diagnosis in NSCLC, each oncogene, under the selection pressure of an active targeted agent may develop acquired resistance after initial benefit in a number of different ways, allowing intra-oncogene piecharts of acquired resistance mechanisms to be described. Key features to consider when considering a rebiopsy - either of the tumor or of a surrogate of the tumor (cf-DNA) is the ease and risks of rebiopsy, its false positive and false negative rates and the potential 'actionability' of the data generated. These factors allow rebiopsies for research purposes to be differentiated from those that could inform changes in clinical care immediately. Rebiopsies of systemic disease, became standard when osimertinib was used post 1st- or 2nd-generation EGFR TKIs to look for T790M. With the move of osimertinib to the first line setting, the need to detect T790M has becoem less, but other mechanisms of resistance in the post 1/2nd generation EGFR TKI setting, separate from T790M, and in the post-osimertinib setting including small cell transition and MET amplification are also likely to change clinical management and maintain the role for biopsies in EGFR mutant disease. In ROS1 rearranged lung cancer - the lack of efficacy of lorlatinib and crizotinib to G2032R clinically, but the possible activity of repotrectinib in trials, can make the case for a rebiopsy and reanalysis post-crizotinib or lorlatinib in ROS1+ disease. Actionable second drivers remain under exploration. In ALK rearranged lung cancer, on target mutations are multiple - preclinical data suggesting specific drugs for specific mutations post-crizotinib can be identified remains partially determined, with multiple caveats about the preclinical-clinical transferability of data. The ALK master protocol will address some of these issues. However, perhaps the biggest issue relates to the potential for non-ALK related second drivers to be actionable, suggesting the methodology of testing in the acquired resistance setting, as in EGFR, should be broad. Rebiopsies performed in the setting of CNS progression, in the absence of prior overt CNS benefit, are of limited practicality or use at present, however, with the advent of CNS penetrant drugs for key oncogenes, true CNS acquired resistance may emerge and some form of CNS sampling may become relevant.

MONDAY, SEPTEMBER 9 11:00–12:30

ES18.02 WHEN TO SWITCH TO A NEW TKI:IMAGING BASED CRTIERIA OR POSITIVE LIQUID BIOPSY?

J. Yang

National Taiwan University Hospital, Taipei/Taiwan

The discovery of specific mutations and associated addicted pathways in lung adenocarcinoma cells has led to the development of many targeted therapies useful for corresponding activating mutation. In addition, conventional chemotherapy and novel immunotherapy such as PD1/PDL1 antibodies are also very effective for lung cancer patients with or without specific driver mutation. Patients with metastatic lung cancer nowadays can be treated with multiple lines of effective treatment. Patients who receive more lines of therapy tend to live longer than those who had only receive limited number of treatment. In order to maximize the overall survival outcome of metastatic lung cancer patient who receives systemic treatment, it is important to find out the best first line choices and the best timing to change the treatment regimen to second line and so forth. Tumor reduction or stabilization by imaging criteria has been used widely for a long time in chemotherapy and targeted therapy era. RECIST (Response evaluation criteria in solid tumors) has been adopted as a uniform criteria for cancer clinical trial to classify the tumor response to certain treatment. However, in order to accommodate different cancer types and sites of metastasis, several variants of RECIST emerged to better evaluate the treatment response and necessity of maintain the present treatment. In daily practice, changes of tumor size in the image provide the best guidance for clinicians to continue or change regimen for the patients. In patients who has no reliable evaluable radiological image for follow up, such as patients who presented with effusion, bone metastasis, leptomeningeal metastasis or tumor with poor margin, patients' clinical performance and alterations in tumor markers occasionally can provide clinicians information for judgement. The introduction of cell free plasma tumor DNA for the molecular diagnosis of cancer gave us a new change of how to manage the patients properly when changing regimen to prolong patients chance to survive or improving quality of life are attainable. There are a least 3 important applications for cell free tumor DNA detection. First is to provide information of specific mutation at the time of diagnosis or progression, so that a corresponding targeted therapy can be chosen as the best treatment of choice. Second is to use quantitative amount of specific mutation found in plasma cell free DNA to follow patient's tumor. The presumption is the amount of specific mutation may represent the tumor load of the treated patients. The 3rd possible application is to use the novel mutations detected in the plasma at the time of diagnosis or during treatment follow up to select a theoretical best combination for patients. There are ample of analysis reported in the literature for the first and second possible applications of plasma cell free DNA. The evidence for the 3rd possible application is accumulating. However, there is no emphasis of using this vast information gathered in the plasma to guide the right timing to switch regimen. In addition, there has been a trend to continue original treatment in slow progressing patients beyond imaging progression, or to treat oligo-progressing sites with local irradiation or surgery in order to keep the original treatment. These approaches certainly will further complicate the rationale decision of right timing to change regimen. Thus, a few options exist for patients who are receiving targeted therapies. One is to use conventional ways of RECIST progression by imaging studies to change the treatment to further lines. The treatment outcome may be more predictable, because most of the clinical trials follow this dogma. A second choice is to treat patients beyond progression by RECIST and follow physicians judgment to switch the regimen. Several recent clinical trials use this criteria to change regimen and collect the treatment time as duration-of-treatment, or time-to-treatment-failure. The 3rd possible timing is to switch regimen according to plasma DNA alterations, for example, emergence of activating mutation when plasma tumor DNA was previously eradicated by current targeted therapy; add another targeted therapy when a new parallel pathways amplification is predicted from the plasma sample analysis. This strategy lack the support of prospective clinical trial data and was purely based on direct scientific deduction or instinct and a few case reports. Therefore, studies specifically designed to address the switch timing is very important. Unfortunately, the effort devoted to this area is lacking.

MONDAY, SEPTEMBER 9 11:00–12:30

ES18.03 NEW STRATEGIES TO OVERCOME RESISTANCE IN EGFR MUTATED NSCLC

P. Bunn, Jr

Univ. of Colorado Cancer Center, Aurora/United States of America

Activating EGFR mutations occur in 15-50% of lung adenocarcinomas with a higher frequency in never or light smokers and individuals of East Asian origin. First and second generation EGFR tyrosine kinase inhibitors (TKI) such as gefitinib, erlotinib, afatinib and dacomitinib are associated with high response rates (50-75% and median progression free survival rates of 9-14 months. Failure in the CNS is frequent because these agents have poor CNS penetration and the most frequent cause of systemic failure is the development of T790M resistance mutations. Other reported mechanisms of resistance to first and second generation EGFR TKIs include small cell transformation, AXL overexpression, HER2 mutation and overexpression, Wnt pathway overexpression and other less common alterations. Standard platinum doublet chemotherapy is generally used for those with small cell transformation and these cases usually have Rb loss and p53 mutation. The addition of cetuximab to first or second generation EGFR TKIs did not appear to improve outcomes. Osimertinib is a third generation EGFR TKI whose advantages include high sensitivity to both activating EGFR mutations and T790M mutations with lesser sensitivity to wild type EGFR. Osimertinib also crosses the blood brain barrier. A randomized phase III trial, AURA3, demonstrated that osimertinib was superior to chemotherapy and was associated with decreased CNS relapse in the second line setting after failure on a first generation EGFR TKI due to T790M. These data with second line osimertinib led to a first line phase III randomized trial, FLAURA, comparing osimertinib to either gefitinib or erlotinib. Osimertinib was associated with a significantly longer PFS, a significantly longer time to CNS progression, a significantly longer duration of response and a longer overall survival that had not reached significance at most recent analysis. Patterns of resistance to first line osimertinib are only emerging now but include alterations that have specific targeted therapy such as MET amplification (15%), BRAF mutations (3%), HER2 amplification (1%), ALK fusions (1%), PI3K mutations (3%), KRAS mutations (2%), C797s or other resistance mutations (2%), SCLC transformation (5%), CDK and cell cycle alterations (2-5%). Because these have specific non-chemotherapy treatment options, NGS testing should be done on blood ctDNA and if negative on tissue at the time of progression. For those without these actionable alterations, chemotherapy is the next standard therapy although combinations of chemotherapy with checkpoint inhibitors with or without anti-VEGF agents is under investigation due to a positive subset analysis of the IMPOWER 150 trial. The addition of checkpoint inhibitors to first line TKIs has proven to have increased toxicity with low activity. Another way to delay or prevent resistance is to use combinations in the first line therapy. Combinations of EGFR TKIs with anti-VEGF therapies, with anti-MET therapies, with anti-EGFR antibodies, and with chemotherapy are in progress. Initial trials combining erlotinib with bevacizumab demonstrated improved PFS but not OS. Current trials are combining newer EGFR TKIs such as osimertinib with anti-VEGF antibodies such as bevacizumab or ramicirumab are in progress. Trials using anti-VEGFR TKIs are also in progress. Preclinical studies indicated that combining anti-EGFR antibodies such as cetuximab or necitumumab with EGFR TKIs could overcome some resistance led to other ongoing clinical trials combining these agents. Amplification of MET is a common mechanism of resistance to EGFR TKIs, so the combination of MET TKIs with EGFR TKIs is rational and trials are ongoing. Understanding the mechanisms by which EGFR mutant cells can persist in the presence of initial EGFR TKIs remains a priority for future investigation. The adjuvant use of EGFR TKIs after surgical resection of early stage NSCLC patients with EGFR mutations has clearly established superiority in recurrence free survival but not in overall survival. It appears that there is insufficient cell kill to lead to an increase in the cure rate but additional survival based adjuvant trials such as "ALCHEMIST" are ongoing. Neoadjuvant studies could provide downstaging because the response rates are high. It is not clear whether this would be more likely to provide an increase in cure rates compared to adjuvant use of these agents. These neoadjuvant trials are providing surgical samples to explore mechanisms by which cells persist after EGFR TKI therapy. This incredibly important information could lead to rational combinations that could increase pCR rates in early stage patients and improved outcomes in advanced stage patients.

MONDAY, SEPTEMBER 9 11:00–12:30

ES18.04 NEW STRATEGIES TO OVERCOME RESISTANCE IN ALK REARRANGED NSCLC

S.-H. Ou

University of California Irvine, Orange/United States of America

Since the discovery of ALK+ NSCLC in 2007, there are now 6 ALK TKI have been approved or in clinical development. These 6 ALK TKI can be generally divided into 3 generations. First-generaion (Crizotinib). Second-generaion (Alectinib, Ceritinib, Brigatinib, Ensartinib). Third-generation (Lorlatinib). The advantages of the second-generation ALK TKI or beyond is better potentcy an excellent improved CNS penetration. The mode of progression in ALK+ NSCLC are 4 fold and can be single or combination according to individaul patients: developed of acquired second site ALK mutations, CNS progression, bypass activation, and histological transformation. For second site ALK mutations, sequencing ALK TKIs that will overcome the particular second site mutation(s) or proceed to the most potent ALK TKI is likley be successful. For CNS progression, lorlatinib has demonstrated CNS activity in CNS progression from second generation ALK TKIs (ceritinib, alectinib). Additionally the use of stereotactic radiation (SRS) or whole brian radiation can contral CNS progression but clinicians should look out for radiation necrosis. For second bypass activation such as (i.e. RAS, SRC, EGFR, Kit) in vritro pre-clinical modles of combining specific bypass inhibitor and ALK TKI were albe to inhibit growth of these resistance cell lines or patient dervied PDX model, clinical trials are on-going but to date clinical data are lacking. Additional the use of chemotherapy especailyl pemetrexed-based chemotherapy in addition to ALK TKI has showen to be more efficacious than just switching to chemotherapy while discontinuing ALK TKI For histologic transformation most commonly small cell transformation, the switching to small cell regimen is only viable option at this point. The addition to immunotherapy to chemotherapy (e.g. IMpower133 regimen) or IO + IO combination (e.g. chckmate-032) should be explored in small cell tranformation as mode of progression in ALK+ NSCLC.

ES19.01 BENEFITS AND LIMITATIONS OF SYSTEMIC THERAPY FOR MALIGNANT PLEURAL EFFUSION

A. Tsao

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Systemic therapy for metastatic non-small cell lung cancer is directed by molecular profiling. Ideally, genetic sequencing and PD-L1 immunohistochemistry should be performed on tumor cells obtained from malignant pleural effusions where the diagnosis of non-small cell lung cancer is evident. This discussion will review the recommended up to date testing practices and the subsequent systemic therapy decisions for patients with metastatic non-small cell lung cancer.

MONDAY, SEPTEMBER 9 14:00–15:30

ES19.02 BEST ENDOSCOPIC TOOLS FOR THE BEST RESULTS

M. Munavvar

Lancashire Teaching Hospitals, Preston/United Kingdom

Undiagnosed pleural effusion is an increasingly common clinical problem and represents significant burden of disease both to patients and healthcare resources. With the increase in annual incidence of both primary and secondary pleural malignancies, better diagnostics and treatment options are very much needed. Medical thoracoscopy, also known as local anaesthetic thoracoscopy [2], is a procedure where a rigid or semi-rigid scope is inserted into the pleural cavity via a port for direct visualisation of the pleura and biopsy of abnormal areas, besides completion of talc poudrage, where appropriate. It is usually performed under conscious sedation and local anaesthesia. This procedure avoids risks of general anaesthesia and single lung ventilation, required for video-assisted thoracoscopic surgery (VATS) and therefore can be performed in patients who are unfit for anaesthesia/surgery. The procedure of thoracoscopy is performed in a controlled environment such as in an operating theatre setting, endoscopy suite or treatment room with adequate staffing. Diagnostic advantage A significant number of cases of pleural effusion are undiagnosed after a single diagnostic pleural aspiration and the diagnostic yield of pleural fluid cytology is only approximately 60% [3]. A second aspiration only modestly increases diagnostic yield by 15% and a third sample is non-contributory [3]. A blind pleural biopsy (also known as closed pleural biopsy) increases the diagnostic yield above pleural fluid cytology by only 7-27% [3]. In mesothelioma however, the diagnostic yield of pleural fluid cytology is even lower, at around 32% [4]. A blind pleural biopsy only increases sensitivity to around 50% [5]. Medical thoracoscopy is substantially superior in diagnostic power compared to pleural fluid cytology and blind pleural biopsy. As it allows direct visual assessment of the pleura and subsequent biopsy of the abnormal areas, it maximises diagnostic yield to >90% in malignant pleural diseases [5,6]. Rigid thoracoscopy generates similar diagnostic yield compared to semirigid thoracoscopy in exudative pleural effusions but larger biopsy samples can be obtained during rigid thoracoscopy [5,6].The sensitivity of medical thoracoscopy in malignant mesothelioma appears to be equally good and the efficacy of rigid medical thoracoscopy in regards to diagnosis in pleural malignancy is as high as VATS [2]. With the increasing need to secure an accurate diagnosis and plan optimal treatment in possible pleural malignancy, medical thoracoscopy offers a high diagnostic yield earlier in the patient journey. Therefore, this is the preferred procedure where the option exists and helps to reduce the need for repeated diagnostic procedures and reduces the time taken to establish diagnosis and commence appropriate treatment. Medical thoracoscopy as a therapeutic procedure Another advantage of medical thoracoscopy is that it is a diagnostic and therapeutic procedure in the same setting. Complete drainage of pleural fluid can be achieved during the procedure and talc poudrage can also be performed during medical thoracoscopy. It is a highly effective method of pleurodesis with an efficacy of 84% at 1 month, which is at least equivalent to talc slurry via a seldinger chest drain, with possibly increased efficacy in the subgroup of patients who have breast or lung carcinoma and without trapped lung [2]. Medical thoracoscopy is also effective in the management of TB pleurisy and empyema. Septations and adhesions in complex infected effusions can be divided during thoracoscopy which can facilitate accurate chest tube placement and drainage. ES19.03 RCT'S ON MALIGNANT PLEURAL EFFUSION TALC PLEURODESIS MANAGMENT

N. Maskell

University of Bristol, Bristol/United Kingdom

This talk will focus on 2 recently completed multicentre RCT's in talc pleurodesis for malignant pleural effusions; IPC plus trial (NEJM 2018) and the TAPPS trial (in submission). A summary of these 2 trials is below: IPC Plus - *Methods:* Over a period of 4 years, we recruited patients with malignant pleural effusion at 18 centers in the United Kingdom. After the insertion of an indwelling pleural catheter, patients underwent drainage regularly on an outpatient basis. If there was no evi- dence of substantial lung entrapment (nonexpandable lung, in which lung expansion and pleural apposition are not possible because of visceral fibrosis or bronchial ob- struction) at 10 days, patients were randomly assigned to receive either 4 g of talc slurry or placebo through the indwelling pleural catheter on an outpatient basis. Talc or placebo was administered on a single-blind basis. Follow-up lasted for 70 days. The primary outcome was successful pleurodesis at day 35 after randomization. *Results:* The target of 154 patients undergoing randomization was reached after 584 patients were approached. At day 35, a total of 30 of 69 patients (43%) in the talc group had successful pleurodesis, as compared with 16 of 70 (23%) in the placebo group (haz- ard ratio, 2.20; 95% confidence interval, 1.23 to 3.92; P=0.008). No significant be- tween-group differences in effusion size and complexity, number of inpatient days, mortality, or number of adverse events were identified. No significant excess of blockages of the indwelling pleural catheter was noted in the talc group. *Conclusions:* Among patients without substantial lung entrapment, the outpatient administration of talc through an indwelling pleural catheter for the treatment of malignant pleural effusion resulted in a significantly higher chance of pleurodesis at 35 days than an indwelling catheter alone, with no deleterious effects. (Funded by Becton Dickinson; EudraCT number, 2012-000599-40.) TAPPS - *Methods* We recruited patients with malignant pleural effusion from 17 United Kingdom hospitals over 5 years. On an open-label basis, patients were randomly assigned to receive either 4g talc poudrage at thoracoscopy under conscious sedation, or chest tube insertion under local anesthetic followed by 4g talc slurry. Follow-up lasted for six months. The primary outcome was pleurodesis failure rate three months after randomization, defined as the need for further pleural intervention during follow-up. Secondary outcomes including mortality and cost-effectiveness were also assessed. *Results* The target of 330 patients was reached after 583 were approached. At three months, pleurodesis failure rate was 36/161 (22%) with poudrage and 38/159 (24%) with slurry (adjusted odds ratio (OR) 0.91, 95% confidence interval (CI) 0.54-1.55, p=0.74). No statistically significant differences were noted in any secondary outcome. Numbers of adverse events were similar between groups. Using a standard threshold, poudrage had a 36% probability of being cost-effective. *Conclusions* In patients with malignant pleural effusion, there appears to be no additional clinical or cost-effectiveness benefit to choosing talc poudrage at physician-led thoracoscopy over talc slurry through chest tube. *(Funded by the United Kingdom National Institute for Health Research).*

ES19.04 HOW TO DEAL WITH A TRAPPED LUNG

Y.C.G. Lee

Sir Charles Gairdner Hospital, Perth/Australia

Trapped lung, now also called nonexpandable lung, refers to the observation when an underlying lung fails to fully expand upon removal of pleural fluid or air [1]. It occurs in ~30% of patients with malignant pleural effusions (MPEs) and may arise from thickened visceral pleura (inhibiting lung expansion) or from endobronchial tumor obstruction. The pleural space in patients with nonexpandable lung is usually under high negative pressure. This can lead to transudative fluid accumulation by Starling's equation, in addition to the underlying MPE formation. This condition is often difficult to manage as fluid often keep recurring to fill up the trapped lung space. Patients with MPE and trapped lung often present with breathlessness. It is important to recognize that removal of the fluid can still provide symptom relief despite the nonexpendable underlying lung [2]. A trial of fluid drainage to determine if the patient has symptoms benefits is worthwhile. The current belief is that breathlessness from MPE is a result of altered respiratory mechanics when the hemithorax expands to accommodate the volume of the effusion (see our review [2] for details). Patients with nonexpandable lungs usually do not benefit from pleurodesis due to the lack of apposition of the visceral and parietal pleura. Indwelling pleural catheter (IPC) is now a recognized first choice management of MPE in patients with a nonexpendable lung, as recommended in the latest American thoracic Society MPE guidelines (2018) [3]. Several large randomized studies in recent years have testified to the benefits of IPC management of MPEs. The TIME-2 study [4] showed that IPC offered benefits to breathlessness and chest pain similar to conventional talc slurry pleurodesis. The AMPLE trial [5] showed that patients with MPE managed with IPC spent fewer days in hospital and required fewer pleural invasive procedures in their remaining life while enjoying the same level of symptom and quality-of-life improvements as those patients treated with talc pleurodesis. The recently published AMPLE-2 study [6] compared daily catheter drainage vs symptom-guided drainage in patients with MPEs and an IPC. Interestingly 50% of those with initial trapped lung who underwent daily drainage eventually developed spontaneous pleurodesis that allow removal of the catheter. The numbers however were small and the results require verification. Conventionally it is believed that surgical decortication of the lung in MPE patients with visceral pleural thickening may allow the lung to re-expand and thus permit successful pleurodesis. Limited objective data exist to support this belief (see our recent review [7]). In the VATS-Meso trial [8] and other observational series, patient who underwent VATS pleurodesis +/- pleurectomy have higher risks of complications especially prolonged post-operative air-leak and thus hospitalization. The planned AMPLE-3 randomized trial will compare IPC treatment with surgical pleurodesis for MPE. Patients with MPEs and underlying nonexpandable lung are often excluded in clinical trials and thus their optimal management remains unclear. They represent a sizeable subset of MPE patients and deserve specific attention in future research. REFERENCES 1. Light RW, Lee YCG. *Textbook of Pleural Dieaseas.* 3rd ed. ES19.05 SURGICAL MANAGEMENT OF MALIGNANT PLEURAL EFFUSION

A. Sihoe

The University of Hong Kong, Hong Kong/Hong Kong PRC

At first glance, it would seem that the thoracic surgeon has little role to play nowadays in the management of malignant pleural effusion (MPE). Substantial advances have been made in the understanding of the pathophysiology of MPE and its diagnosis. There is broad consensus that pleurodesis should generally be given at the bedside rather than in the operating theatre, while intractable cases can be managed with indwelling catheters. Even where interventions into the chest are required, the advent of 'medical' thoracoscopy appears to have diminished the role of surgeons in managing MPE. However, it would be wrong to presume that thoracic surgeons may be completely excluded from the MPE scene. There remain situations were surgery is still required for a definitive diagnosis or effective palliation. Surgeons continue to have more extensive experience with biopsy, drainage, and 'rapid pleurodesis' – yielding high rates of success. More importantly, minimally invasive Video-Assisted Thoracic Surgery (VATS) has evolved significantly in recent years. Uniportal VATS is becoming increasingly utilized, and is often complemented by technological advances such as non-intubated anesthesia. The latest advances in minimally invasive thoracic surgery have ensured that the high success rate of surgery is now coupled with surprisingly little – if any – functional or physiological 'cost' to the patient with MPE. The 'VATS' available today is not the same VATS from even a few years ago. This presentation provides an overview of the current surgical options available in the management of MPE. The modern thoracic surgeon remains fully equipped and prepared to contribute to the multi-disciplinary care of patients with this complication.

ES20.01 WHY IT MATTERS FOR PATIENTS TO QUIT - WHAT WE'VE DONE

A. Shankar

DRBRAIRCH, All India Institute of Medical Sciences, NEW DELHI/India

Smoking after a cancer diagnosis causes adverse outcomes including increasing overall mortality, cancer specific mortality, and risk for second primary cancer. Continued smoking is also associated with increased toxicity from cancer treatment. The best method to prevent the adverse effects of smoking is to assist patients with quitting. However, large surveys consistently demonstrate that while most providers ask about tobacco use and advise patients to quit, most oncologists unfortunately do not provide assistance. Predictive barriers to providing assistance with quitting include a lack of time, education, and resources. Continued smoking after a diagnosis can result in substantial added cancer treatment costs, which can be used to justify resources to assist patients with quitting. Methods to assist patients include counseling and pharmacotherapy. Considering in person or phone based approaches to cessation support is important to implement effective and sustainable changes within each practice setting. As approaches are implemented, significant opportunity exists to increase the efficiency of smoking cessation in cancer care. Additional opportunities exist for identifying optimal cancer treatment strategies for cancer patients who smoke. The key to realizing the clinical and financial benefits of addressing tobacco use in cancer care is the systemic incorporation of standardized

approaches to identifying tobacco use, providing assistance for patients to quit, and tracking tobacco use after diagnosis in combination with monitoring clinical outcomes."

ES20.02 TOBACCO CONTROL INTEGRATION IN CANCER CARE: THE CANADIAN EXPERIENCE

W. Evans[1], R. Truscott[2], E. Cameron[2], C. Timmings[3], M. Haque[2], M. Halligan[3], S. Rana[2], D. Keen[3], L. Rabeneck[2]

[1]*McMaster University, Hamilton/Canada,* [2]*Cancer Care Ontario, Toronto/Canada,* [3]*Canadian Partnership Against Cancer, Toronto/Canada*

The evidence that smoking cessation improves outcomes for cancer patients is irrefutable. Continued smoking after a diagnosis of cancer can increase all-cause and cancer-specific mortality, result in increased adverse treatment effects and cause a higher incidence of recurrence and second malignancies (1,2). In 2011, Cancer Care Ontario (CCO) noted the potential benefits of smoking cessation in two seminal papers (3,4) and established a Steering Committee to create an implementation framework for a provincial smoking cessation initiative. The framework provided guidance on standard program elements, optional regional initiatives and central administrative support (5). Required elements included screening of all new ambulatory cancer patients using a standardized tobacco screening question to identify current and recent smokers (smoked within past six months); appointment of regional smoking cessation Champions; training for healthcare providers on the health benefits of smoking cessation for cancer patients; referral of patients willing to accept help in quitting; and submission of performance metric data. Optional elements of the framework were the intensity of the regional smoking cessation intervention and location of smoking cessation services (cancer centre or host hospital vs external provider). Central administrative support included a secretariat within the division of Prevention and Cancer Control, and a central database within Analytics and Informatics. Patients were to be screened for smoking status by a nurse or physician using the 5As (ask, advise, assess, assist, arrange) model of smoking cessation. The screening question asked is "Have you used any form of tobacco in the last six months?" To assess a patient's willingness to quit, the question asked is "Are you interested in learning about what is available to help you avoid smoking/using tobacco in the future?" Centres were to develop an inventory of regional smoking cessation resources. Potential resources included the Canadian Cancer Society's Smokers' Helpline – a quit line accessible by phone, web and text-based messages (6), trained pharmacists and family physicians, public health units and hospital and community-based smoking cessation clinics. In 2016, based on the Ontario initiative, the Canadian Partnership Against Cancer (CPAC) offered funding to all provinces to plan, implement or evaluate smoking cessation initiatives within cancer centres. Seven provinces and two territories made submissions in response to CPAC's request for proposals, leading to multiple new efforts within cancer agencies across Canada to assist cancer patients to stop smoking (7). Cancer Care Ontario used funding from CPAC to implement educational initiatives for both providers and patients (e.g., development of posters, multilingual brochures and videos), and to conduct a survey to determine best implementation processes. Monthly teleconferences with the regional Champions and annual face-to-face meetings to review progress and celebrate successes were critical success factors. Other factors that contributed to a successful implementation were strong leadership from the Steering Committee (now Advisory Committee), commitment from CCO executive and clinical leadership and the use of performance metrics and performance management. The initial five key performance metrics were: 1) proportion of ambulatory cancer patients screened for smoking status; 2) proportion of those screened who were current or recent smokers; 3) proportion of smokers advised to quit smoking; 4) proportion of those advised to quit who were recommended a referral to smoking cessation services; and 5) proportion of those offered a referral who accepted a referral. Two metrics (tobacco use screening and accepted a referral) are reviewed on a quarterly basis by senior CCO executives with the regional cancer centre leaders in order to drive change. Targets are set and performance metrics on smoking cessation are used, amongst others, to determine the overall ranking of a cancer centre within the province of Ontario. Most of the 14 regional cancer centres are achieving the target of 75% of new ambulatory cancer patients screened for tobacco use but fall below the target of 25% for acceptance of a cessation referral. This poor performance led to the adoption of an "opt-out" approach in which patients are automatically referred to smoking cessation services unless they specifically refuse. It is critical that busy oncologists not be overburdened, and that other frontline staff assume responsibility for implementing the smoking cessation program. "Scripts" can communicate to patients that the physician wants them to stop smoking in order to get the best results from treatment. Using 3As (ask, advise, act) also minimizes the burden on staff. CPAC has disseminated these learnings across Canada and engaged all 10 provinces and three territories in a 2019-21 funding initiative requiring an evaluation plan with 15 quality indicators. Already, a 10% increase in the level of implementation of evidence-based tobacco cessation programs within ambulatory cancer settings across Canada has occurred (56% adoption in 2017/18; 66% adoption in 2018/19). The approaches to smoking cessation vary by jurisdiction (7,) but the culture within cancer centres is evolving with a growing realization that it is never too late for a cancer patient to stop smoking, and acceptance that smoking cessation must be integrated into cancer treatment for it to be truly considered quality cancer care. MONDAY, SEPTEMBER 9 14:00–15:30

ES20.03 TOBACCO CONTROL INTEGRATION IN CANCER CARE: THE JORDAN EXPERIENCE

F. Hawari

King Hussein Cancer Center, Amman/Jordan

Tobacco control is an integral component of any action plan that aims to reduce cancer incidence and mortality. Efforts at King Hussein Cancer Center, the only comprehensive cancer center in Jordan and the region, started 10 years ago. We sought to address the tobacco epidemic in Jordan on multiple fronts. In Jordan, tobacco prevalence exceeds 60%. About 50% of patients presenting with a cancer diagnosis are smokers. Integrating tobacco control in general and tobacco dependence treatment in patients suffering from cancer is pivotal. Smoking in patients with cancer has been shown to impact cancer treatment, increase complications from cancer treatment, increase cancer recurrence, increase the odds of development of secondary malignancies and eventually decrease overall long-term survival. Throughout the last 10 years our tobacco dependence tretament program grew in services and scope. The program addressed three major components required for tobacco control in cancer patients: First, patient-centered clinical tobacco dependence treatment service. Second, tobacco dependence treatment training and education for health-care providers. Third, research that addresses tobacco dependence in cancer patients. Our program provides 6 smoking cessation clinics every week dedicated mainly to our cancer patients. We have managed to address training needs for our staff by establishing a tobacco treatment specialist training program, the first ever to be accredited by The Council

for Tobacco Treatment Training Programs outside the USA. We studied outcomes of our treatment program and developed means to improve referral to smoking cessation clinics as well as improve the abstinence of our patients. In addition, we studied knowledge, attitude and perception of our health care providers working at our institution; a step especially important in a country where significant numbers of health care providers are smokers. Finally, we studied the impact of our tobacco dependence treatment program on the survival of our patients. Understanding the impact of smoking cessation on short-term survival of patients with cancer (2 years) highlights the importance of integrating such programs as part of the acute treatment phase of these patients. Cancer registry and smoking cessation clinic data for cancer patients diagnosed between 2012 and 2016 were analyzed. Approximately 19% of cancer patients were seen at the smoking cessation clinic. In a sub-sample of 2,387 patients, a significant two-year survival advantage was observed for smokers who had visited the smoking cessation clinic and confirmed that they had not smoked on at least two of their 3, 6 or 12-month follow-up visits (HR 2.8, 95% confidence interval [CI] = 1.7–4.5) relative to those who never went to the smoking cessation clinic. Those at the smoking cessation clinic who were abstinent at only one follow-up point also exhibited a survival advantage (non-abstainers at the smoking cessation had comparable survival to those who were not seen at the clinic). In conclusion, tobacco control in patients with cancer has an important role in the outcome and survival of these patients and must be integrated in their short and long-term plan of care.

ES20.04 TOBACCO CONTROL IN INDONESIA

S. Andarini

Faculty of Medicine University of Indonesia Persahabatan Hospital, Indonesia, Jakarta/Indonesia

Indonesia is the largest archipelago country of more than 17,000 islands over 5,200 km width, with population over 260 million makes it fourth most populated country in the world. As the largest economy in South East Asia, and member of G20 country, Indonesia's economy growth is second fastest growing economy after China. A changing in socioeconomic profile of Indonesia is in paralel with increase prevalence of tobacco smoking. Current data showed prevalence of current adult male tobacco smoking is 64.9% which predicted to increase to 79% in the year of 2030, while youth male prevalence of current tobacco use is 23.0% and current cigarette smoking is 21.4%. This number is highest for daily smoking rate in male, and two third Indonesian women are regularly exposed to second-hand tobacco smoke. Indonesia's life expectancy increased between 1990 and 2016 at 8 years to 71.7 years (7.4 years for male and 8.7 years for female). Double health burden due to mix of communicable and noncommunicable diseases. Of all proportional mortality, 35% are cardiovascular diseases, 12% cancer, 6% chronic respiratory diseases, 21% communicable, maternal, perinatal and nutritional conditions, 6% injuries, 6% diabetes. Noncommunicable disease are estimated to responsible for 73% of all death in Indonesia. The increasing leading causes of DALYs in 2017 as compared to 1990 are ischaemic heart disease, cerebrovascular diseases, diabetes, COPD, lung cancer. Tobacco listed as fourth risk factor of cause of death after high systolic blood pressure, dietary risks, high fasting plasma glucose. Tobacco control remains contradictionary within the country, despite strong national tobacco control program and government law implementation, Indonesia has yet to sign the WHO Framework Convention on Tobacco Control. National tobacco control program in Indonesia were transformed into specific national government objectives in tobacco control, such as national agency of technical unit for tobacco control, through MPOWER activities. **M**onitor tobacco use and prevention policies were implemented in Indonesian Law Article 26/2009 for Health and translated in Goverment Ordinant Article 109/2012 for the Security and Restriction of Addictive Substance of Tobacco and other several Presidential Decrees and Ministerial Decrees. **P**rotect people from tobacco smoke were implemented in Ministerial Decree, and Provincional Decree for for Tobacco Smoke Free policy. **O**ffer help to quit tobacco use were included in Ministerial of Health Decree and implemented in National Smoking Cessation Program. **W**arn about the dangers of tobacco were translated in Ministrerial Decrees Article 56/2017 for tobacco health effect warning in tobacco products and pictorial warning of tobacco smoke. **E**nforce bans on tobacco advertising, promotion and sponsorship were implemented through Indonesian Broadcasting Law Article 46 Clause 3B prohibits promotion of addictive substances, and **R**aise taxes on tobacco were implemented in Ministry of Finance Decree article 222/2017 regarding using, monitoring and evaluation of tobacco tax income. Moreover, Presidential Decree article 44/2016 and Ministry of Industry Decree Article 64/2014 for Regulation and Control of tobacco industry. Tobacco and related indutries argued against tobacco control policy by mentioning largescale effects of tobacco industry for Indonesian economy, and controlling tobacco industry will create massive unemployment, and economic crisis. Ministry of Industry of Republic Indonesia mentioned that tobacco industry creates 5.98 million employments, in which 4.28 million in manufacture and distribution, and 1.7 million people working in tobacco farming. In 2018, export rate of tobacco as cigarettes and cigar were 931.6 million USD, increasing 2.98% as compared to 2017. Tobacco company links closely to small medium enterprises as the tobacco company's social responsibility (CSR) program. One CSR program as retail community, was founded in 34 provinces, 408 cities which included 60,000 small business retail. Other tobacco related industry's CSR are including sports, youth and creative activities nationwide. Since 1968, Indonesia National Health insurance system was only implemented for formal sector, individual, civil servants, police and military member, but, since 2014, Indonesian Government launched Universal Health System called Jaminan Kesehatan Nasional (JKN) for all Indonesian. In 2017 approximately 180.7 million people are insured through JKN, 70% of total population and planned to reach 95% target in 2019. While tobacco industry tax income were IDR 153 trillion (approximately USD 10.9 billion) in the year of 2018, tobacco related lost due to early death and disease were IDR 4,200 trillion (one third of national GDP), and economy related lost due to tobacco consumption were approximately IDR 596 trillion. This should be bear in mind, that amount of tax income from tobacco company is incomparable to high burden loss due to tobacco related morbidity and mortality. ES20.05 TOBACCO CESSATION AFTER CANCER DIAGNOSIS: DECLARATION FROM IASLC

J. Jassem

Medical University of Gdańsk, Gdańsk/Poland

Tobacco Cessation After Cancer Diagnosis: Declaration from IASLC Tobacco use is a well established cause of cancer, contributing to about 1 in 3 cancer deaths annually. Whereas detrimental effects of smoking are well recognized, the harms of continued smoking after a cancer diagnosis are undervalued (1). Smoking by cancer patients and survivors causes adverse treatment outcomes, including increased overall mortality, cancer related mortality and risk for second primary cancer, and considerably increases cancer treatment toxicity (2,3). The clinical effects of smoking after a cancer diagnosis has a substantial effect on increased cancer treatment costs (4). Smoking cessation after a cancer diagnosis can improve cancer treatment outcomes (1), but most cancer patients who smoke at the time of diagnosis persist in a smoking habit during long term follow-up (5). Unfortunately, oncologists often do not work with their patients to quit, and do not provide tobacco cessation assistance for continuing tobacco users (6,7). Large analyses of IASLC members demonstrate that although most oncologists recognize that smoking

causes adverse outcomes, approximately 90% ask about tobacco use and 80% advise patients to quit, only few offer assistance with quitting (8). There is a clear and unmet need to address tobacco use in patients with cancer. The diagnosis of cancer is "the teachable moment", allowing health care professionals the best opportunity to discuss with patients their lifestyle habits, including nicotine addiction (9). An enhanced focus on smoking cessation at the time of a cancer diagnosis and its active promotion may increase patients' motivation to quit. All patients should be screened for tobacco use and advised on the benefits of tobacco cessation. In patients who continue smoking after diagnosis of cancer evidence-based tobacco cessation assistance should be routinely and integrally incorporated into multidisciplinary cancer care. Smoking status should be a required data element for all prospective clinical studies, and clinical trials of patients with cancer should be designed to determine the most effective tobacco cessation interventions (10). Recognizing the critical importance of smoking cessation to increase the efficacy of cancer treatment, these postulates will be a subject of IASLC Declaration presented at the 20th World Conference On Lung Cancer in Barcelona. ES21.01 OPTIMAL IMAGING FOR STAGING OF OMD

K. Irion[1], B. Hochhegger[2]

[1]*Manchester University NHS Foundation Trust, Manchester/United Kingdom,* [2]*Pontificia Universidade Catolica do Rio Grande do Sul (PUCRS), Porto Alegre/Brazil*

The role of imaging in oligometastatic disease in NSCLC: The current guidelines include a contrast-enhanced CT of the chest and upper abdomen as the baseline imaging investigation of lung cancer patients. A contrast-enhanced CT or MRI of the brain is indicated in patients who present with neurological signs/symptoms[1]. An additional investigation with PET-CT and MRI could be considered, "but only if their results could alter the treatment strategy"[2]. Lung cancer patients who are candidates to a radical treatment should be referred to a PET-CT if the initial investigations indicate a potentially curable disease[2]. Not infrequently, the identification of unsuspected metastasis on the PET-CT changes the initial staging to a stage IV, in a significant number of cases. A radical treatment can be considered for those with oligometastatic disease (OMD), which is defined by the National Cancer Institute as: "a small number of metastatic tumors in one or two other parts of the body"[3]. Discerning additional lung lesions as benign or malignant can be improved with the use of MRI[4,5]. Considering the limitations of PET-CT for detecting brain and liver metastases, MRI should be considered to avoid a futile extended radical treatment in this select group of patients[5]. This presentation will discuss the role of imaging in OMD patients being considered for extended radical treatment. 1. ES21.02 BIOLOGICAL DISEASE CHARACTERIZATION OF OMD

D. Gerber

UT Southwestern Medical Center, Dallas/United States of America

Variation in the characterization of OMD

Trial	OMD characteristics	OMD timing
Iyengar et al (2017)	· ≤6 sites of extracranial disease (including primary) · ≤3 sites in liver or lung ·Up to 2 contiguous vertebral metastases considered a single site	After first-line therapy and without progression
Gomez et al (2016)	· ≤3 metastatic sites · Any N1-3 thoracic nodes considered a single site · Satellite lesions counted as separate sites	After first-line therapy and without progression
Parikh et al (2014)	· ≤5 metastatic sites	After first-line therapy and without progression
Cheruvu et al (2011)	· ≤8 metastatic sites	At time of initial staging
Khan et al (2006)	· 1-2 metastatic sites · Definitive (surgery and/or chemoradiation) treatment of thoracic disease	After treatment of thoracic disease

Recent years have seen a marked increase in interest in the concept of oligometastatic disease (OMD) in non-small cell lung cancer (NSCLC). Lacking a precise and consistent definition, OMD is generally considered to represent a relatively favorable clinical state, with more indolent biology, a limited number of disease sites, and potential for prolonged periods of disease control. Discussions of oligometastatic NSCLC area inexorably linked with management considerations, specifically the use of local therapies such as surgery and radiation therapy. There are numerous clinical and biological rationales to support such approaches: (1) disease progression most commonly occurs in original sites of gross disease[1]; (2) metastatic sites may propagate secondary metastases (parallel progression model)[2]; (3) solid tumors are composed of faster growing (sensitive) and slower growing (resistant) cell populations (Norton-Simon hypothesis)[3]; (4) resistance depends on spontaneous mutations and therefore increases with time (Goldie-Coldman hypothesis).[4] Nevertheless, several questions regarding the characterization and optimal management of OMD remain (Table 1). Up to how many sites of disease constitute an oligometastatic state? Does a "site" of disease comprise a single lesion or neighboring tumors? Does the anatomic site matter? For instance, brain metastases have historically been considered a more favorable location for definitive treatment of OMD, and their emergence may reflect pharmacokinetic failure rather than molecular evolution.[5,6] Additionally, there are likely meaningful clinical differences between OMD states depending on whether they are defined at diagnosis (de novo), after initial exposure to systemic therapy (induced), recurrence, or progression. OMD may

also have a distinct biologic phenotype. The metastatic cascade includes loss of cellular adhesion, increased motility, primary tumor invasiveness, entry into and survival in the circulation, and entry into and colonization of distant organs.[7] Tumor dormancy, regulated in part by interferon signaling, may impact the number, location, and timing of metastases.[8] Expression of genes that positively regulate the cell cycle may determine whether cancer growth occurs as polymetastasis versus oligometastasis. Ideally, ongoing and future clinical trials will collect biospecimens for discovery and validation of OMD biomarkers, thereby enabling the identification of cases most likely to benefit from OMD treatment paradigms. ES21.03 INTERPRETING THE CURRENT DATA FOR LOCAL CONSOLIDATIVE TREATMENT IN THE SETTING OF OLIGOMETASTATIC DISEASE: WHERE DO WE STAND?

D. Gomez

Memorial Sloan Kettering Cancer Center, New York/United States of America

Over the past 15 years, several retrospective and single arm prospective studies suggested a benefit for local consolidative therapy (surgery, radiation therapy, or interventional radiologic ablation) in the setting of oligometastatic disease. More recently, a small number of randomized trials have provided further data regarding the utility of an agressive approach with regard to progression free and overall survival. With the considerable amount of emerging evidence, it can be difficult to aggregate and interpret the major themes across studies. This presentation will discuss the composite data of local consolidative therapy in oligometastases, with a particular focus on high impact non-randomized studies and the limited randomized trials addressing this topic. The presentation will then provide major conclusions that can be the basis for analysis going forward. Attendees will thus be provided with a summary of the current evidence in the oligometastatic disease context and a basis for future directions.

ES21.04 OPTIMAL SYSTEMIC TREATMENT OF OMD

H. Kunitoh

Japanese Red Cross Medical Center, Tokyo/Japan

A series of randomized trials (1-3), 2 of them specifically conducted for non-small cell lung cancer (NSCLC) patients (2,3), have shown that those with OMD could get clinical benefit from the addition of local ablative therapy to the standard systemic treatment. All 3 trials demonstrated improvement of progression-free survival (PFS), and 2 of them suggested overall survival (OS) benefit (1,2). OS was the primary endpoint of the 2 studies. In each of the trials, however, the "standard systemic treatment" was not specified; in fact, it was merely described that the systemic therapy was determined by the treating oncologists from a set of "standard-of-care options" (3). It would be easy to imagine that the "standard-of-care options" for OMD in these trials would be no different from those for other stage IV diseases. For NSCLC, they are cytotoxic chemotherapies according to histologic subtypes, appropriate target-based therapies when the tumors have druggable targets, and, more recently, immune-oncology (IO) drugs when the tumors have potentially predictive markers, such as PD-L1 (4) or tumor mutation burdens (5). The question is, is the optimal systemic therapy of OMD really exactly same with the "standards" of other, more advanced, poly-metastatic stage IV NSCLC? First of all, let me suppose that the disease is truly oligo-metastatic, meaning there are no other metastatic foci than those which are detected by the image scans. In this scenario, you do not require systemic therapy at all; the disease is "cured" by a series of local ablative therapies, since no other diseases exist. However, in the vast majority of the patients, this would not be the case. Instead, there should be some other "microscopic" metastases which are undetected by the scans, evade the local therapies, and get relapsed without systemic treatment. By focusing on the "microscopic metastases" status, you could make analogy to post-operative adjuvant therapy. After the apparently curative surgery, without no "macroscopic" metastases in sight, we usually use conventional chemotherapies for prevention of recurrence. It is hoped that these "cytotoxic" drugs would eradicate the residual cancer cells, leading to true "cures". The long-tails of the survival curves, with increased number of long-term survivors with the adjuvant chemotherapy (6), show that this theory actually works. On the other hand, use of target-based drugs as post-operative adjuvant therapy has so far had only limited success (7,8). The PFS is elongated, without OS benefit (7). It appears that the patients do as good with the use of "targeted" drugs after relapse, and those drugs suppress tumors only as long as they are taken (9). In other words, they appear "cytostatic" and unable to "cure" the disease. Results of IO adjuvant trials are not yet available, but the "long-tails" of the survival curves of IO treatment make us hope for strong cytotoxic, "cure-oriented" effect. Therefore, when you aim at "cure" of the OMD, you should choose cytotoxic chemotherapies and/or IO drugs. However, if you are to "control" the disease and get some OS improvement, target-drugs are strong candidates. Let me see the topic from another viewpoint. The "local ablative" therapies employed in OMD are surgery and (stereotactic) radiotherapy. Which systemic therapy would make a better partner to which local therapy? Almost all target drugs are eventually turned ineffective, due to acquired resistance. However, in some cases, you could elucidate the resistance mechanism and conquer it (10), with modification of the target-based "precision" medicine. At present, investigation of the tumor itself is the most certain method, as expressed in the "tissue is the issue" slogan. Very often, however, tiny pathological specimens obtained from transbronchial or CT-guided biopsies are insufficient for the full molecular analysis. Surgical resection of the tumor has advantages both in terms of curative therapy and supply of ample specimens. It also minimizes the late effect on pneumonitis, which is a rare but dreadful toxicity of target-based tyrosine kinase inhibitors. Taken together, use of surgery would be (more) appropriate when you use target-based drugs in OMD. On the other hand, there are some clinical data that prior use of radiotherapy is associated with better outcome of IO therapy, implying the so-called "abscopal" effect (11). Investigations are on-going, which are aimed at showing synergistic effect of stereotactic radiotherapy and IO treatment (12,13). This could be applied in the management of OMD. So, in conclusion, what is the optimal systemic treatment of OMD? It depends on the aim of the therapy, cure vs elongation of PFS/OS, as well as on the choice of main local therapy, surgery vs radiotherapy. Future studies should specify the aim of the clinical investigation, not only to maximize the efficacy of local therapies and benefit to the patients, but to increase the statistical power of the clinical trials. ES21.05 CLINICAL TRIALS TO ADVANCE THE FIELD OF OMD

T. Berghmans

Institut Jules Bordet, Brussels/Belgium

Oligometastatic disease (OMD) in non-small cell lung cancer (NSCLC) is a complex pathology. Four settings can be displayed where synchronous OMD (sOMD), occurring at the time of initial diagnosis, was the most evaluated in clinical trials. Other potential situations are oligorecurrence (rOMD), developed after optimal local control of a localised tumour, oligoprogression (pOMD) corresponding to a progression in a limited number of metastatic sites, and oligopersistant disease (peOMD) after/on systemic therapy. Several non-randomised phase II studies demonstrated the feasibility adding local ablative therapy (LAT) to systemic therapy in sOMD. Design, number of metastatic sites, type of LAT (chemoradiotherapy [CTRT], surgery, stereotactic radiotherapy [SBRT]) and endpoints largely differed among studies. A first pilot study (1) showed that surgery at the primary and the single metastatic sites after induction chemotherapy (CT) was feasible with 57% complete resection (R0) and 11 months median survival (MST). The same approach was recently confirmed in another prospective study with 71% R0 and 46.5% 5-years survival (2). Later, a phase II study conducted in The Netherlands and recently updated (3) demonstrated, when combining LAT (surgery or radiotherapy) to systemic therapy, MST of 13.5months but more essential, 5 and 6-years survival rates of 7.7% and 5.1% respectively. Other phase II studies, including NSCLC with <6 metastases, confirmed those results whether considering overall survival (4), metabolic response (5) or progression-free survival (PFS) (6). The first randomised phase II trial (RCT) compared, in sOMD with < 3 metastases non-progressing after CT, LAT (surgery, SBRT, CTRT) plus maintenance to maintenance only. The study closed early after first interim analysis and 49 randomised patients. Updated data confirmed improved PFS (14.2 months vs 4.4 months; p = 0.022) and MST (41.2 months vs 17 months; p = 0.017) favouring the LAT arm. A second small-sized phase II RCT closed early after interim analysis (8). 29 sOMD patients (≤5 metastases) not progressing after CT were randomised between SBRT plus maintenance or maintenance. Also median PFS improved from 3.5 months to 9.7 months (p = 0.01) in the LAT arm. All these data need confirmation in larger RCT. Four phase III trials are or will be ongoing. SARON (NCT02417662) is comparing standard CT alone to CT plus SBRT in sOMD with ≤ 3 metastases. In the OMEGA trial (NCT03827577), patients with synchronous or metachronous oligometastatic NSCLC (1-3 metastatic lesions) were considered for LAT (surgery or RT) or not in addition to systemic therapy. SINDAS (NCT02893332) is assessing the role of SBRT in addition to tyrosine kinase inhibitor in sOMD EGFR muted NSCLC with ≤ 5 tumoral sites (inclusive primary site; lymph nodes being considered as a metastatic site). Finally, HALT (NCT03256981) is a phase II-III RCT evaluating SBRT for pOMD during targeted therapy in NSCLC harbouring activating mutations. All these studies are presenting with various designs and primary endpoints, but also differences in staging procedures resulting in major difficulties for definite conclusions on the usefulness of LAT in OMD patients. In order having similar populations among clinical trials, we need that a common definition is used by all investigators. In this way, the EORTC Lung Cancer Group proposed a definition for sOMD based on a consensus from thoracic oncology experts (8). Using common definition and staging assessment, and finding predictive factors for a better patient's selection should be addressed in future clinical trials. 1. Downey et al. ES22.01 IMMUNOTHERAPY IN RESECTABLE NSCLC

P. Forde

Sidney Kimmel Comprehensive Cancer Center, Baltimore/United States of America

Immune checkpoint blockade with inhibitors of the PD-1/PD-L1 interaction have improved survival substantially for patients with advanced non-small cell lung cancer. Despite many clinical trials of different combination regimens, the benefit from perioperative platinum doublet chemotherapy in resectable lung cancer is modest with an approximate 5% improvement in 5 year survival over surgery alone. This session will review the background of systemic therapy for resectable lung cancer and data reported to date with single agent PD-1 blockade, PD-(L)1-based immunotherapy combinations, and chemotherapy combined with anti-PD-1. Ongoing phase 3 clinical trials of neoadjuvant and adjuvant immunotherapy will be discussed and future directions both in novel science and clinical trials explored.

ES22.02 A MILESTONE IN LOCALLY ADVANCED NSCLC

S. Peters

Centre Hospitalier Universitaire Vaudois, Lausanne University, Lausanne/ Switzerland

Stage III NSCLC encompasses locally advanced tumours with infiltration of locoregional nodes and central thoracic structures and accounts for about a third of newly diagnosed NSCLC[1]. It represents the most advanced stage of NSCLC in which treatment is delivered with curative intent, but eventually more than 60% of patients die from their disease. Stage III NSCLC patients must strictly be discussed in a multidisciplinary tumor board, whereat the definition of resectability suffers from a certain heterogeneity across centers. Resectability is usually defined by the degree of invasion of lymph nodes, most often excluding multilevel or bulky N2 and N3 disease as well as invasion of the oesophagus, aorta and myocardium. Controversy exists on the role of surgery in stage III NSCLC since two large randomized trials investigated either induction chemoradiation therapy followed by resection versus radiotherapy[2], or induction chemotherapy followed by resection versus radiotherapy[3]. Both studies failed to demonstrate a difference in survival[2-5], however these treatment strategies are evidence-based and can be pursued in restectable NSCLC[6]. In the surgical scenario, randomised trials and meta-analyses have consistently shown that either adjuvant or neoadjuvant chemotherapy added to surgery results, with a better survival than surgery alone[7,8]. Adding preoperative radiotherapy to chemotherapy in patients with stage IIIA/N2 NSCLC did not improve the clinical outcome in a phase 3 randomised trial[9]. The role of adjuvant radiotherapy in stage IIIA/N2 after neoadjuvant chemotherapy followed by surgery has been evaluated in a unique randomized trial with awaited results (Lung ART, NCT00410683). Early NSCLC stages offer a theoretical unique curative scenario for the development of immunotherapy startegies, with limited disease volumes, a relative immune system preservation as well as unique oportunities for the investigation and assessment of new biomarkers. Perspectives, rational, hopes and ongoing attempts to combine immunotherapy in the surgical setting or alterenatively complementary to chemoradiation will be discussed, with a focus on locally advanced disease. ES22.03 NEW HOPE IN SCLC?

L. Horn

Vanderbilt Ingram Cancer Center, Nashville/United States of America

Lung cancer is the leading cause of cancer-related death worldwide. Small cell lung cancer (SCLC) accounts for approximately 15-20% of cases. This aggressive tumor is characterized by rapid growth, early development of disseminated disease and dramatic responses to first line chemotherapy. For decades, first line therapy has traditionally included four to six cycles of platinum-based chemotherapy. While up to 80% of patients respond to first-line chemotherapy, the majority eventually relapse with a median survival of 8 to 12 months for patients with extensive stage disease and 12 to 20 months for those with limited stage disease. Until recently, topotecan was the only FDA approved second line therapeutic option. The shortcomings of traditional chemotherapy, as well as the limited role of targeted therapy in SCLC, led to the investigation of novel mechanisms to target lung cancer and specifically the discovery of immune checkpoint inhibitors. Immune checkpoint inhibitors work by blocking interactions between T cells and antigen presenting cells (APCs) or tumor cells. By inhibiting this interaction, the immune system is effectively upregulated and T-cells become activated against tumor cells. There are three major classes of checkpoint inhibitors. Ipilimumab and tremelimumab inhibit T-lymphocyte antigen-4 (CTLA-4); nivolumab and pembrolizumab target the programmed cell death-1 receptor (PD-1); and atezolizumab, durvalumab, and avelumab block PD-L1, the ligand of PD-1. Prior studies have shown lack of PD-L1 expression on tumor cells in patients with pulmonary and extra pulmonary SCLC. While PD-1 and PD-L1 are expressed in the tumor stroma of small cell carcinomas. [1] In addition PD-L1 has been shown to be prognostic in patients with SCLC.[2] The aggressive nature of SCLC is underscored by its high mutational burden, including loss of the tumor suppressor genes p53 in 75%–90% and retinoblastoma in almost 100% of tumors.[3] Higher tumor mutation burden has been associated with outcome in patients with select tumors treated with checkpoint inhibitor therapy, including non-small cell lung cancer. [4] Recently singly agent nivolumab and combination nivolumab and ipilimumab were shown to have activity in the second and third line setting for patients with advanced SCLC with response rates of approximately 10% and 20% respectively. Combination nivolumab and ipilimumab appeared particularly promising in patients with tumors with high tumor mutation burden and in 2018 nivolumab received approval in the third line setting for patients with advanced SCLC. [5] However, disappointingly Chekckmate 331, a large phase III trial of patients who had progressed on first line platinum-based chemotherapy, found nivolumab was not superior to topotecan or amrubicin in the second line setting. Recently a combined analysis of patients treated on the Keynote 158[6] and 028 trial[7] with pembrolizumab in the second line setting demonstrated a response rate of approximately 20% in patients, with a greater benefit in patients with tumors that were PD-L1 positive. In the first line setting, a single arm phase II trial demonstrated no benefit to maintenance pembrolizumab following induction chemotherapy in patients with advanced SCLC with a progression free survival of less than 2 months. [8] Earlier this year, a phase III trial (Checkmate 451) also found maintenance nivolumab with or without ipilimumab following induction chemotherapy in patients with advanced small cell lung cancer was not superior to placebo, suggesting this is not the optimal strategy in patients with advanced stage disease. Importantly, he Impower 133 phase III trial demonstrated combination chemotherapy with carboplatin, etoposide and atezolizumab was superior to chemotherapy alone in patients with advanced SCLC with a significant improvement in progression free and overall survival leading to FDA approval and a new standard of care for patients with advanced disease. [9] Two large phase III trials Keynote 604 and Poseidon are comparing a similar strategy with pembrolizumab and durvalumab respectively, with data anticipated in the upcoming year. While progress has finally been made. Limited tissue specimens in patients with SCLC remain a challenge and many unanswered questions remain including the optimal patient population in which these agents will have benefit (PD-L1 positive or negative, tumor mutation high or low), the optimal duration of therapy, the appropriate combinations (can we improve upon chemotherapy with a different checkpoint inhibitor), and the safety of these agents long term, particularly in patients with comorbid disease. ES22.05 ROLE IN THYMIC EPITHELIAL TUMOURS

R. Hui

Westmead Hospital and the University of Sydney, Sydney/Australia

Although thymic epithelial tumours (TETs) are rare, they are the commonest primary tumours of the anterior mediastinum. TETs are heterogenous with histological classification into thymoma and thymic carcinoma. Subtypes of thymomas include A, AB, B1, B2 and B3 depending on the presence of spindle cells, the relative proportion of lymphocytes and abnormal epithelial cells. The commonest histological subtype of thymic carcinoma is squamous cell, others include sarcomatoid, adenocarcinoma, basaloid etc. The traditional Masaoka-Koga staging system is widely used to stage TETs (I: no breaching of capsule; II: invasion through capsule to involve surrounding fatty tissue; III: invasion into nearby organs; IV: pleural/pericardial spread or distant metastases), while TNM staging (T1a: with or without invasion into mediastinal fat; T1b: mediastinal pleura; T2: pericardium; T3/T4: nearby organs; N1: peri-thymic anterior mediastinal nodes; N2: deep thoracic or cervical nodes; M1a: separate pleural or pericardial nodules; M1b: distant metastases) has been introduced more recently. The prognosis of TETs depends on both histology and disease extent. Thymomas are usually more indolent with 10- year overall survival rate of >80% for

stage I and II, but thymic carcinoma confers poorer prognosis with 5-year survival of around 50% for stage III and 25% for stage IVa. The treatment of choice for early stage disease is surgical resection with curative intent. Concurrent chemoradiation can be considered for unresectable locally advanced TETs. 10-15% of resected TETs recur and radical radiation may be appropriate for local recurrence. In unresectable stage III and IV disease with spread to pleural and pericardial cavities or beyond, standard first-line systemic treatment is platinum-based chemotherapy, usually with cisplatin, doxorubicin and cyclophosphamide. Although TETs are reported to be chemo-sensitive with a response rate (ORR) of 50% for thymomas and around 20% for thymic carcinoma, they ultimately will progress and research into second-line treatments besides chemotherapy is important. Targeted therapies including sunitinib and everolimus with disease control rate (DCR) of >80% in previously treated TETs have been reported. Cancer treatment landscape has been rapidly evolving in recent years due to the successful development of PD1 blockade in many cancer types including melanoma, non-small cell lung cancer, bladder cancer, renal cell cancer, head and neck cancer, etc. The function of thymus during childhood in the production, differentiation and maturation of immunocompetent T cells together with the observation of high level of PD-L1 expression in normal thymus and TETs suggest a possible role of immunotherapy in TETs. Of 40 eligible patients with chemotherapy refractory thymic carcinoma in a phase 2 study, pembrolizumab provided an ORR of 22.5%, DCR of 75%, median progression-free survival (PFS) of 4.2 months, and median overall survival (OS) of 24.9 months with 1-year OS rate of 71%. Exploratory analysis in this study suggested an association of high-level PD-L1 with longer PFS and OS. A similar phase 2 study of pembrolizumab after at least 1 line of chemotherapy in Korea included 7 patients with thymoma and 26 patients with thymic carcinoma achieving an ORR of 27% with DCR of 100% in thymoma and ORR of 19% with DCR of 73% in thymic carcinoma. A phase 1 study with avelumab showed confirmed ORR of 29% with DCR of 86% in 7 thymoma patients and stable disease in the 1 thymic carcinoma patient. As thymus is involved in positive and negative T cell selection process for self-major histocompatibility complex molecules, thereby inducing self-tolerance avoiding auto-immunity, one third of thymoma is associated with autoimmune diseases, the commonest being myasthenia gravis. Other associated autoimmune conditions include systemic lupus erythematosus, pure red cell aplasia, syndrome of inappropriate anti-diuretic hormone secretion, bullous dermatoses autoimmune blistering diseases, polymyositis, dermatomyositis, pernicious anaemia, haemolytic anaemia, scleroderma, Sjogren's syndrome, rheumatoid arthritis, ulcerative colitis, Takayasu syndrome, Grave's disease etc. However, autoimmune disorders are much less likely to occur in thymic carcinoma. It is not surprising that a significant incidence of immune-related adverse events (irAE) is evident with immune-checkpoint inhibitors in the treatment of TETs with higher frequency of irAE in thymoma than in thymic carcinoma. 71% of patients with thymoma and 15% of patients with thymic carcinoma treated with pembrolizumab in the Korean study experienced grade 3-4 irAE including 12% hepatitis, 9% myocarditis, 6% myasthenia gravis, 3% thyroiditis, colitis, nephritis and myoclonus. The other phase 2 pembrolizumab study in patients with thymic carcinoma also reported similar incidence of 15% severe irAE with 5% myocarditis. IrAE was observed in 63% of patients in the phase 1 avelumab study with 38% myositis and 13% enteritis. PD-L1 status did not predict irAE. In conclusion, the main issue of PD1 blockade in TETs is common irAEs with higher frequency in thymomas. Therefore, immunotherapy is still not standard of care, needing further research to identify possible biomarkers to spare patients with less likelihood to benefit taking the risk of serious irAEs. There may be a role of immunotherapy in advanced TETs with aggressive pathology after failing chemotherapy, but thorough discussion with patients about the potential irAEs is warranted. ES23 OPTIMAL MANAGEMENT OF N2 DISEASE IN THE ERA OF IO
TUESDAY, SEPTEMBER 10 11:30–13:00

ES23.01 MEDIASTINOSCOPY WITH INVASIVE STAGING: ARE THEY STILL CRUCIAL?

A. Turna

İstanbul University-Cerrahpaşa Cerrahpasa Medical School, İstanbul/Turkey

There are more multiple treatment strategies for non-small cell lung cancer(NSCLC) that should be selected based on staging of the disease. Nodal status indicates N component of staging and studies invariably show that upfront surgical resection of patients with mediastinal lymph node involvement (i.e., N2 or N3) is not recommended. Evidence suggest that, T1-4N2-3M0-1c patients should firstly receive oncological treatment; otherwise, surgical treatment could be deemed to be futile. Accordingly, mediastinal lymph node involvement prediction as accurate as possible is recommended before any treatment planning. PET-CT, Endobronchial ultrasonography-transbronchial aspiration (EBUS-TBNA), endoscopic ultrasound-guided-fine-needle aspiration(EUS-FNB) have all inherent limitations. Mediastinoscopy has been defined to be gold standard for preoperative disclosure of mediastinal lymph node metastasis. However, small biopsy material due to being an incisional biopsy, practically low number of explored mediastinal stations (usually median number of 2 or 3) led to approximately 10% of false negativity rate. Also studies showed that, even the fact that, mediastinoscopy has been recommended to be performed in all patients except the patients with non-discrete lymph node involvement or in the patients with peripheral cT1a-cN0M0 patients, a fraction of thoracic surgeons prefer to comply with the published guidelines. Video-assisted mediastinoscopy lymphadenectomy(VAMLA) was developed to reduce the false negativity rate below statistically non-significant levels (below 5%). It involves dissection of at least 5 lymph nodes stations and some evidence suggest that, VAMLA is associated with better survival rate beyond selection bias phenomenon. Transcervical extended mediastinal lymphadenectomy (TEMLA) is a technically more advanced mediastinal lymph node dissection procedure that is a definition of a resection of lymph nodes from #1-9 bilaterally including aorticopulmonary and anterior mediastinal lymph nodes. The accuracy of TEMLA has been reported to be 98.4%. Taking all those achievements into consideration, VAMLA or TEMLA or at least video-mediastinoscopy should be performed before selecting a therapeutical option in a patient with potentially resectable operable NSCLC. However, recent advancements in computational science could propose us that, possibly, there is enough information for us to predict mediastinal lymph node positivity without performing any invasive procedure. Artificial Intelligence (AI) is accomplished by computers that use algorithms, pattern matching, rules, deep learning and cognitive computing to approximate conclusions using previously defined analog or digital parameters. AI aimed to mimic the brain's neural networks. It uses multiple layers of non-linear processing units to teach itself how to understand data classifying the record or making predictions. In a study, we aimed to evaluate the value of artificial neural network(ANN) for mediastinal nodal metastasis, by using only clinical and radiologic data. In our data set, ANN predicted mediastinal nodal involvement perfectly (AUC:1) in both training and test groups. When we used 'traditional' univariate and multivariate analyses, younger age (<65) (AUC:0.59) and higher SUVmax (>2.5)(AUC:0.67) were associated to be mediastinal nodal involvement. ANN prediction was better and it was even more sensitive than VAMLA! However, specificity of ANN resulted to be less than 0.9 in some training analyses. The major limitations of ANN include its variability, non-transparency and non-consistency. Nevertheless, there is a possibility that, ANN could provide better predictions and it may help us to identify and narrow down the patients who need invasive staging. However, the usage of ANN in medicine has been continuously expanding. Future studies are needed to understand the exact place of ANN in mediastinal staging.

ES23.02 WHICH N2 PATIENTS ARE CANDIDATES TO SURGERY IN THE ERA IF I/O?

E. Vallieres

Swedish Cancer Institute, Seattle/United States of America

The role of surgery in patients with pre-resection documented N2 disease remains a subject of controversy. In some institutions, any clinical N2 disease identified preoperatively is considered non-surgical and these patients are offered upfront definitive chemoradiation therapy (DefCRT) without planned resection. In other institutions, a selective approach to N2 patients will consider surgery as part of a multimodality approach where surgery may be offered first followed by adjuvant cytotoxic chemotherapy (AC) with or without sequential post-operative radiation therapy (PORT), or where surgery will be offered after induction chemotherapy or induction chemoradiation therapy. Due to variability in N2 disease presentation, factors determining this selective approach vary between institutions and may include the bulk of N2 nodal involvement (size), extent of N2 involvement (single vs multistation, microscopic vs macroscopic), the presence or absence of extracapsular nodal involvement, the need to perform a pneumonectomy or not, and mediastinal sterilization after induction therapy. Historically, response to induction therapy with clearance of N2 nodal involvement following induction therapy has been shown to bode for a better prognosis after surgical resection. Unfortunately, even after complete resection following induction therapy, many patients develop distant metastases, with brain metastases prevailing. In 2018, the PACIFIC trial showed that adding an immune checkpoint inhibitor (IO) durvalumab for up to one year after completion of DefCRT in non-surgical stages cIIIa and cIIIB patients led to a significant and unprecedented overall survival in this population of patients. (Antonia, NEJM 2018) In patients with resectable NSCLC (cIIIA and less), recent small phase I clinical trials of either single-agent induction IO (Forde, NEJM 2018) or concurrent induction chemoimmunotherapy (Provencio, JTO abst. 2018) given before surgery have demonstrated feasibility, acceptable toxicity, and unprecedented pathological response rates. It remains to be seen if these pathologic responses will translate into improved overall survival in this patient population. Extrapolating from these early observations, one may think that induction IO (likely with concurrent cytotoxic chemotherapy) may possibly allow us to offer surgery to a larger proportion of patients with clinical N2 disease in the future as we observe higher response rates to induction therapies which may translate in better survival. Others may want to extrapolate from the Pacific trial results and hypothesize that surgery followed by adjuvant IO may become a desirable option. Though encouraging, there is a paucity of data to help guide us in the incorporation of IO therapy perioperatively for patients with clinical N2 disease. As such, the role for IO in multimodality treatment for N2 disease remains undefined. Unknown are the true impacts of periop IOs in this patient population and what is the optimal combination and timing of these multimodality treatments. There are more unanswered questions than established guidelines: (1) whether "IO first then surgery" is superior to "surgery first then adjuvant IO", (2) whether an induction IO strategy followed by resection would be superior to DefCRT followed by IO in this population of potentially resectable cN2 IIIA patients, (3) if induction IO is shown to be superior, how many cycles preop, (4) do we need to continue IOs post op, if so, for how long, (5) whether there will be a role for surgery after major response to IO, and (6) how will we select patients for resection when major pathological response rates will be in the 80% range (7) do we need to utilize biomarkers, tumor mutation burden, or genotyping in patient selection, (8) What is the best biomarker to predict response, among other questions. The easy answer at this stage is to treat these patients on trials where the impact of IOs can be rigorously studied. Ideally, I personally would want to compare: (1) Induction vs adjuvant IOs for surgical patients with cN+ disease, (2) Induction IO followed by resection vs DefCRT followed by IO. The duration of periop IO also needs to be evaluated and these studies should include cost analysis as well. For the surgeons, as systemic treatments improve, our duty is to perform sound oncological surgery with minimal morbidity and minimal to absent mortality. I believe that preop IO may allow us to consider surgical resection for a larger proportion of cIIIA N2 patients in the future.

ES23.03 IS CT/RT FOLLOWED BY I/O THE STANDARD OF CARE FOR ALL N2 AND SELECTED N3 PATIENTS?

W. Eberhardt

Universitaetsmedizin Essen and Ruhrlandklinik, Essen/Germany

Background: Immunotherapy consolidation with PD-L1-Ab has changed the current standard treatment for unresectable patients with stage III NSCLC (in Europe with PD-L1-exp by IHC > or = 1%) who are not progressing following definitive chemoradiotherapy[1,2,3]. More and more issue comes up for which patients this new strategy should be adopted, and for whom these data do not represent the new standard. Here we will try to analyze current evidence of stage selection for this multimodality approach. Methods: We analyzed the existing evidence on outcome results of stage III NSCLC subsets based on the new 8th-version of the IASLC/UICC staging classification and expert consensus[4,5] and current outcome data on stage III subsets within large landmark randomized trials[6,7,8,9,10] and possible permutations of chosen multimodality treatment approaches. Results: The PACIFIC Trial included only unresectable patients with stage IIIA and stage IIIB (based on the old UICC7 staging classification)[1,2,3]. No detailed data on T- and N-subgroups as well as transferring the data to the new UICC8 stage subsets IIIA/IIIB/IIIC were given in the manuscript[1]. Definition of "unresectable stage IIIA and IIIB" was probably best carried out as "individual local descision within tumor boards including thoracic surgeons to define disease resectability status". Nevertheless, no clear definition on selection for unresectable disease is given in the trial description of the PACIFIC publication. The overall two- and three-year-survival results were excellent and showed a significant and clinically meaningful benefit for patients receiving PD-1-antibody consolidation for one year[2,3]. Based on current evidence and consensus[4,5] about 15 to 20% of stage III patients are still ocnsidered to be potentially resectable. The majority of these belong to the IIIA(N2) diasease subset. Only one recently published clinical phase-III trial included subgroups with T4N0 (stage IIIB UICC7/stage IIIA/UICC8)[8]. Outside of multimodality groups with specific expertise, stage IIIB(UICC8) and stage IIIC(UICC8) are considered unresectable and would definitely be put on definitive chemoradiotherapy protocols. Only three large randomized trials[6,7,8] included resectable patients subsets of stage IIIA(N2)-disease (INTERGROUP 0137, SAKK, ESPATUE). The treatment strategies within these trials were induction chemotherapy followed by surgery versus induction chemotherapy followed by radiation and followed by surgery[6], induction chemoradiotherapy followed by surgery versus definitive chemoradiotherapy[7]or induction chemotherapy followed by concurrent chemoradiotherapy and surgery versus induction chemotherapy followed by concurrent chemoradiotherapy and definitive chemoradiation boost[8]. All three trials including surgery in at least one of the randomization arms gave a detailed description of T- and N-subgroups in their overall patient characteristics. All three clinical trials had PET-CT and detailed mediastinal staging techniques included into the initial patient selection descision (either mediastinoscopy or recently EBUS). All three trials had excellent overall survival outcomes in each of their randomization arms. Five-year survival results were somewhere betweeen 20% and 44% observed in the three randomized trials. In all three trials no significant difference was noted for OS between the different randomization arms while the OS results in all treatment groups of the studies can be considered excellent. However, in all three trials a low accrual rate was generally noted, and the overall duration of the clinical trials was around six to eight years in all three, pointing to a considerable selection procedure of patient inclusion. The two large randomized clinical phase-III trials investigating modern chemoradiation techniques[9,10] included per definition only "unresectable stage IIIA and IIIB patients subsets" (following the old UICC7/UICC6 classification). However, in both trials (PROCLAIM and RTOG 0617) no detailed TN-subgroups were given, but they included rather IIIA and IIIB definitions based on PET-CT staging as well as biopsy confirmation of N2- or N3-tumor-positive lymph nodes at staging work-up. FIve-year overall survival data turned out somewhere around 30% of the initially included patient groups within the two trials. The only group that showed a significantly worse outcome was that with the higher total radiation dose of 74 Gy in the RTOG study (no comment on this issue here). Nevertheless, all survival outcomes showed overall excellent five-year survival data in these two chemoradiation trials, too. Median OS data were between 25 and 29 months observed. There are considerable difficulties to compare all six randomized trials (PACIFIC, RTOG

0617, PROCLAIM, SAKK-TRIAL, INTERGROUP 0139, ESPATUE) based on the difficulties to compare patient selection and included TN-subgroups. Thus the above mentioned relevant differences in patient selection and accrual between the pure chemoradiation trials and the randomized trials including surgical arms cannot be overcome by comparing TN-data from these studies. All three definitive chemoradiation trials did only give IIIA and IIIB subset numbers of their patient population. However, patient accrual was much faster in all three definitive chemoradiation studies, pointing to a less selective patient inclusion into these trials. Some of the differences in the observed OS and PFS results noted could in fact be based on these different patient selection procedures rather than on differences between the individual treatment strategies. Conclusion: Based on a differential analysis of the recent five largest randomized phase-III trials with multimodality treatment of stage III NSCLC, we cannot readily compare the patient selection for "pure" concurrent chemoradiotherapy trials on one hand, to that within multimodality trials including surgery in at least one trial arm on the other side. This strongly points to the fact, that we cannot currently widen up any indication for an inclusion of immunotherapy for subsets of patients with potentiallly resectable stage III NSCLC. Patient with resectable stage III (mostly IIIA) should either be treated within multimodality protocols including surgery (based on the local expertise) or should be offered to participate within clinical trials that try to implement immunotherapy with PD-1 or PD-L1 antibodies into this multimodality setting including surgery. Several clinical studies wirth induction chemoimmunotherapy followed by surgery or induction chemoimmunotherapy/chemoradiationimmunotherapy followed by surgery are currenlty being performed by different multimodality treatment groups. The practice-changing results of the PACIFIC trial for unresectable stage III disease leave us very enthusiastic, that this new approach could also improve the results for potentially resectable stage III patients groups in NSCLC. [1]Antonia, NEJM 2017 [2] Antonia, NEJM 2018 [3] Gray, ASCO 2019 [4]Goldstraw, J Thorac Oncol 2016 [5]Eberhardt, Ann Oncol 2015 [6]Pless, Lancet 2015 [7]Albain, Lancet 2009 [8]Eberhardt, J Clin Oncol 2015 [9]Senan, J Clin Oncol 2016 [10] Bradley, Lancet Oncol 2015

ES23 OPTIMAL MANAGEMENT OF N2 DISEASE IN THE ERA OF IO
TUESDAY, SEPTEMBER 10 11:30–13:00

ES23.04 OPTIMAL SUPPORTIVE CARE DURING AND AFTER CONCURRENT CHEMORADIOTHERAPY AND I/O

D. De Ruysscher[1,2], K. Nakaerts[2]

[1]*Maastricht University Medical Center, Maastricht/Netherlands,* [2]*University Hospitals Leuven/ KU Leuven, Leuven/Belgium*

Concurrent chemotherapy and radiotherapy (CCRT) is the treatment of choice for most fit patients with locally advanced NSCLC. Recently, adjuvant durvalumab has improved the overall survival further. However, CCRT is a toxic treatment. Treatment-related deaths occur in a few percent of patients and many suffer severe side effects that require medical interventions and even in-patient care. In contrast to extensive research on infections and emesis, most data on other important side effects are scant. Two examples of this are acute esophagitis and cough and dyspnea. *Correlation between dysphagia and endoscopic findings* In a prospective trial with 38 patients receiving radiotherapy alone for lung cancer, an endoscopy was done during radiotherapy when patients had received a dose of 30-40 Gy on the esophagus. Eighteen patients (47 %) had dysphagia of any grade, but only in 12 of them (67 %) endoscopy showed esophagitis. Of the remaining 20 patients without complaints, 5 (25 %) had endoscopic signs of esophagitis. Gastritis was found in 18 patients (47 %), with or without esophagitis. In another study, 82 NSCLC patients were evaluated by endoscopy. There was a good correlation between the RTOG clinical score for dysphagia and the endoscopic findings (Spearman rank correlation coefficient 0.428; p< 0.0001). All patients with clinical grade 3 dysphagia had endoscopic grade 2 or 3 esophagitis. Also in case of RTOG grade 2 dysphagia, all patients had endoscopic esophagitis, although 40 % had endoscopic grade 1 and 27 % had endoscopic grade 3 esophagitis. Of patients with or without only mild (grade 1) dysphagia, 11 % showed grade 3 endoscopic esophagitis. Sixteen percent of patients has esophageal candidiasis, but its relation with dysphagia or endoscopic grade of esophagitis was not reported. No data on the incidence of gastritis were given. *Effect of radiotherapy on esophageal motility* An impaired esophageal motility may also lead to dysphagia. The esophageal transit time (ETT) before and during (10 Gy and 30 Gy) radiotherapy alone was evaluated in 11 patients. An increase in the ETT was seen in 9 of 11 patients (82%) (p<0.05). The ETT was also investigated in 18 breast cancer patients receiving radiotherapy to the inner quadrants of the breast using a dose of 50 Gy/ 25 fractions. The cranial part of the esophagus received a mean dose of 6 Gy/ 25 fractions, and the distal two-thirds a mean dose of 15.3 Gy/ 25 fractions. Comparing the ETT before and after radiotherapy, for the upper third and the distal two-thirds of the esophagus, the ETT increased from 4.77 ± 1.08 sec. to 6.92 ± 2.15 sec., from 11.22 ± 2.85 sec to 23.30 ± 5.65 sec. and from 11.61 ± 2.97 sec. to 23.74 ± 5.70 sec., respectively (p<0.001). Because of the motility impairment even at very low radiotherapy doses, the use of proton pump inhibitors is logical. *Prevention and treatment of acute esophagitis* In a randomized study with advanced NSCLC patients, treated with radiotherapy alone or radiotherapy plus amifostine, amifostine reduced the incidence of esophagitis in week 4 during radiotherapy from 42 % (31/73) to 4 % (3/73) (p<0.001), without decreasing the tumor response 2 months after treatment. In a larger randomized series of the RTOG, 243 stage II-III NSCLC patients were enrolled and randomized between carboplatin-paclitaxel concurrent chemo-radiotherapy with or without amifostine. No significant differences between the arms regarding overall survival, disease-free survival or long-term toxicity were observed. In another study, 60 stage III NSCLC patients were randomized between concurrent carboplatin-paclitaxel and radiotherapy with or without amifostine. No significant difference in esophagitis was observed. Therefore, amifostine has no consistently proven effect of preventing acute radiation-induced esophagitis. In a small double-blind study, 14 stage III NSCLC patients were randomized between placebo or prophylactic indomethacin. Endoscopically-assessed esophagitis seemed to be milder, but no firm conclusions could be drawn. Another small, placebo-controlled randomized trial, investigated naproxen in 28 stage III NSCLC patients receiving radiotherapy alone. There were no differences in clinical or endoscopic esophagitis rates. Eight patients (29 %) developed esophageal candidiasis, with no difference between the groups. A placebo-controlled randomized trial could not demonstrate a beneficial effect of sucralfate on dysphagia. In NRG/ RTOG 1012, patients were randomized between prophylactic Manuka honey, either in liquid or in lozenge form, and standard supportive care during concurrent chemo-radiotherapy for NSCLC. Standard supportive care consisted of a compound containing viscous lidocaine, an antacid such as magnesium aluminum oxide, and liquid or solid oxycodone, 5–10 mg, every 3 hours as needed. The primary endpoint was patient-reported pain on swallowing utilizing an eleven point (0–10) scale at 4 weeks (Numerical Rating Pain Scale, NRPS). Fifty-three patients were randomized to supportive care, 54 randomized to liquid honey and 56 to lozenge honey. There was no significant difference in the primary endpoint of change in the NRPS at 4 weeks between arms. There were no differences in any of the secondary endpoints except for opioid use at 4 weeks during treatment between the supportive care and liquid honey arms (p=0.03), with 52 % vs. 67 % of patients experiencing no pain with liquid honey. No difference was observed with lozenge honey. with more patients on the supportive care arm taking opioids. However, the differences were only observed at 4 weeks and not at the end of radiotherapy. From this example, already, it is clear that more in-depth knowledge of the physiopathology of radiation injury is needed. A joint task force between ESTRO and ESMO members will address a spectrum of supportive care interventions in patients receiving concurrent chemotherapy and radiotherapy for lung cancer.

ES23.05 THE FUTURE OF SYSTEMIC THERAPY IN STAGE III

P. Garrido

Hospital Universitario Ramon y Cajal. IRYCIS, Madrid/Spain

Stage III NSCLC comprises a very heterogeneous group of patients with regard to tumor extent, prognosis, and treatment options. It represents between 25-30% of NSCLCs and the majority of them are unresectable. Potentially curative treatment of unresectable stage III necessitates adequate locoregional control as well as control of the micrometastatic disease that is likely to be present in most patients. Several randomized clinical trials dating back

as far as 20 years and metanalysis have shown the superiority of cisplatin-based chemotherapy and radiotherapy over radiotherapy alone. Sequential versus concomitant approach has been directly compared in several trials; almost all of them showed a trend in favor of concomitant treatment. These results clearly supported the use of concomitant chemoradiotherapy as standard of care for these patients[1] fit enough to tolerate the risk of severe toxicity, particularly grade 3-4 esophagitis that is the most common adverse effect of the concomitant approach. Attempts to improve outcomes have included studies of radiotherapy dose escalation and new chemotherapy combinations, as well as adding biological agents and cancer vaccines to existing regimens. Technical radiotherapy modifications, including intensity-modulated radiotherapy and particle beam therapy, have also been investigated. In spite of it, the long-term survival has remained largely unchanged for many years, with only 15% of patients are alive at 5 years. In the last years, immune-checkpoints blockade revolutionized the standard of care of metastatic NSCLC. The PACIFIC study is an randomized, double-blind, placebo-controlled, multi-centre, phase 3 study to evaluate the efficacy and safety of durvalumab compared with placebo, as sequential therapy in patients with locally advanced, unresectable stage III NSCLC who have not progressed following definitive, concurrent platinum-based chemotherapy and thoracic RT. The study was positive for both primary endpoints progression- free survival (HR=0.51; 95%CI: 0.41-0.63)) and overall survival (HR=0.68; 95%CI: 0.49-0.99; p=0.00251)[2]. This benefit was observed in both non-squamous and squamous histology as well as in both stages IIIA and IIIB NSCLC. Based on this study, there is a new standard of care for unresectable stage III NSCLC patients. Nevertheless, improving outcomes for patients with stage III disease remains a challenge and many questions have to address in well-designed clinical trials. 1.- Postmus PE, Kerr KM, Oudkerk M et al. ES25.01 LIQUID BIOPSY: STATE OF THE SCIENCE

E. Jantus-Lewintre[1,2,3]

[1]*CIBERONC, Spain/Spain*

I. The present. Molecular diagnosis in cancer certainly requires the analysis of a tumor biopsy. However, in lung cancer, there is still a 20- 30% of tissue failure rates for tumor genotyping in routine pathological samples. As a consequence, liquid biopsy (LB) has emerged as a valid alternative source of information for the analysis of tumor specific alterations. LB refers to specimens obtained from body fluid such as blood, urine, saliva, cerebrospinal fluid, among others. In the complex matrix represented by blood, the main clinical developments have focused on the analysis of: i) circulating tumor DNA (ctDNA), which represents a small part of cell free circulating DNA released from tumor cells and, ii) circulating tumor cells (CTCs), defined as disseminated cancer cells in the bloodstream. Each of these materials offers unique opportunities to test different biomarkers and to analyze characteristics of the tumors. The advantages of the use of blood samples are clear: i) it is a minimally invasive way to get relevant tumor information, ii) serial samples can be obtained capturing tumor evolution in real time, iii) LB abrogates the limitations associated with tumor heterogeneity, since nucleic acids or tumor cells present in circulation recapitulate the information belonging from different tumor locations (primary tumor and metastases), iv) the development of new sensitive assays for analyses of ctDNA and CTCs allow the assessment of minimal residual disease and v) the costs of LB analysis are comparable with other molecular biology techniques already used in the clinical setting in addition to the reduced risks of complications associated with tissue biopsy. All these factors accelerated the implantation of LB in the clinical practice in oncology in several scenarios, especially in lung cancer. I.1.Lung Cancer. Clinical applications of liquid biopsies. At present, LB is no longer a promise but a reality allowing better treatment selection, real-time monitoring of lung cancer patients and early detection of acquired resistances. Figure 1 highlights the biological basis of LB as a source for biomarkers analysis and key clinical applications in lung cancer. •Personalized therapeutics/ Resistance detection: regarding the detection of tumor-associated genetic alterations in LB samples, there are a lot of scientific data demonstrating similar response rates to targeted therapies than the obtained in tissue biopsies. In particular, in the context of NSCLC patients with progressive or recurrent disease during treatment with TKIs, the IASLC guidelines suggest the use of LB-first algorithm to detect resistance mechanism. For those lung cancer patients receiving immune-based therapeutic treatments, recent data show that assessment of tumor mutational burden in plasma (bTMB) correlated with the values found in tissue and predicts efficacy of immune-checkpoint inhibitors. •Detection of minimal residual disease: Persistent detection of ctDNA or CTCs after local therapy or after adjuvant treatments was found associated with poor clinical outcome. In this particular clinical setting it is important to highlight that sensitivity of the methods used for ctDNA or CTCs evaluation really matters. •Real-time monitoring of disease: this is one of the most interesting application of LB, since tissue biopsies are intrinsically unable to capture tumor heterogeneity while ctDNA can comprehensively recapitulates clonal evolution over time, allowing to early detect and track the emergency of resistance mutations. II. The future. Current assays for LB analysis do not meet all the needs required for the fully implementation of the Precision Oncology. There is still room for improvement to reach its maximum informative potential. Hopefully, studies on exosomes, platelets, cfRNAs, metabolites, will help to have a more integrative picture of tumor status at each time it is evaluated. One of the clinical applications in which LB is called to play a key role is in the screening and early detection of lung cancer. In this regard, there are some interesting data coming from multiparametric (DNA and protein) plasma analysis. However, caution is required since there are still some important issues, such as clonal hematopoiesis, that need to be further considered. Another important challenge for LB is standardization. It is necessary to cross-validate platforms, standardize pre-analytical issues, compare sensitivity of different methodological approaches and also to work in the harmonization of bioinformatic tools for data analysis. It is clear that in the near future, tests based on the analysis of "liquid biopsies" will be more generalized, offering complementary information to tissue biopsies and providing valuable information to early diagnose lung cancer, to detect molecular progressions even prior to radiographic or clinical progression and as a source for real-time treatment monitoring. ES25.03 LEVERAGING THE QUANTITATIVE NATURE OF CFDNA GENOTYPING FOR LUNG CANCER CARE

C. Paweletz

Dana-Farber Cancer Institute, Boston/United States of America

Nearly 70 years after the discovery of free-floating DNA in the blood, also known as cell free DNA (cfDNA) (1), plasma genotyping of cfDNA is transforming cancer care with promise in non-invasive genotyping, early diagnosis, and disease prognostication by detection of minimal residual disease (MRD). At present the most widespread use of cfDNA in lung cancer is detection of mutations in *EGFR* and *KRAS* or re-arrangements in *ALK*and *ROS1* in the metastatic setting. In fact, the only FDA approved liquid biopsy test among all cancers is Roche's Cobas plasma EGFR mutation test for non-small cell lung cancer. (NSCLC) (2), while many diagnostic companies have developed PCR or next generation sequencing (NGS) laboratory developed tests that are commonly reimbursed by payors in house. Next-generation sequencing (NGS) permits broader inquiries, allowing assessment of the mutation status of thousands to millions of bases. The use of cfDNA in early cancers is confounded by the fact that early detection demands ultra-sensitive assays of low abundant biological markers. As proof of concept Bettegowda et al. performed digital PCR on cfDNA of 640 cancer patients of varying cancer type and stage. Intriguingly they found that rates of tumor DNA differed by tissue of origin, and 47% of stage I cancers and 55% of stage II cancers had detectable circulating tumor DNA (ctDNA) (3). An observation that as we and others have confirmed is a main source for false negatives (4). At present, NGS efforts are focused either on targeted approaches using either barcoded targeted amplicon (TAmSeq) or hybrid capture approaches (CAPP-Seq) covering 10Mb to 50Mb at reported sensitivities of 0.01% to 0.50% for fit for purpose build NGS assays. However, pushing assay sensitivity increases false positives. Recently, we and other have found that false positives are reported in many commercial assays and are routinely attributed to 'tumor heterogeneity'. These can be attributed to DNA shed from normal cells, including germline variants or non-cancerous somatic variants from clonal hematopoiesis (CH) (5-8). The latter is particularly challenging because CH can involve cancer-associated genes (e.g. TP53, JAK2, KRAS). To limit false positives and to investigate the common link between cancer-related mutations within the blood and underlying malignancies broad sequencing of cfDNA should also detect other cancer-related mutations, such as inactivating mutations in tumor suppressors and include assaying of the patients blood cells to filterout germlines. Thus, deep and broad sequencing could provide sensitivity needed to detect low levels of cfDNA alterations in early stage patients. Indeed, Abbosh et al. perform multi region whole-exome sequencing of early-stage NSCLC tumors to show an abundance of clonal mutations in these tumors (9). Abbosh and colleagues provide an intriguing solution to this issue by requiring the detection of two or more SNVs for the determination of the presence of cancer.In this presentation we present factors affecting ultras sensitive assays with particular emphasis on interpretation of commercial tests and future use of cfDNA assays in early cancers.

ES25.04 LIQUID BIOPSY: UTILITY FOR EARLY DETECTION

A. Vivancos

Vall d´Hebron University Hospital and Institute of Oncology (VHIO), Barcelona/Spain

Personalized treatment according to molecular profile is standard of care in advanced NSCLC patients. Epidermal Growth Factor Receptor (*EGFR*) activating mutations predict sensitivity to first- and second-generation anti-EGFR tyrosine kinase inhibitors (TKIs) in patients with non-small cell lung cancer (NSCLC). However, obtaining a tissue biopsy remains a limitation in NSCLC patients. Liquid biopsy is a non-invasive method that allows the detection and quantification of tumor somatic mutations in plasma, although around 20% of all tumors don't appear to shed DNA into the bloodstream. Here, we aimed to correlate the presence and amounts of ctDNA in plasma of NSCLC patients with several clinical parameters, as well as obtaining serial data on non-shedding patients throughout their course of illness. We collected 280 serial blood samples of 40 patients with NSCLC diagnosis harboring *EGFR* sensitizing mutations in their tumor biopsy. Extracted ctDNA was tested for five common *EGFR* mutations (exon 19 deletion, L858R, L861Q, T790M and C797S) by highly sensitive and quantitative Droplet Digital PCR (ddPCRTM; Bio-Rad), at a limit of detection between 0.1-0.5% and quantified the percentage of mutant alleles of EGFR. Of these patients, 16 provided one plasma sample (32%) and the other 34 (68%) provided multiple blood collections with an average of 5 follow-up plasma samples. All patients received targeted TKI therapy before or during the study. Lines of treatment, Progression free survival (PFS) and overall survival (OS) were annotated for each patient in the cohort. Out of the 40 patients evaluated, we detected presence of baseline ctDNA in 32 patients (80%). Such parameter was independent of the sensitizing mutation; tumors harboring exon 19 or exon 21 mutation tend to equally shed DNA into the bloodstream (78% and 80%, respectively). After a median follow up of 36.1 months, and immature survival data, the PFS and OS are higher among patients with baseline ctDNA positive compared to patients without ctDNA detected: 22 months vs. 13.6 months and 35 vs. 24 months, respectively. T790M and C797S resistance mutations were detected at different prevalences, depending on the TKI treatment regimen, and were always subclonal in plasma as compared to the clonal EGFR mutation (indel 19/L858R). We observed that, for the whole period analyzed in non-shedding patients, ctDNA was never detected. In our series, sensitizing *EGFR* mutations in plasma were identified in 80% of the patients by ddPCR. Acquired resistance mutations in *EGFR* appeared to be subclonal, which might impact detection in liquid biopsy. Shedding is a complex biological entity that warrants further research in order to improve our understanding on its impact in prognosis.

ES26.01 THE IMPACT OF SPECIALIST NURSING INTERVENTION IN LUNG CANCER

A. Leary[1,2]

[1]*London South Bank University, London/United Kingdom,* [2]*University of South Eastern Norway, Oslo/Norway*

The Impact of Specialist Nursing Intervention in Lung Cancer Alison Leary on behalf of Iain Stewarta, Aamir Khakwania, Richard B. Hubbarda, Paul Beckettb, Diana Borthwickc, Angela Toddd, Alison Learye, Laila J. Tataa A Division of Epidemiology and Public Health, University of Nottingham, NG5 1PB, UK B Derby Teaching

Hospitals NHS Foundation Trust, DE22 3NE, UK c Edinburgh Cancer Centre, Western General Hospital, EH4 2JT, UK d School of Nursing and Midwifery, University of Sheffield, S10 2LA, UK e School of Primary & Social Care, London South Bank University, SE1 0AA, UK Introduction In the UK the role of the Clinical Nurse Specialist is well established. Lung Cancer Clinical Nurse Specialists (LCNS) often start a therapeutic relationship with patients and families before formal diagnosis has been made. LCNS often manage the care of people with lung cancer but in an environment of austerity their worth to employers is still questioned. This series of studies examined the impact of the LCNS on outcomes for lung cancer patients. The focus of this abstract is one of the studies which looks at receipt of treatment for lung cancer. Treatment choices for people with lung cancer may be influenced by contact and engagement with lung cancer nurse specialists (LCNSs). We investigated how service factors, LCNS workload, and LCNS working practices may influence the receipt of anticancer treatment. Materials and methods English National Lung Cancer Audit data and inpatient Hospital Episode Statistics for 109,079 people with lung cancer surviving 30 days from diagnosis were linked along with LCNS workforce census data and a bespoke nationwide LCNS survey. Multinomial logistic regression was used to determine adjusted relative risk ratios (RRRs) for receipt of anticancer therapies associated with LCNS assessment, LCNS workforce composition, caseload, LCNS reported working practices, treatment facilities at the patients' attending hospitals, and the size of the lung cancer service. Results Assessment by an LCNS was the strongest independent predictor for receipt of anticancer therapy, with early LCNS assessments being particularly associated with greater receipt of surgery (RRR 1.85, 95%CI 1.63–2.11). For people we considered clinically suitable for surgery, receipt was 55%. Large LCNS caseloads were associated with decreased receipt of surgery among suitable patients (RRR 0.71, 95%CI 0.51–0.97) for caseloads >250 compared to ≤150. Reported LCNS working practices were associated with receipt of surgery, particularly provision of psychological support (RRR 1.60, 95%CI 1.02–2.51) and social support (RRR 1.56, 95%CI 1.07–2.28).

LC, lung cancer.
* Relative risk ratio adjusted for LCNS assessment and timing, workforce banding, average caseload size per LCNS, therapy availability and service size, as well as patient's age, sex, performance status, stage, comorbidity, and socioeconomic deprivation. Clustered by English Regional Cancer Network.

Conclusion LCNS assessment, workload, and working practices are associated with the likelihood of patients receiving anticancer therapy. Enabling and supporting LCNSs to undertake key case management interventions offers an opportunity to improve treatment uptake and reduce the apparent gap in receipt of surgery for those suitable Early nurse specialist contact is associated with greater receipt of therapy. •Receipt of surgery is less likely where nurse specialists have large caseloads. •Therapy receipt is more likely if key nursing interventions are routinely provided. •Managing nurse specialists' workload could address disparities in therapy uptake. Are working practices of lung cancer nurse specialists associated with variation in peoples' receipt of anticancer therapy? (2018) Stewart, Iain et al. ES26.02 REHABILITATION AFTER TREATMENT OF THORACIC MALIGNANCIES

C. Wells

University of Maryland Medical Center, Baltimore/United States of America

In this presentation the speaker will focus the talk on the collaborative model between the Departments of Nursing and Rehabilitation Services in the promotion of functional recovery of hospitalized adults. The speaker will incorporate the current literature regarding early mobilization and rehabilitation and the program's effects on outcomes. The talk will also examine the physical impairments and functional limitations associated with cancer associated frailty. Finally, the speaker will share some priminary data from the efforts at the University of Maryland Medical Center on the implementation of a collaborative mobilization and rehabilitation program to address barriers to recovery and hospital discharge.

Keywords: Rehabilitation, Functional Recovery, Early Mobilization Program

ES26.03 ACHIEVING HOLISTIC CARE IN HARD TO REACH PATIENT COHORTS

P. Magabanyane[1], J. Tewaternaude[2]

[1]*Asbestos Relief Trust, Kuruman/South Africa,* [2]*Asbestos Relief Trust, Cape Town/South Africa*

Achieving Holistic Care in Hard to Reach Patient Cohorts Against the odds - Achieving Holistic Care in Hard to Reach Patient Cohorts Phemelo Magabanyane (Author presenter) Registered Nurse, Midwife, Community health Nurse, Primary Health Care & Palliative Care Nurse Background:This abstract outlines the functionality of a holistic palliative care service under the unique circumstances of Kuruman, South Africa. This district comprises 186 villages with a total population of 241 836 people with only 39 clinics, three community health centres, two district hospitals, one oncology unit and no intensive care unit, the closest being 250 km away in the nearest city, Kimberley. The Kuruman Oncology unit is one of three specialist outreach programs, developed with the aim of improving accessibility to quality healthcare in rural areas. The need for the oncology and palliative care outreach program in Kuruman stems from the town's proximity to the crocidolite asbestos hills. Although mining stopped in 1998 and asbestos was banned officially in 2008, the legacy of asbestos – both occupational and environmental – lives on in the form of mesothelioma, and - in a situation of low smoking rates - lung cancer. The suffering of those affected by mesothelioma and lung cancer was worsened by the absence of palliative care and in-patient hospice services. 12 years ago, two asbestos trusts decided to initiate Kuruman's first and only fully functional palliative care service: a nurse. Discussion: Kuruman's semi-arid and under-resourced setting requires innovation, specialised training and good management to address palliative care needs. Although inadequate infrastructure lessens accessibility, cultural attitudes and beliefs hinders biomedical treatment, favouring traditional methods or simply keeping dread illnesses private. Resistance is further influenced by low literacy levels and a fear of attending tertiary institutions where people are perceived to die. Although these areas are the prime focus of our educational seminars, patients remain rooted in their beliefs and practices, hence often die from asbestos related diseases sooner than if they'd sought treatment from appropriate facilities. Despite this, our program has, since 2007, cared for 1987 asbestos affected patients. Our palliative care service was envisioned and enacted to facilitate the best feasible services to thoracic malignancy patients. With the hospital's oncology service, the Cancer Charity Workers (CCW), and patients' families, a collective evolved to effect holistic support – in health, psychologically, spiritually, and financially - including those everyday grinding tasks of end-of-life care. Financial support of the CCW from the Relief Trusts, CCW becoming an NGO, more formalised use of Community Health Care givers, becoming a grantee of a major Foundation, and the appointment of a second palliative care professional nurse by the Trusts have been recent developments in our functionality. Through community meetings, educational seminars, and free lung screenings, the collective has been able to identify greater numbers of cancer sufferers residing in remote areas and to encourage and channel palliative care services to them. Summary: Palliative care's principle of holistic care built on creating compassionate relationships between carer and patient produces better outcomes for the patient, their family, and the healthcare professionals involved. This service relies on a dedicated team of poly-organisational multidisciplinary professionals who are committed to realising and meeting the needs of the community. It is devoted to education, patient care, and furthering research on the optimization of the palliative healthcare system. Co- Authors: Dr Jim teWaterNaude, Fatimah Patel, Amira Wallace

ES26.04 THE IMPACT OF EARLY NURSING INTERVENTION ON OUTCOMES FOR THORACIC ONCOLOGY PATIENTS

I. Nohavova

Charles University in Prague, Prague/Czech Republic

Introduction: The roles of nurses vary from cancer screening, detection, and prevention, to active clinical assessment, treatment administration or symptom management. These various aspects play part when raising public awareness of important role of prevention. One of the very effective examples of an early health intervention is prevention of no tobacco use uptake or quitting using tobacco products in order to enhance health outcomes. The latest WHO/Europe report[1] "European tobacco use – trends report 2019" shows tobacco use continues to be a paramount public health issue. At the same time, it is estimated 90% of lung cancers (incl. tracheal or bronchal) could be avoided if tobacco use is eliminated. Sadly, the WHO European Region has the highest proportion of tobacco use in the world, with an estimated 29% of population using tobacco. Nurses can help. Methods: A review of guidelines and recommendations for nurses to use in daily practice will be presented. Results: Not applicable Conclusions: With prevention must be the key priority action, such focused early nurses interventions can contribute to timely diagnosis of the cancer positively impacting outcomes of thoracic oncology patients, including quality of life and care experience. Nurses are ideally positioned to assume this role. This presentation will explore current evidence related to the role of cancer nurse in early interventions to thoracic cancer patients' outcomes. The session will include discussion and recommendations to increase role of nurses in prevention of tobacco use. References: 1. WHO (2019). European Tobacco Use: Trends Report 2019. ES26.05 EARLY INTERVENTION AND REHABILITATION FOR PATIENTS NEWLY DIAGNOSED WITH THORACIC MALIGNANCIES

M. Quist

Copenhagen University hospital, Copenhagen/Denmark

This presentation will outline the rationale, role and evidence supporting early Intervention and rehabilitation for patients newly diagnosed with thoracic malignancies. Thoracic malignancies are associated with high disease burden and increased inactivity. Newly diagnosed Individuals with thoracic malignancies experience complex symptoms, which can include dyspnoea, fatigue and pain. These frequently lead to a cycle of inactivity and functional decline. Individuals with thoracic malignancies are less physically active than similar aged healthy peers at time of diagnosis, with less than 40% meeting the physical activity guidelines (1). Following diagnosis, physical activity levels are lowest whilst patients undergo treatment and do not recover back to pretreatment levels within six months. Progressive functional decline occurs over time, with reduction in exercise capacity and muscle strength (1). In thoracic malignancies, reduced exercise performance is associated with poorer functional independence, worse cancer treatment tolerability and higher all-cause mortality (2). People with thoracic malignancies, who are less physically active, have worse symptoms, and poorer exercise capacity and health-related quality of life (HRQoL) compared to those who are more active (1). This is supported and linked with the research by Gralla et al in 2014 (3) who identified key issues that patients with thoracic malignancies mainly fear. Gralla el al described the five rated issues which were: maintaining independence, ability to perform normal daily activities, ability to sleep, not being a burden for caregivers and not being fatigued, in a survey among 660 patients with lung cancer. Moreover, up to 44% of patients

with thoracic malignancies experience depression and anxiety symptoms, which is consistently higher than other cancers types, and psychological distress has also been proven to affect anti-cancer treatment and mortality (4). Supervised high-intensity exercise training is associated with improved exercise capacity and QOL in most cancer patients (5). Systematic reviews have reported that both pre- and postoperative exercise interventions are safe and feasible for patients with operable thoracic malignancies, and suggest benefits on exercise capacity, symptoms as fatigue and some domains of QOL (6). However, this evidence does not include patients with advanced inoperable thoracic malignancies. Although research groups have previously shown that exercise in these patients is safe, feasible, and beneficial (7), conclusive randomized controlled trials (RCT) still remain to be carried out to determine the effect of exercise for patients with advanced inoperable thoracic malignancies. But larger RCT within this group of patients is currently finished and ongoing and within the next few years the evidence will increase. Next step though is to implement evidence into daily practice. 1. Granger CL, McDonald CF, Irving L, Clark RA, Gough K, Murnane A, et al. SUNDAY, SEPTEMBER 8 07:00–08:00

IBS01.01 SYSTEMIC OR LOCAL TREATMENT: WHAT TO DO FIRST?

B. Solomon

Peter MacCallum Cancer Center, Melbourne/Australia

In the era of increasingly effective systemic treatments including EGFR and ALK tyrosine kinase inhibitors we will review the rationale for aggressive treatment of oligometastatic or oligopersistent disease in order to improve long term treatment outcomes. In the setting of oligometastatic disease to the brain, treatment of one or more sites of brain metastases with effective systemic treatment with stereotactic radiotherapy may allow whole brain radiation to be avoided or delayed. For extracranial disease, locally ablative therapies to solitary sites of metastases may enable potentially curative approaches to primary tumours. Further, benefit for treatment of oligo-persistent sites of disease after intial systemic treatment with local consolidative therapy has been demonstrated. Central to aggressive local approaches are appropriate staging investigations including MRI Brain and FDG-PET scan to determine the extent of metastatic disease.

IBS01.02 STRATEGIES TREATMENT AFTER OLIGOPROGRESSION

F. Cappuzzo[1,2], L. Landi[2]

[1]*Medical Oncology Unit Ravenna, Ravenna/Italy,* [2]*AUSL Romagna-Ravenna, Ravenna/Italy*

Lung cancer remains the leading cause of cancer-related mortality with more than 50% of the cases diagnosed at advanced stage. For decades, metastatic Non-Small-Cell Lung Cancer (NSCLC) has been considered as incurable disease with limited therapeutic opportunities. In such context, local ablative therapies (LAT), mainly represented by surgical metastasectomy, was the sole treatment with curative intent for selected patients with single brain or adrenal lesion. However, improvements in the knowledge of cancer biology coupled with progresses in systemic therapy positively impacted the duration and quality of life. This is the case of NSCLC carrying epidermal growth factor receptor (*EGFR*) activating mutations or anaplastic lymphoma kinase (*ALK*) rearrangement, where targeted therapies have changed the natural history of the disease, with median survival exceeding 4 years. Beyond *EGFR*mutations and *ALK*rearrangement, additional actionable alterations have been identified, including*BRAF*mutations or *ROS1*rearrangements as the latest entered in clinical practice. Specific therapies are now available in clinic for all of these aberrations, with osimertinib, alectinib, crizotinib or the combination of dabrafenib and trametinib as the best first-line option for individuals harboring alterations respectively in the *EGFR*, *ALK*, *ROS1*or *BRAF*. Unfortunately, after an initial response all patients eventually progress. From a clinical point of view, there are two main patterns of progression including rapid and systemic progression or slow, limited and often indolent progression. In the first scenario, shift to a second line therapy is recommended. In the other case (oligoprogressive disease), LAT plus continuation of front-line inhibitor given beyond progression seems the best option. The oligoprogressive state is characterized by a limited number of sites in progression, implying that the other sites remain controlled and therefore sensitive to systemic treatments. The advent of non-invasive techniques such as stereotactic radiotherapy, radiofrequency, and mini-invasive surgery has led to a precise re-evaluation of LATs in this situation. Local treatment of the oligoprogressive lesions may allow modification of the natural history of the disease, maintenance of effective systemic targeted treatment and, ultimately, to improved survival. In addition, some LATs have the advantage that can be repeated over time in difficult-to-treat organs as brain. Data validating an aggressive local therapeutic approach in oligoprogressive NSCLC patients are currently limited and essentially retrospective. Several international trials are ongoing and their results could contributing in better defining the role of radical local treatment in oligoprogressive advanced NSCLC patients. Unfortunately, even if the addition of a LAT contributes in disease control, majority of patients finally relapse and die for additional metastatic spread. Therapy options at the time of oligometastatic progression are largely influenced by previous therapies, site of progression and molecular portrait of the disease. Molecular characteristics are of particular relevance for defining the possibility of sequential use of additional target agents. This is the case of T790M EGFR mutation occurring in the vast majority of patients progressing after old generation EGFR TKIs for which osimertinib is superior to standard platinum-doublet chemotherapy. Viceversa, in absence of the acquired mutation (T790M negative), chemotherapy or combinations of chemotherapy and immunotherapy should be the preferred choice. In conclusion, molecular target therapies and more recently immunotherapy significantly improved survival of patients presenting with metastatic disease at diagnosis. However, acquired resistance inevitably occurs, limiting patient survival. A subset of patients presenting oligometastic disease represent a unique subgroup of patients who can benefit from LAT followed by continuation of systemic therapy. Randomized clinical trials are needed the role of LAT in this context.

IBS02 MAKING SENSE OF TREATMENT WITH SO MANY OPTIONS: MY ALGORITM
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS02.01 MAKING SENSE OF TREATMENT WITH SO MANY OPTIONS: MY ALGORITM - A EUROPEAN VIEW

N. Reguart

Hospital Clínic Barcelona, Barcelona/Spain

The treatment paradigm for metastatic non-small cell lung cancer (NSCLC) continues to evolve quickly due to the introduction of immunotherapy and new targeted therapies as well as our increasing knowledge of molecular signaling pathways. As a result of treatments becoming more efficacious and more personalized, outcomes for selected patients with NSCLC are increasing. Algorithms change rapidly and those published one year ago are already outdated today. In this interactive session, we will discuss current treatment algorithm / recommendations for advanced NSCLC patients, those whose tumors have driver oncogenes as well as wild-type lung tumors. We will describe the decision-making process to arrive at a treatment recommendation for a particular patient from the perspective of three different areas of the world: Europe, North-America and Australia. Recommendations for the best standards of care, based on evidence-based medicine and local clinical practice guidelines will be covered and applied in this case to the European local-practice context.

Keywords: Algorithms, NSCLC, treatment

IBS02 MAKING SENSE OF TREATMENT WITH SO MANY OPTIONS: MY ALGORITM
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS02.02 MAKING SENSE OF TREATMENT WITH SO MANY OPTIONS: MY ALGORITM - A NORTH AMERICAN VIEW

R. Lilenbaum

Yale Cancer Center, New Haven/United States of America

The Treatment of Lung Cancer: Can it be logical? The treatment of lung cancer has evolved dramatically in the past decade. Targeted therapy, and more recently immunotherapy have provided not only new and better treatment options, but have radically transformed the understanding of the biology of the disease. For the individual

practitioner, and even for the thoracic oncologist expert, it can be challenging to keep up with the new advances and apply the data to clinical practice. Consensus guidelines have become a popular vehicle to educate and support decision making at the individual level. Oncologists often rely on recommendations from professional societies, such as ASCO, IASLC, ESMO, and NCCN, to refresh their knowledge and to identify a treatment algorithm that is appropriate for a specific patient. There is however significant heterogeneity among the guidelines in terms of methodology and strength of recommendations. Guidelines are based on systematic reviews of the literature, and interpreted by a recognized panel of experts. The recommendations should be rated based on the quality of the evidence. Translating the recommendation into a treatment decision requires consideration of additional factors, clinical and non-clinical, that balance the weight of the evidence with the uniqueness of the patient's circumstances. In general, when the evidence is strong, and the patient falls into the subset for whom the recommendation is intended, the intervention should be offered. Conversely, if the recommendation is weak, or the patient has factors that cofound the clinical context, clinicians need to be more discretionary and consider alternative options. Just as important, guidelines can discourage the use of ineffective, unproven, or even harmful therapies. They also serve as a platform for discussions among clinicians, or between clinicians and patients when controversies about treatment arise. Another level of decision tool is a clinical pathway, which provides an evidence-based, step by step protocol for delivering care to patients with specific diseases and stages. Studies have documented that use of pathways is associated with improved outcomes and often lower costs. Several health care systems across the US have implemented pathways for cancer care, with varying degrees of adherence. One type of pathway often used in oncology focuses on chemotherapy regimens. Committees of national experts provide recommendations as to the most appropriate regimens for a specific stage and disease, such as advanced non-small cell lung cancer, with and without a molecular target. The options are ranked based on efficacy; toxicity; and costs, usually in this order. Institutions may acquire the pathway from a vendor, or decide to rely on their own experts to develop recommendations. These guidelines should be updated frequently. Financial aspects become more relevant in chemotherapy pathways. In cases where efficacy and toxicity do not differ significantly among the regimens, differences in cost ultimately determine the order of prioritization. Because drug costs account for a large component of the financial well being of a cancer hospital, Pharmacy Committees are often asked to develop guidelines for selection of the more cost-effective therapies, and pathways can assist in this process. Other potential benefits of clinical pathways include the ability to collect information on providers' practices; identify outliers with respect to priority regimens; and flag regimens that have limited efficacy data in a particular setting. Above all, pathways promote standardization of care within institutions, particularly when oncologists are spread across multiple sites. Guidelines and pathways are designed primarily to improve quality and consistency of care, and are not meant to replace clinical judgement. At a time when advances in cancer treatment outpace any one individual's ability to keep up with the new information, they serve as a valuable resource for physicians and patients alike.

IBS03 PERSONALIZED MANAGEMENT OF ELDERLY PATIENTS WITH STAGE III NSCLC
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS03.01 MANAGING LOCALLY ADVANCED NSCLC IN THE ELDERLY IN 2019

C. Langer

University of Pennsylvania, Philadelphia/United States of America

In the management of locally advanced (LA) non-small cell lung cancer (NSCLC), at least 10 studies over the past 25 years have shown superiority for chemoradiation over radiation (XRT) alone; more recently, concurrent chemoradiation has proven superior to sequential or asynchronous chemotherapy followed by XRT. Retrospective analyses evaluating outcomes in the elderly receiving these regimens have generally demonstrated similar progression-free (PFS) and overall survival (OS) compared to their younger counterparts on study, albeit with increased toxicity.[1,2,3] Generally, those over 70 years of age were under-represented on these trials compared to the NSCLC population at large - while more than 40% of those diagnosed with LA-NSCLC were 70 years of age or older, fewer than 20% of those enrolled on relevant clinical trials were elderly.[4] Virtually all of the earlier efforts were cisplatin-based, which made the routine use of this approach in elderly patients outside of clinical trials somewhat problematic, particularly in the face of age-associated co-morbidities that might preclude or limit the application of platinating agents. Since the beginning of the new millenia, non-cisplatin regimens, generally using weekly carboplatin in combination with a taxane or other partner agents active in NSCLC have been shown to yield "equivalent" efficacy with less toxicity. For elderly patients treated outside of a clinical trial, I generally favor weekly carboplatin (AUC 2) coupled with weekly solvent-based paclitaxel (45-50 mg/m2) in conjunction with a minimum dose of 60 Gy administered over a 6-7 week period. At least one trial from Japan conducted exclusively in the elderly with LA-NSCLC showed superior OS for concurrent XRT and low dose daily carboplatin vs XRT alone with median survival of 22.4 mos compared to 16.5 mos in the control group (HR 0.64).[5] However, monotherapy with carboplatin during XRT is not considered the standard approach in LA-NSCLC. The only randomized trial to compare cisplatin- to carboplatin-based combinations in LA-NSCLC was a Japanese study which randomized patients to either MVP during thoracic XRT or to weekly carbo and either irinotecan or paclitaxel; this study showed virtually no difference in long term outcome (18 to 20% 5 year survival), with pacitaxel/carboplatin proving better tolerated.[6] These results are dissatisfying, but clearly better than historic controls with XRT alone (5-7% 5 year OS). To date, unfortunately, in North American, we have no prospective, randomized, head-to-head comparisons of cisplatin based treatment vs. paclitaxel/carboplatin or other carboplatin-based regimens in stage IIIA/B NSCLC. Retrospective data from the VA and the SEER database, however, suggest little difference in long term OS.[7] The results of RTOG 0617 would tend to validate paclitaxel/carboplaitn as a "viable" regimen in "good prognosis" LA-NSCLC pts with median survival in the 23 to 29 month range for weekly paclitaxel/carboplatin during radical XRT, with no advantage for 74 Gy over 60 Gy or the addition of cetuximab.[8] More recently, the PACIFIC trial showed that patients with LA-NSCLC who received "consolidative" durvalumab, a PDL1 inhibitor, for up to a year, after responding to or stabilizing on concurrent chemoradiation, could enjoy a three-fold increase in PFS (16.8 vs 5.6 mos) and a 10% absolute improvement in OS (66.3% vs 55.6%).[9] These benefits were both statistically significant (HR 0.68) and clinically meaningful; and the PACIFIC regimen featuring concurrent chemo-radiation followed by durvalumab has emerged as the "standard of comparison" if not the "standard of care" in fit individuals with LA-NSCLC, regardless of age. Of note, the HR for OS benefit in PACIFIC in those 65 years of age and older was 0.76 (95% CI: 0.55 - 1.05) vs 0.62 (95% CI: 0.44-0.88) for patients under 65. Whether this approach should be applied to patients whose tumors do not harbor PDL1 expression or whose tumors have an oncogenic driver such as EGFR mutations remains controversial. References: 1. IBS03 PERSONALIZED MANAGEMENT OF ELDERLY PATIENTS WITH STAGE III NSCLC
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS03.02 SURGERY FOR ELDERLY PATIENTS WITH STAGE III NON-SMALL-CELL LUNG CANCER (NSCLC)?

B. Passlick

University of Freiburg, Freiburg/Germany

About 40 % of the patients with newly diagnosed Non-small-Cell Lung cancer are between 65 to 75 years old and more than 15 % are older than 75 years at the time of diagnosis. Elderly patients have in general a reduced cardiopulmonary performance status, including a higher risk for ischemic heart disease and COPD. Furthermore higher co-morbidity can be expected (renal, metabolic, and cerebral). The major question whether surgery should be offered to patients of more than 70 years are whether there is a higher morbidity and mortality in elderly patients and the second question is, whether curative surgery approach is worthwhile in patients over 75 years. The question whether a higher age is associated with a higher morbidity in elderly patients has been investigated by different studies, most of them with a retrospective design. While in older studies from

the 80-ies of last century (i.e. lung cancer study group) there was an elevated mortality in patients over 70 years, this was not true anymore in publications from the late 90th of last century and current publications: For example in a recent publication from the Japanese association of chest surgeons the postoperative mortality was 2 % in patients between 70 - 79 years old and it was 2.2 % in patients over 80 years old. Furthermore, there is only a little influence of the age with respect to the postoperative lung function parameters. If we try to analyze whether surgery is worthwhile in elderly patients, we have to realize that men who are now 85 years old have a mean life expectancy of 5.3 years and women of 6.3 years. Furthermore, there is no survival difference in surgically treated patients for stage III lung cancer which are younger or older than 70 years old. In a Japanese study patients over 80 years have achieved a long term survival of more than 50 % after surgery for lung cancer. Limited resections can be successfully performed in patients with limited cardio pulmonary function parameters. In summary, the morbidity and mortality in elderly patients is not elevated after surgery and the median cancer specific long term survival is not different as compared to younger patients. IBS04 HYPERPROGRESSIVE DISEASE
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS04.01 BIOLOGICAL MECHANISMS

E. Garon

David Geffen School of Medicine at University of California, Los Angeles, Los Angeles/United States of America

Inhibitors of programmed cell death 1 (PD-1) and one of its ligands, PD-L1, have rapidly been incorporated into the treatment of patients with lung cancer and other malignancies. In lung cancer, when used as single agents, a minority of patients respond to PD-1 or PD-1 inhibitors. Although some patients now receive these agents along with chemotherapy, many patients still receive single agent inhibitors of immune checkpoints such as PD-1 or PD-L1. A phenomenon of hyperprogression has been described among patients undergoing therapy with immune checkpoint inhibitors. There is a great deal of literature describing the radiographic criteria associated with hyperporgression. Although there is wide agreement that a portion of patients do meet these radiographic criteria, the extent to which inhibitors of PD-1 and PD-L1 can induce the growth of lung cancer is a topic generating a great deal of interest. Studies are beginning to assess potential mechanisms underlying this pnenomenon. Assessment is complicated by the fact that some patients are likely to rapidly progress based solely on lack of effective therapy, and therefore, the group of patients meeting the described radiographic criteria for hyperprogression may be heterogeneous.

IBS05 LUNG CANCER GENETICS TO BEAT LUNG CANCER
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS05.01 KRAS MUTANT LUNG CANCER

P. Jänne

Dana Farber Cancer Institute, USA/United States of America

*KRAS*mutations are the most common oncogenic alteration in Caucasian patients with advanced non-small cell lung cancer (NSCLC), detected in approximately 25% of patients with adenocarcinoma. Although *KRAS*mutations were discovered over 30 years ago, no approved targeted therapies exist for *KRAS*mutant NSCLC. *KRAS*mutations occur most commonly in codon 12 and less frequently in codons 13 and 61. The development of KRAS mutant lung cancer is most closely associated with a history of current or former smoking although *KRAS*mutations can also occur in up to 15% of never smokers who develop lung cancer (1). While *KRAS* G12C mutations are the predominant mutation subtype in smokers, G12D mutations are the most common subtype of KRAS mutations in never smokers. Until recently, no direct targeted therapies existed for KRASmutant lung cancers and the therapeutic efforts have mostly focused on targeting downstream effector pathways including the MAPK and PI3K/AKT pathways. MEK inhibitors have limited single agent activity (response rates 10-20%) and initial enthusiasm from a randomized phase II trial of selumetinib/docetaxel vs. docetaxel suggested a potential benefit of adding chemotherapy to a MEK inhibitor (2). However, the initial findings could not be reproduced in a larger randomized phase III trial (3). The CDK4/6 inhibitor abemaciclib has also been evaluated as a single agent in KRASmutant lung cancer based on both preclinical data and as a result of the phase I trial which demonstrated a differential benefit in patients with KRASmutant NSCLC (4). However, a phase III trial, randomizing previously treated KRASmutant NSCLC to either abemaciclib or erlotinib failed to demonstrate an improvement in overall survival. It has increasingly been recognized that not all KRASmutant cancers are the same. Not only are there a variety of allelic variants of KRAS, there several subtypes of co-mutations within KRAS mutant cancers (5). Approximately 30% of KRASmutant tumors harbor a concomitant alteration in TP53 which another 30% harbor concomitant mutations in LKB1/STK11. Mutations in LKB1/STK11most commonly result in loss of function of the LKB1/STK11protein(5,6). Immune checkpoint blockade (ICB), administered as a single agent or in combination with chemotherapy, is an effective therapy in lung cancer (7). While strategies to identify biomarker to predict optimal response to ICB are diverse, LKB1/STK11mutations are associated with lack of response to both single agent ICB or when administered together with combination chemotherapy. Ongoing efforts are focusing on understanding the mechanistic basis for the lack of response to ICB in LKB1/STK11mutant tumors and levering this understanding to develop new strategies to enhance responsiveness of this subset of NSCLC to ICB. New therapeutic approaches to target KRAS are rapidly entering the clinic. These include inhibitors or SHP2, SOS1 and the direct inhibitors of KRAS G12C. Novel structural insights into into the KRAS protein helped identify a unique allosteric site formed in the presence of the G12C mutation. These insights led to the identification of potential drugs that could occupy this pocket and covalently bind KRAS G12C (8). Multiple companies are now developing KRAS G12C inhibitors including Mirati Therapeutics (MRTX849) and Amgen (AMG510). Encouraging early clinical signs of efficacy have been observed. Over the next few years, clinical data will emerge on the efficacy of direct KRAS G12C inhibitors, the impact of concomitant genomic alterations, the mechanisms of acquired resistance as well as combination treatment strategies. In addition, continued studies of KRAS biology and new therapeutic studies will also hopefully lead to new treatments for patients with non-G12C KRASmutations. References 1. IBS05 LUNG CANCER GENETICS TO BEAT LUNG CANCER
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS05.02 FUNCTIONAL GENOMIC APPROACHES TO IDENTIFY NOVEL THERAPEUTIC TARGETS IN LUNG CANCER

T. Zou, M. Meyerson

Dana-Farber Cancer Institute, Boston/United States of America

Despite the discovery and availability of targeted therapies and immunotherapies, lung cancer remains the leading cause of cancer death worldwide. Importantly, most lung cancer patients are not eligible for targeted therapies because their tumors lack an actionable genomic alteration. Moreover, immunotherapy-based regimens fail to induce treatment responses in a substantial proportion of lung cancer patients (1-3). Therefore, the identification of novel therapeutic modalities remains critical to improving outcomes in lung cancer care. Lung cancer cells may harbor specific genomic or functional alterations that render them vulnerable to particular genetic perturbations (4,5). Discovery of these synthetic lethal interactions may provide opportunities to develop novel classes of therapeutics for this disease. Through systematic analysis of genome-scale loss-of-function datasets (6,7), we identify adenosine deaminase acting on RNA (ADAR or ADAR1) as an essential gene for the survival of a subset of lung cancer cell lines (8). ADAR1-dependent cell lines display increased expression of interferon-stimulated genes. Moreover, activation of type I interferon signaling in the context of ADAR1 deficiency can induce cell lethality in non-ADAR1-dependent cell lines. ADAR deletion causes activation of the cytoplasmic double-stranded RNA sensor, protein kinase R (PKR). Disruption of PKR signaling, through inactivation of PKR or overexpression of either a wild-type or catalytically inactive mutant version of ADAR1, partially rescues cell lethality after ADAR1 loss, suggesting that both catalytic and non-enzymatic functions of ADAR1 may contribute to preventing PKR-mediated cell lethality. Taken together, these data nominate ADAR1 as a potential therapeutic target in lung cancers displaying elevated interferon-stimulated gene expression and underscore the ability of functional genomic approaches to uncover novel genetic vulnerabilities in lung cancer. Malignant pleural mesothelioma (MPM) is an aggressive malignancy with increasing prevalence and poor prognosis. Despite a still increase in incidence, it remains an orphan disease and studying limited numbers of MPM cases hampers the derivation of solid conclusions. The combination of two databases including clinical as well as pathological information will allow researchers to improve the knowledge and facilitate decision-making in patients with MPM. The European Thoracic Oncology Platform (ETOP) Mesoscape project and the European Society of Thoracic Surgeons' (ESTS) database are designed to address clinical, pathological, and molecular characteristics of mesothelioma patients and their impact on outcome. The joined analysis of both databases is a unique approach to real-time data reflecting the reality of mesothelioma characteristics, treatment and prognosis in Europe. Materials and Methods: A decentralized biobank with fully annotated tissue samples is established for ETOP Mesoscape. Selection criteria for participating centers included sufficient number of cases, and documented ethical approval. Patient selection is based on availability of comprehensive clinical data with adequate follow-up, and adequate quantity and quality of formalin-fixed tissue.The ESTS database is a clinical database with pre-operative, intra-operative and post-operative data. A minimum set of data is captured, including demographic, histology, treatment, staging and follow up data. The characteristics between the two databases are compared using the Fisher's exact test (for categorical variables) and Mann-Whitney test (for continuous variables), while Kaplan-Meier method (with log-rank test). Results: Up to 29 May 2019, the ETOP Mesoscape included information on 497 patients from 10 centers, diagnosed between 1999-2018. In the ESTS database, as of April 2019, 2269 patients are included, diagnosed between 1989-2019. Patients in both databases are primarily men (84% in the ETOP, 71% in the ESTS), of 0/1 ECOG Performance status (46/46% and 59/29% in ETOP and ESTS respectively), with known previous exposure to asbestos (75% and 93%) and median ages 64 and 67 years old. Significant differences are detected between the two data sources with respect to gender, exposure to asbestos and age (p-value <0.001). The primary histology of patients is epithelioid (72% in ETOP and 70% in ESTS), followed by biphasic (22%; 17%) and sarcomatoid (6%; 9%) (not significantly different between the two databases). Clinical staging is available for 77% of the patients in ETOP, but only for the 28% in the ESTS database. The stage distribution (I/II/III/IV) is 14/29/42/15% in the ETOP and 23/21/41/16% in the ESTS (significantly difference p<0.001). Among the biomarkers common in both data sources, Calretinin and WT1 are detected in the vast majority of patients tested (Calretinin: 97% in both cases; WT1: 89% and 87% in the ETOP and ESTS database respectively). For the ETOP cases 90% (of those tested) are CK5/6 positive, 91% D2-40 positive and 97% Pan-CK positive. Palliative treatment has been administered in 41% of the ETOP cases. Among them, 84% received palliative chemotherapy (with the vast majority 92%, using multiple agents). Palliative surgery was undertaken in 32% (62 of 194 patients with available information) and palliative

radiotherapy for 13% of the patients. Complete resection has been performed in 59% of the ETOP Mesoscape patients. This was combined with induction chemotherapy (81%), while adjuvant chemotherapy and radiotherapy was administered in 4% and 37% respectively. The surgical approach adopted for the ESTS patients was either video-assisted thoracoscopic surgery (VATS) (59%) or thoracotomy (41%) based on a subset of 887 patients with available information. Post-operation treatment information is available for 620 ESTS patients. Among them, 71% received chemotherapy, 54% underwent surgery and 15% radiotherapy. Conclusion: We present the combined results from the ETOP Mesoscape and the ESTS database, one of the largest databases. These two series allow us to report on mesothelioma epidemiology and treatment. Up to now, the comparison of the baseline characteristics of the patients of the two data sources revealed some statistically significant differences with respect to gender, age, exposure to asbestos and clinical stage. As tissue from all ETOP Mesoscape patients is preserved locally and is available for detailed molecular investigations, Mesoscape provides an excellent basis to evaluate the influence of molecular parameters on the disease outcome, besides providing an overview of the molecular landscape.

IBS06 MULTIMODALITY TREATMENT - REALTIME DATA FROM NATIONAL REGISTRIES
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS06.02 REAL TIME DATA FROM US (SEERS)

M. Van Gerwen[1], E. Taioli[2], N. Alpert[1], A. Wolf[3], R. Flores[4]

[1]Institute for Translational Epidemiology, Icahn School of Medicine at Mount Sinai, New York/United States of America, [2]Institute for Translational Epidemiology, Icahn School of Medicine at Mount Sinai, New York/United States of America, [3]Department of Thoracic Surgery, Icahn School of Medicine at Mount Sinai, New York/United States of America, [4]Department of Thoracic Surgery, Icahn School of Medicine at Mount Sinai, New York/United States of America

The association between asbestos exposure and malignant mesothelioma has been well established. Exposure to asbestos mainly occurs through work although environmental exposure has been documented. Several countries have put in place an active epidemiologic surveillance of mesothelioma cases. Through a PubMed and Google Scholar search using the key words "*mesothelioma*" and "*registry*", and by reviewing data sources of studies described in a review of environmental exposure and malignant mesothelioma, we identified existing mesothelioma registries. Countries with mesothelioma specific registries are Australia, Belgium, France, Germany, Italy, Japan, South Korea, South Africa, Turkey, and the UK. Nation-wide coverage is obtained in Italy, Australia and South Korea. Registries in Australia, France, Italy, and South Korea use interviews to obtain exposure data from the patient or a close relative, although none of these countries has a tissue bank. The UK has a mesothelioma tissue bank although it is not linked with the National Mesothelioma Audit registry. All registries have or will develop linkage with death index registries to monitor survival outcomes. (Table 1) The Scandinavian countries including Norway, Sweden, Finland and Denmark, have a population based cancer registry that includes mesothelioma and is linked to other databases, such as an occupational database, thus has more comprehensive information on each case. Mesothelioma surveillance in the US to date Currently, no nation-wide, mesothelioma specific registry exists in the US. Various existing databases are used to investigate mesothelioma, for instance the National Cancer Database has been used to look at prognostic factors; gender and race differences in mesothelioma survival have been studied using the Surveillance, Epidemiology, and End Results (SEER) database. All these datasets suffer of a time-lag between case occurrence, reporting, registration and eventually data availability for research purposes; these are serious limiting factors in the case of mesothelioma. Because of the rarity and lethality of the disease, a real-time capture registry is needed to thoroughly collect exposure data, complete data on treatments, quality of life before and after treatment, symptoms and pain management. All these elements are lacking in the existing databases. Because the US mesothelioma incidence is not decreasing as quickly as predicted and new cases still occur as well the fact that mortality rates are steady overtime, the overall health burden due to mesothelioma in the US still remains. Although the use of asbestos has been restricted or banned since 1980, several scientific questions remain open due to the long latency period between exposure and mesothelioma clinical occurrence, and to gaps in knowledge of the carcinogenesis process. Data on occupational and environmental asbestos exposure and co-exposure to other carcinogens are needed. Certain patterns, such as differences in outcomes by gender, differences in incidence rates by race, as well as geographic clusters of increased number of cases, are hard to explain with the existing data. Possible next steps towards a US mesothelioma registry "Real time" enrollment is important in order to systematically collect information on asbestos and other exposures through interviews with mesothelioma patients or a close relative. Furthermore, optimal coverage, preferably population based and nation-wide, and a simplified consent process are needed in order to capture a maximum number of cases. A centralized quality control system, standardized data collection methods, and the ability to link to relevant other existing registries are important in order to integrate the registry with clinical and prognostic information. Additionally, consistency in the design and questionnaire content with other countries would be ideal, in order to conduct comparisons and possibly pool the data. The flexibility to add or modify modules to tailor to future research questions are other preferable features for a US mesothelioma registry. (Figure 1) A discrete amount of work has been devoted to molecular markers such as mesothelin and certain germline mutations as prognostic factors. The role of these biomarkers could be validated on larger populations of patients if a comprehensive registry that includes tissue is implemented. Summary and conclusions In conclusion, with the remaining health burden due to mesothelioma, the changing landscape of asbestos exposure, and the many unanswered scientific questions, a nation-wide, real-time US mesothelioma registry is urgently needed. Methods for data sharing, linkage to existing tissue banks, and data access should be implemented and tested on a small scale before being implemented nationwide. One of the most practical outputs of these efforts would be the ability to conduct pragmatic trials that could be built out of a "real time" case capture system.

Table 1: Overview of mesothelioma registries

	Country	Treatment information	Tissue bank	Patient interview	Family interview (for all or deceased cases)	Exposure information	Nationwide coverage	Linkage with death information	Active monitoring system	Only pathologically confirmed cases and/or pathology information available	Mandated reporting	Outcomes

IBS06 MULTIMODALITY TREATMENT - REALTIME DATA FROM NATIONAL REGISTRIES
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS06.03 JAPANESE DATA

S. Hasegawa[1], H. Yamamoto[2], M. Hashimoto[1], E. Fukui[2], K. Suzuki[1], Y. Sato[1], S. Endo[1], M. Chida[1]

[1]*The Japanese Association for Chest Surgery, Kyoto/Japan,* [2]*The University of Tokyo, Bunkyo-ku/Japan*

Annual surveys of cardiothoracic surgery throughout Japan has been conducted by the Japanese Association for Thoracic Surgery (JATS) since 1986 in order to establish the statistics for the number of procedures by operative category[1]. Regarding malignant pleural mesothelioma (MPM), however, only annual case numbers of both diffuse and localized MPM have been registered since 1996. From 2009 onward, surgical technique, 30-day mortality, and in-hospital mortality have been also described. According to the JATS survey, all-kind of surgery for MPM increased 76% during 1996 and 2016: 164 cases in 1996 and 289 cases in 2016. JATS survey also revealed dramatic increase of pleurectomy/decortication (P/D) cases during 2009 to 2016: proportion of P/D surgery in all curative-intent surgery was 1.4% (2/142) in 2009 and 53.3% (73/137) in 2016. Methods In 2011, the National Clinical Database (NCD) of Japan adopted an annual web-based nationwide data collection system[2]. Since NCD is associated with the Japanese Surgical Board Certification System, it contains detailed perioperative clinical information such as preoperative patient characteristics, operation time, blood loss, intraoperative accidents, pathological TNM stages, postoperative adverse events, redo-surgery, 30-day and in-hospital mortality, cause of death, and so on. Approximately 10 million surgical procedures from >5000 hospitals have been collected by 2017. An NCD specifically for general thoracic surgery was launched in 2014[3]. This time, we conducted an analysis on MPM surgery in Japan using the Japan NCD. Results (Table 1) In the period of 4 years between 2014 and 2017, a total of 622 curative-intent surgery was performed in Japan. Median age was 66 years (IQR, 61-71), and 87.6% were male. A median BMI was 22.6 (20.3-24.8), and 77.3% was ECOG PS0. Induction therapy was given in 40.8% of patients. Extrapleural pneumonectomy was performed in 279 patients (44.9%) and P/D in 343 (55.1%). Blood transfusion was required in 320 (51.4%) patients (Figure 1). Injury of major intrathoracic organ occurred in 22 (3.5%) patients. Morbidity rate was 40.0% (249/622). Thirty-day mortality and in-hospital mortality were 1.1% and 3.2%, respectively (Table 1). Conclusion In addition to the above JATS survey and Japan NCD, a nationwide, prospective, observational study of patients with MPM has just completed 2-year's patient accrual[4]. It is promising that these Japanese data will substantially contribute to understanding MPM in near future. 1 Thoracic and cardiovascular surgery in Japan in 2016. IBS07 ENHANCING RECOVERY IN THE TREATMENT OF THORACIC MALIGNANCY
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS07.01 ENHANCED RECOVERY FOR THORACIC SURGERY

A. Kerr

University Hospitals Birmingham, Birmingham/United Kingdom

Background Enhanced Recovery After Surgery (ERAS) also known as "fast track surgery", was pioneered back in the 1990s by Henrik Kehlet in colorectal surgery. It has developed as a multimodal evidenced based approach which has been designed and tested to enable patients to recover more quickly after major surgery thus reducing the length of hospital stay and the associated costs, Its aim is to minimise the physical and psychological stress response to surgery and has been proven effective in many different areas, by delivering multiple interventions throughout the entire patient journey from referral to discharge and beyond. Over the years the evidence modified this approach and now ERAS programmes are growing in popularity and are becoming more established across a range of surgical specialities, but there is still a little way to go

in thoracic surgery to build evidence and recommendations on the elements of the ERAS programme. Methods The main principles for ERAS programmes are; to enable the patients to be as healthy as possible before surgical treatment, receive the best possible care during their operation and have the best possible care while recovering (picture 1). There are as many as 45 enhanced recovery items throughout the entire pathway. The ideal start to the ERAS pathway is to optimise the pre-operative health which should commence when the referral from primary care is made. Interventions for smoking cessation and managing pre-existing comorbidities such as diabetes and hypertension are key elements in getting the patients in the best possible condition for surgery. Other pre surgery interventions are prehabilitation, nutritional screening, and patient information to manage expectations and discharge planning. Key recommendations for the admission on the day of surgery are to give patients pre surgery carbohydrate loading drinks and minimise their fasting period. In terms of intraoperative items, minimally invasive surgery, less opioid use, avoidance of urine catheters and fluid management are recommended elements. In the post-operative and follow-up phase, early oral hydration and nutrition to enable the removal of intravenous therapy, early mobilisation within 24 hours, early chest drain removal to facilitate discharge with a recommendation for telephone follow-up if applicable; these recommendations are becoming more common in thoracic surgery. Results In specialties such as colorectal, gastric and liver surgery the ERAS pathways are well established with good supporting evidence demonstrating a reduction in hospital length of stay, postoperative complication rates and cost reductions. Recommendations and guidance in thoracic surgery ERAS programmes has been published by the Enhanced Recovery after Surgery Society and the European Society for Thoracic Surgery (1). Some recommendations are based on high quality evidence; however in some cases thoracic surgery specific evidence is simply not available to support the recommendations therefore evidence from other surgical specialities has been extrapolated to thoracic surgery. The key recommendations include: pre surgery smoking cessation - a known risk factor for developing post-operative pulmonary complications (however there is a strong debate around smoking cessation timing prior to surgery); malnutrition increases risk of complications therefore nutritional screening is highly recommended as well as minimising starvation; the use of carbohydrate loading the evidence is low but the recommendation is strong due to proven reduction in insulin resistance in the context of general surgery. Patient education has been shown to reduce anxiety and improve expectations for both patients and carers. It is not clear if patients with good lung function and exercise capacity benefit from Prehabilitation but the evidence for the high risk group is strong, thus is highly recommended. There also is a strong recommendation for avoiding sedatives and the use of regional/non-opiate analgesia for pain relief, adequate control of nausea and vomiting, video-assisted approach when possible with early removal of chest drains. The guidance recommendation is high for dedicated pre-op counselling, prehabilitation, carbohydrate loading, use of regional anaesthetic techniques and short acting anaesthetic agents, dexamethasone to prevent post of nausea and pain, use of digital drainage with no external suction and early mobilisation after surgery but the evidence level is low. The impact of ERAS on the long term outcomes is another aspect that is yet to be determined. As the recommendation grade for most of the elements is strong, the use of a systematic perioperative care pathway has the potential to improve outcomes after surgery. Conclusion These guidelines outline recommendations for the perioperative management of patients undergoing lung surgery based on the best available evidence. However there are barriers to implement many aspects of the ERAS programme due to lack of evidence, so there is still a need for large-scale, multicenter randomised trials to test aspects of the pathway. IBS07 ENHANCING RECOVERY IN THE TREATMENT OF THORACIC MALIGNANCY
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS07.02 THE IMPACT OF PREHABILITATION ON PATIENTS HAVING LUNG CANCER SURGERY

D. Sanchez-Lorente

Hospital Clinic of Barcelona, Barcelona/Spain

Surgical resection remains the best treatment option for patients with early stage of non-small cell lung cancer. However, it may be responsible of postoperative complication and mortality, especially in patients with impaired pulmonary function. Enhanced recovery after surgery (ERAS) programs have been focused mainly in minimal invasive surgery approach during lung resection and respiratory rehabilitation after surgery. Preoperative exercise-based intervention (Prehabilitation) has demonstrated reduction of morbi-mortality in other surgeries but in thoracic surgery continues to be under discussion. Impaired lung function with low predicted postoperative forced expiratory volume in first second (ppoFEV1) or/and diffusing capacity for carbon monoxide (ppoDLCO) are considered risk factors for anatomic lung resection. Cardio-pulmonary exercise test (CPET) is the gold standard technique to predict postoperative morbi-mortality. It seems reasonable to think that if we are able to improve FEV1 or CPET we will reduce postoperative risks.The implementation of a preoperative respiratory rehabilitation could optimize patient's physical capacity before surgery and improve outcomes and enhance recovery. The aim of this presentation is to identify the effectiveness and safety of prehabilitation programs in thoracic surgery and review its impact on patients having lung cancer surgery. Define the type of exercise and its duration, and the group of patients with best benefit. During the presentation we will be able to check that Prehabilitation is a safe intervention without side effects in patients. High-intensity interval training (HIT) with duration of 2 to 6 weeks seems to be the best exercise programme in a prehabilitation intervention but it exists heterogeneity in terms of intensity and duration. Prehabilitation increase exercise capacity and significantly enhances pulmonary function. But the reduction of postoperative complication and mortality has not been clearly demonstrated. Different criteria selection, type of intervention and small sample size, in addition to no randomization, could justify disparate results. It seems that not all patients can benefit from prehabilitation and it could be indicated only in patients with impaired lung function. Further randomized clinical trials with enough patients, correct duration of HIT (2 to 6 weeks) and focused in COPD patients are needed to clarify the suitability of prehabilitation. Meanwhile, safety of prehabilitation and good results of some studies support this intervention in high-risk patients. This conclusion is supported by the recent published ERAS society and Eurpoean Society of Thoracic Surgeons (ESTS) guidelines for enhanced recovery after lung

surgery, which recommends prehabilitation should be considered for patients with borderline lung function or exercise capacity, despite the low scientific evidence.

IBS08 ROLE OF PATHOLOGIST IN THE ERA OF IMMUNOTHERAPIES
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS08.01 HARMONIZATION OF PD-L1 IHC INCLUDING LDT

L. Bubendorf

University of Basel, Switzerland/Switzerland

Given the great advances in immuno-oncology, systematic testing of virtually all NSCLC for PD-L1 expression by IHC has become a standard in many pathology laboratories. This has initially been driven by the approval of Pembrolizumab for first line monotherapy of metastatic NSCLC with a tumor proportion score (TPS) of at least 50%. At the same time, the pathology and oncology community has been challenged by as many as five different PD-L1 IHC assays related to different clinical trials with different PD1/PD-L1 checkpoint inhibitors in NSCLC and cancers of other organs. The use of different antibody clones and assays for IHC within different trials cannot be explained by a specific rationale but rather by economic reasons and opportunities. Unfortunately, most pharmaceutical companies would not adopt an assay that has previously been developed and used by a competitor. They rather team up with an antibody manufacturer to develop their own predictive marker for their own drug. Pathologist are then left with sorting out the dilemma and look for the most feasible solution to provide reliable predictive PD-L1 testing and enable the best possible treatment decisions. Clearly, it is out of question that pathology laboratories would be able or willing to provide all available assays using different automated immunostainer platforms for two major reasons: First, it is usually unknown to the pathologist at the time of testing, which particular PD1/PD-L1 inhibitor will be the chosen for an individual patient, as this depends on the preference of the medical oncologists and the actual result of the PD-L1 IH testing. Second, for many institutions, it is too expensive to maintain different automated immunstainer platforms and to establish different expensive PD-L1 assays in parallel, all of which need to undergo continuous or periodical internal and external quality control. Therefore, whenever possible, pathology laboratories try to establish one single PD-L1 IHC test that is as concordant as possible with several trial-related PD-L1 assays. Notably, the predictive IHC assays with the trial-related antibody clones are much more expensive than typical diagnostic antibodies used in pathology for decades, and this extra expense if often not properly reimbursed by the health insurance system. This explains why many laboratories still use laboratory developed tests (LDTs) for PD-L1 IHC using the non-clinical trial related antibody E1L3N (Cell Signaling) or concentrated, trial-related anti-PD-L1 antibodies. Given this apparent dilemma there have been numerous studies aiming at harmonizing the landscape of PD-L1 IHC testing. They have repeatedly shown that the concordance between the currently most relevant assays (DAKO 28-8, -DAKO 22C3, and Ventana SP263) was sufficient to allow for interchangeable use. This enables laboratories of to provide PD-L1 assay testing to select patients for treatment with Pembrolizumab, Nivolumab and Durvalumab on either the Ventana Benchmark Ultra or the DAKO AL48 immunostainer platform. On the other hand, the Ventana SP142 assay related to Atezolizumab has clearly lower sensitivity for PD-L1 expression on tumor cells (TC), and is thus suitable to select for treatment with nivolumab or pembrolizumab based on different TPS threshold. Similarly, the latest DAKO clone 73-10 that is related to Avelumab, appears to be the most sensitive one and might therefore not be interchangeable with any of the other PD-L1 assays. Published data and results from external quality assurance (EQA) programs indicate that it is possible to set up LDTs that match the staining results of the PD-L1 IHC assays. Nevertheless, LTDs still have higher failure rates emphasizing the necessity of rigorous validation and quality control. PD-L1 IHC has been adopted by several programs of external EQA programs including NordiQC, Quip, and UK NEQAS. Notably, NordiQC showed good results of trial-related related commercial PD-L1 IHC assays, and the results of LTDs improved over time. In particular, the sufficiency rate for E1L3N rose from a low 25% (2/9) in the first run to a high 89% (8/9) in the second run. Post-analytical PD-L1 scoring is also a challenge. Training and continuous exposure to PD-L1 IHC in routine practice can help to shorten the learning curve. In fact, the interobserver concordance of TC scoring was found to be higher among pathologist who had received specific training. Continuous monitoring of PD-L1 IHC values for comparison with the results of other institutions via an online database is emerging as another useful tool to control and fine tune of performance of PD-L1 IHC analysis of single pathologists or institutions, as demonstrated by the BIO-PATH biomarker tracker (https://www.biopath.ch/mha/). IBS08 ROLE OF PATHOLOGIST IN THE ERA OF IMMUNOTHERAPIES
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS08.02 BEYOND PD-L1 IHC (TMB, IMMUNE MICROENVIRONMENT)

M. Mino-Kenudsen

Massachusetts General Hospital, Boston/United States of America

PD-L1 expression by immunohistochemistry (IHC) is currently the only FDA-approved biomarker for immune checkpoint inhibitor therapy (ICI). However, there are multiple issues associated with PD-L1 IHC including the presence of multiple IHC platforms, each anti-PD-1/PD-L1 agent coupled to the specific PD-L1 IHC assay and spatial and temporal heterogeneity of PD-L1 expression in the tumor. Importantly, PD-L1 expression is not the best biomarker to predict response to PD-1/PD-L1 blockade given the relatively low specificity.(1) To improve the prediction of response to ICI, several biomarkers have been studied. Of those, tumor mutation burden (TMB) and immune microenvironment are emerging as predictive biomarkers. TMB is commonly defined as the total number of somatic coding mutations and is considered a surrogate for the amount of neoantigens based on the notion that the greater the number of nonsynonymous mutations in a given tumor, the more probable it is that some of the mutations will be immunogenic, providing targets for T-cell attack.(2) Rizvi and colleagues have shown higher synonymous mutation burden in tumors associated with improved objective response, durable clinical benefit, and progression-free survival (PFS) in two independent NSCLC patient cohorts treated with pembrolizumab.(3) Subsequently, the efficacy of TMB predicting response to ICI has been reported in several clinical trials. In the CheckMate 026,(4) which failed to confirm the efficacy of Nivolumab compared to the standard chemotherapy for advanced NSCLC patients as the first line, the biomarker subanalysis revealed that PFS of patients with high TMB was significantly longer than those with low and medium TMB when treated with Nivolumab, but the reverse was true when treated with chemotherapy. Further, upon stratified by both TMB and PD-L1 expression level, patients with both high TMB and high PD-L1 expression showed a high response rate (75%) and dramatically improved PFS compared to other groups when treated with Nivolumab, but there were no significant differences in PFS among the groups when treated with chemotherapy. Of note, TMB was measured using whole-exome sequencing (WES) in this study. In the CheckMate 227 study,(5) high TMB ($\geq$10 mutations/Mb) was associated with significantly improved outcomes with nivolumab/ipilimumab, with 1-year OFS of 43% versus 13% for chemotherapy, and the median PFS was 7.2 months versus 5.5 months (hazard ratio of 0.58, P<0.001). For patients with lower TMB, immunotherapy was not superior. Other studies have measured TMB in the blood and reported similar results for treatment with atezolizumab.(6) It is important to note that TMB and PD-L1 expression are independent variables and composite of TMB + PD-L1 expression further enrich for benefits from ICI.(7) Unfortunately, similar to PD-L1 IHC, the TMB

assessment has not been standardized yet. Although conducting comprehensive WES is ideal to assess TMB, it is currently not feasible in daily practice given the high costs, long turn-around time and suboptimal quality and quantity of tissue available from advanced lung cancer patients. Now, targeted panel sequencing or next generation sequencing (NGS) has become a part of clinical practice; thus, it would be desirable to leverage it to assess TMB. However, size and composition of panels, and read depth and coverage are diverse between NGS platforms; thus, the cut-off for high TMB is plat-form dependent. Importantly, TMB values represent a continuum rather than distinct clusters, NGS platforms with small gene panels may be difficult to predict TMB comparably to WES, while larger panels such as the 468-gene MSK-IMPACT panel and 315-gene FoundationOne panel could. Currently, the harmonization efforts on TMB are being conducted in the US (Friends of Cancer Research [FoCR]) and Germany (Qualitatssicherungs-Initiative Pathologie QuIP GmbH [QuIP]) in hope of enabling international and cross-sector standardization of TMB measurement and reporting.(8) As for the immune microenvironment, there are many types of immune cells, including T cells, B cells, myeloid-derived suppressor cells, tumor-associated macrophages and neutrophils. Of those, CD8+ cytotoxic T cells have been recognized as an important player and their density and location have been reported in association with response to ICI.(9) However, not all CD8+ T cells are in the same functional status. For instance, they may be activated characterized by the production of Granzyme B and Perforin and high Ki-67 proliferative index, and they may be exhausted characterized by the expression of LAG3, TIM3 and/or B7H3, among others. Interestingly, Gettinger and colleagues using multiplexed quantitative immunofluorescence have shown that a dormant tumor infiltrating T lymphocyte (TIL) phenotype, characterized by elevated CD3+ TILs with low activation (Granzyme B in CD3) and low proliferation (Ki-67 in CD3), is associated with survival benefit in patients treated with ICI.(10) Thus, we need to evaluate multiple immune markers at the same time to understand the immune microenvironment, preferably using a multiplex platform.

IBS09 CHALLENGES IN TRANSLATING SMALL CELL AND NEUROENDOCRINE TUMOR RESEARCH INTO CLINICAL PRACTICE
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS09.01 IBS09 CHALLENGES IN TRANSLATING SMALL CELL AND NEUROENDOCRINE TUMOR RESEARCH INTO CLINICAL PRACTICE

A. Adjei

Mayo Clinic, Rochester/United States of America

Challenges in Translating Small Cell and Neuroendocrine Tumor Research into Clinical Practice Alex A. Adjei, MD;PhD Mayo Clinic, Rochester, MN, USA According to World Health Organization (WHO) classification of lung tumors in 2015, small cell lung cancer (SCLC) is one of four lung tumors of neuroendocrine origin. Key morphological features of SCLC are dense sheets of small cells, scant cytoplasm, ill-defined cell borders and distinctive nuclear quality. These tumors are typically high grade, manifesting a high proliferation rate, apoptosis and necrosis. Ki-67 is typically 50-100%, and there is neuroendocrine differentiation documented by expression of synaptophysin, chromogranin A, NCAM1 and insulinoma-associated protein 1 (INSM1). These tumors are very aggressive with high metastatic potential. While they are very responsive to initial therapy, there is invariably relapse and 5 year survival overall is less than 10%. A number of agents thought to be very promising, including the antibody drug conjugate Rova-T, and PARP inhibitors have yielded negative results. In this presentation we will review some of these studies to discern any lessons that can be learned from the failed studies. We will discuss promising new agents such as lurbinectedin, and EZH2 inhibitors and DNA damage response modifiers. A number of molecular vulnerabilities of SCLC have been identified. These include loss of TP53 and RB function, expression of the ASCL1, MYC, and Notch signaling pathways and unique neuronal characteristics. In addition, SCLC subtypes defined by differential expression of four key transcription regulators, the achaete-scute homologue 1 (ASCL1), neurogenic differentiation factor 1 (NeuroD1), yes-associated protein 1 (YAP1) and POU class 2 homeobox 3 (POU2F3), have been described. These new insights will be discussed in this presentation. The most significant advancements in the last year shown in Figure 1 below will be described

IBS09 CHALLENGES IN TRANSLATING SMALL CELL AND NEUROENDOCRINE TUMOR RESEARCH INTO CLINICAL PRACTICE
SUNDAY, SEPTEMBER 8 07:00–08:00

IBS09.02 IMMUNOTHERAPY FOR SMALL CELL AND NEUROENDOCRINE TUMORS

S. Goldberg

Yale School of Medicine, New Haven/United States of America

A subset of patients with small cell lung cancer (SCLC) will achieve significant benefit from immunotherapy. Both nivolumab and pembrolizumab have demonstrated responses in patients with advanced SCLC, and atezolizumab in combination with chemotherapy results in an improvement in overall survival (OS) compared to chemotherapy alone. However, the ability to translate findings from the laboratory into patient care has been limited by several challenges. Though some patients will have durable response to PD-1 or PD-L1 agents, the majority of patients will not benefit. Combination strategies have been proposed and subsequently tested to potentially improve outcomes. Although ipilimumab was not effective as a single-agent for patients with SCLC, it has been combined with nivolumab in a phase I trial. The combination appears to be promising with response rates and OS that numerically exceeds that of single-agent PD-1 inhibitor therapy, although a randomized comparison trial has not yet been performed. Still, the majority of patients will not respond to the combination of PD-1 and CTLA-4 inhibition. Other immunotherapy targets have been explored pre-clinically though none have proven to be effective in patients to date. Another challenge in improving outcomes for patients with SCLC is that predictive biomarkers have been elusive. In contrast to non-small cell lung cancer, SCLCs rarely express PD-L1 on tumor cells and its presence has limited predictive value. However, immune cells in the tumor microenvironment more commonly express PD-L1 and may be predictive of benefit from immunotherapy. High tumor mutation burden (TMB) is also found in the majority of patients with SCLC likely due to the heavy smoking history in most patients with the disease. Patients with SCLC with a high TMB have been shown to have better outcomes with PD-1 inhibitors that those with lower TMB, however even those with the highest TMB have a fairly low chance of response or prolonged survival. Despite PD-L1 expression on immune cells and high TMB in most tumors, frequency of tumor infiltrating lymphocytes (TILs) is typically low in SCLC, possibly explaining the lack of response to immunotherapy in most patients with this disease. The benefit of immunotherapy for a subset of patients with SCLC has been proven, yet we are still faced with several challenges to optimize this treatment, including finding effective combination strategies that benefit more patients and developing predictive biomarkers to select those who are most likely to benefit.

IBS10.01 SURGERICAL TREATMENT OF TRACHEAL TUMOURS

W. Klepetko

Medical University Vienna, Vienna/Austria

Tracheal tumors are relatively rare and account only for <1% of all malignant diseases.[1] The most common types of primary tracheal tumors are squamous cell carcinoma and adenoid cystic carcinoma, which represent together two thirds of all primary tracheal tumors.[2] Additionally, patients with secondary tracheal tumors might benefit from resection of the tumor including the trachea. Surgical procedures involving the trachea require a meticulous pre-operative planning, advanced surgical techniques and infrastructural prerequisites. Therefore, surgical resections of tracheal tumors are highly elective procedures at specialized centers. The preoperative work-up includes the histological verification of the tumor via bronchoscopy, which is usually combined with the determination of the estimated extend of resection. Moreover, radiologic imaging, preferably PET-CT, completes the tumor staging. Patients with locally advanced and initially unresectable tracheal tumors might be candidates for neoadjuvant therapy. Usually, neoadjuvant treatment consisting of sole chemotherapy is preferred, as radiation therapy may negatively impact the anastomotic healing. If the patient received induction therapy, the radiological imaging as well as the bronchoscopic evaluation has to be repeated after completion of the induction therapy to confirm the response to the therapy and to plan the surgical procedure. The most common approaches for tracheal resection include cervicotomy, partial or complete sternofissure, and posterolateral thoracotomy. The optimal surgical approach has to be chosen according the location and extent of the tumor. During surgery, special care should be taken to preserve the lateral blood supply of the trachea, to protect the recurrent nerves and to avoid excessive tension on the anastomosis. Inadequate surgical technique increases the risk for anastomotic insufficiency, which is a potentially life-threatening complication. In the literature, anastomotic complications (i.e. partial or complete dehiscence, granuloma or re-stenosis) occur in approximately 9% cases after tracheal surgery. The risk for anastomotic complications increases with the length of resection, diabetes mellitus and previous treatments.[3] As the airway in tracheal surgery has to be shared with the anesthesiologist, an appropriate ventilation strategy during induction of anesthesia, surgical preparation and at the end of the surgical procedure has to be defined. Although the double-lumen tube is routinely used in thoracic surgery, it has only a negligible role in airway surgery. The preferably used devices in airway surgery are the laryngeal mask, single-lumen endotracheal tube, high-frequency jet ventilation catheters and cross-table ventilation using a sterile endotracheal tube. Moreover, extracorporal membranoxygenation (ECMO) support is a valid option for selected, complex resections. It provides the advantage to operate on the patient without any airway device in the surgical field. A veno-venous ECMO is sufficient to fully substitute respiration. However, cardiorespiratory support by a veno-arterial ECMO configuration might be a valid option in some patients. In summary, the ventilation strategy is dependent on the location of the location, availability of devices, experience of the team and personal preferences. Therefore, planning the ventilation strategy is crucial for a successful surgical procedure. Similar to the surgical treatment of other solid malignancies, the major aim of tracheal surgery is the radical resection of the tumor including all loco-regional lymph nodes. The adenoid-cystic carcinoma represents an exemption from this rule. Due to its low-malignant tumor biology and the susceptibility to radiotherapy, even incomplete resection is acceptable in this tumor entity. As the adenoid-cystic carcinoma is characterized by a longitudinal, submucosal growth pattern (Figure 1), there might be a discrepancy between the resection length needed to obtain a complete resection and the technical possibility to perform a tension-free anastomosis. An incomplete resection combined with an adjuvant radiation therapy is therefore a valid treatment option in patients with adenoid-cystic carcinoma. Radiotherapy can be initiated as bronchoscopy confirms complete healing of the anastomosis approximately 6-8 weeks after surgery. Although the treatment of patients with tracheal tumors is demanding, an excellent perioperative and long-term outcome of patients with tracheal tumors can be achieved. In experienced hands, the peri-operative mortality after tracheal resection is <1%.[4] Moreover, surgery in multimodality treatment concept provides a very good long-term overall survival, which is especially true for adenoid- cystic carcinoma in which a 5-year overall survival up to 91% can be achieved.[5] In summary, the surgical treatment of tracheal tumors is technically demanding and should therefore be performed at high-volume centers. Within the heterogeneity of tracheal tumors, the adenoid-cystic carcinoma represents a unique tumor entity. Embedded in a multimodal treatment concept, excellent long-term outcome can be achieved despite incomplete surgical resection. After careful planning by a multidisciplinary team, even extended tracheal resections for malignant disease can be performed safely with a very low morbidity and mortality.

IBS10.02 ENDOSCOPIC TREATMENT OF UNRESECTABLE TUMORS OF THE TRACHEA

J. Sun

Shanghai Chest Hospital, Shanghai Jiao Tong University, Shanghai/China

Surgical excision and reconstruction remain the recommended treatment approachs for patients with trachea tumors. However, it is associated with significant trauma and the risk of severely damaged pulmonary function, and not all patients are therefore willing to receive or fit for surgical resection. Traditional chemotherapy and radiotherapy can't improve the prognosis of these patients, which requires a multidisciplinary treatment. Endoscopic treatments, including electrocoagulation, argon plasma coagulation (APC), laser, photodynamic therapy (PDT), cryotherapy, balloon dilatation, stent placement, etc., have been demonstrated to be effective methods in the treatment of the trachea tumors. For tracheostenosis caused by malignant tumors, the first thing we should do is to relieve the symptoms and keep stable vital signs, so that we can seek chance for the patients to receive other therapies. Ablation therapy only or ablation therapy combined with stent placement are recommended for intraluminal obstructive stenosis. For external pressure stenosis

and mixed stenosis, stent placement only and ablation therapy combined with stent placement are recommended, respectively. Some endoscopic treatments are also recommended for patient with early central lung cancer that is ineligible for surgery by British Thoracic Society Guidelines and American College of Chest Physicians Guidelines [1,2]. Endobronchial ultrasonography can help determine the depth of tumor invasion of the tracheobronchial wall, which can be used for the staging of early central lung cancer to provide guidance for the treatment [3]. Previous study demonstrated that cryotherapy was an effective method in early superficial bronchogenic carcinoma, which could be proposed as a first-line therapy in the population with high carcinogenic risk [4]. Hybrid technology, an innovate technique, combining water jet function with APC, is being used in the clinical practice. It can create a water cushion, providing shelter for the tissues under submucosa, and then the lesion can be ablated effectively and safely (Figure 1) [5]. Endoscopic treatments are performed through natural orifice and have advantages of less trauma, repeatability and lower cost, which is becoming one of the most important treatment methods. Patients can benefit more from endoscopic treatments, especially in patients with unresectable tumors, low-grade malignant trachea tumors, early central lung cancers, and benign trachea tumors.

IBS11 ELECTRONIC CIGARETTES AND HEAT-NOT-BURN TOBACCO PRODUCTS - HOW ARE THEY DIFFERENT
MONDAY, SEPTEMBER 9 07:00–08:00

IBS11.01 IBS11 ELECTRONIC CIGARETTES AND HEAT-NOT-BURN TOBACCO PRODUCTS - HOW ARE THEY DIFFERENT

M. Goniewicz

Roswell Park Comprehensive Cancer Center, Buffalo/United States of America

Introduction: Although combustible tobacco cigarettes remain the most popular nicotine-containing products worldwide, non-cigarette products are evolving rapidly. Use of combustible tobacco remains the number one preventable cause of disease, disability, and death, however the effects of non-cigarette products on population-level health is unknown. Over the last 10 years electronic cigarettes (e-cigarettes) have gained considerable popularity, especially among smokers and youth. With the introduction of the 'Heat-not-Burn' (HnB) products (iQOS from Philip Morris International, Ploom TECH from Japan Tobacco International, and Glo from British American Tobacco) the landscape of tobacco product exposure has changed yet again. Population studies: Some early models of HnB products were developed in the late 1980s; however they did not reach a significant number of consumers and were withdrawn from the market. The introduction of HnB products in Japan in 2014 has been accompanied by an enormous decline in combustible cigarettes. Results from an international survey (International Tobacco Control (ITC) project) showed that that a high percentage of respondents believed HnB and e-cigarettes to be less harmful than cigarettes. Interestingly, smokers in Japan were most likely of 22 countries to believe that HnB were less harmful than cigarettes. Relative harmfulness beliefs of HnB may be both a cause and an effect of their popularity in Japan, fueled by marketing efforts. Ongoing studies will relate these beliefs to reasons for using HnB products, and, with future cohort data, transitions to/from HnB and cigarettes. Concerns have been raised that novel HnB tobacco products may be appealing to youth. Our research have showed that awareness and interest in HnB products among youth in Canada, England and USA was stable between 2017 and 2018, and concentrated primarily among smokers. Perceptions of HnB products are more similar to e-cigarettes than combustible tobacco. Toxicity: HnB tobacco products purport to deliver nicotine while reducing exposure to toxicants compared with combustible nicotine products such as tobacco cigarettes by avoiding directly burning tobacco and instead heating tobacco. We measured nicotine in HnB product and found that it delivered 1.4 mg nicotine from a single cartridge, while e-cigarette and tobacco cigarettes delivered 1.3 mg and 2.1 mg nicotine, respectively. In conventional cigarettes, once tobacco is heated above 600°C, combustion occurs, and smoke containing harmful chemicals is released. HnB have an electrical heating component, like e-cigarettes, that heats processed tobacco to 350°C releasing volatile components that often are not detectable in e-cigarettes. In general, yields of carbonyl and aromatic compounds and amines (except for nicotine) in HnB products have been shown to be between one and two orders of magnitude lower than yields of combustible cigarettes, but relatively similar to those of e-cigarettes. Hypothetically, reducing the aerosol generation temperature can result in lower emissions of tobacco combustion byproducts and reduced toxicity as compared to conventional tobacco cigarettes. Although many combustion by-products may be eliminated in HnB devices, carcinogenic nitrosamines are generated in the process of tobacco curing rather than during combustion, and may be transferred from the HnB into the aerosol that it generates. Our group tested nicotine and four Tobacco-Specific Nitrosamines (TSNAs), potent lung carcinogens, in HnB product iQOS. We compared TSNA levels in aerosols from HnB, e-cigarette and cigarette smoke. TSNA yields were significantly higher in the HnB product than those found in e-cigarettes but significantly lower than those found in tobacco cigarettes. TSNA yields in a smoke from single tobacco cigarette were between 7-17 times higher than TSNA yields in emissions from a single HnB cartridge. Potential health effects: Claims of lowered risk or health benefits for HnB compared to conventional cigarettes are based almost exclusively on industry-funded research, and except limited number of product testing studies, independent research is not available to support these claims as of 2019. To determine the cytotoxic and proinflammatory effects of HnB products, we exposed bronchial epithelial cells aerosol generated from HnB, e-cigarette aerosol, tobacco smoke or air (control) using an air–liquid interface system. Exposure to HnB resulted in decreased cell viability and increased release of pro-inflammatory interleukins as compared to air controls. Tobacco cigarette was the most toxic product. Interestingly, HnB product showed reduced toxicity as compared to tobacco cigarettes but increased toxicity compared to e-cigarettes. Finally, we used animal model to evaluate if short term in vivo exposure to HnB aerosols has the potential to recruit immune cells into the lung. We exposed mice to emissions from HnB, e-cigarette, and tobacco cigarettes. After 2-week exposure, we have made the novel observation that there was a hierarchy in the inflammatory response in the lung following exposure to the different products, with tobacco cigarettes causing the strongest and e-cigarette the weakest responses. Summary: HnB are different from conventional cigarettes and overall appears to deliver less of some toxicants. It is currently not clear whether HnB products may pose lower, the same or higher health risks than combustible cigarettes depending on the disease. HnB products emit more of several important toxicants and carcinogens with more adverse health effects than e-cigarettes.

Comparison of tobacco cigarettes, Heat-Not-Burn (HnB) products, and e-cigarettes.

	Tobacco Cigarettes (TC)	Heat-not-Burn (HnB)	E-cigarettes (EC)
Nicotine	YES	YES	**YES** (most products)
Tobacco	YES	YES	NO
Combustion	YES	NO	NO
Temperature	**YES** (very high during puffs)	**YES** (lower than TC)	**YES** (lower than TC; can be over-heated)
Electronic system	NO	YES	YES

IBS11 ELECTRONIC CIGARETTES AND HEAT-NOT-BURN TOBACCO PRODUCTS - HOW ARE THEY DIFFERENT
MONDAY, SEPTEMBER 9 07:00–08:00

IBS11.02 E CIGARETTES/ ELECTRONIC NICOTINE DELIVERY SYSTEMS: A WORD OF CAUTION ON HEALTH

M. Unger

Thomas Jefferson University, Philadelphia/United States of America

This presentation discusses the introduction, development, and proliferation of new electronic nicotine delivery systems (ENDS) including E-cigarettes and Heat Not Burn Tobacco products. The use of these products is considered a means for improving public health and reducing the mortality attributed to cigarette smoking. The epidemiology and effects of use of various ENDS and their components are described. To date, multiple studies indicate that, despite differences in toxicity, there is insufficient evidence that use of ENDS leads to effective smoking cessation. Research questions will be proposed to address key unanswered questions about the effects of such systems and their role in tobacco risk mitigation in various populations.

IBS11.03 CANNABIS AND LUNG CANCER

J. Jett

National Jewish Health, Napa/United States of America

Cannabis is a generic term that includes cannabinoids, marijuana (MJ) and hemp derived from the plant Cannabis sativa. Documented use dates back several centuries BC. In 1970 the Controlled Substance Act classified cannabis as a Schedule I drug with high abuse potential and no medical use. Other Class I drugs are heroin, LSD and cocaine. Similarly, cannabis is illegal in many other countries. There are many different cannabinoids in cannabis but the two main ones are delta-9-tetrahydrocabinol (THC) and cannabidiol (CBD). The THC is associated with psychoactive effects of euphoria and relaxation and CBD is not associated with the euphoric effects but is associated with anxiolysis. Pharmaceutical grade cannabinoids are scheduled/classified differently and there are several FDA approved medicines in the USA and available is many other countries. Dronabinol (THC) and nabilone are available for chemotherapy induced nausea and vomiting (CINV). Nabiximol (1:1 mixture of THC and CBD) is used for analgesic effects and spacicity due to multiple sclerosis. It is approved for use in many countries but not the USA. (NASEM; Jett et al) Cannabis products can be smoked, vaporized, ingested or applied topically. Smoked or vaporized cannabis reaches the brain within 30 seconds to a few minutes and the effects subside over 1-3.5 hours which makes it easier to titrate the dose/effects than ingested products which results in effects 30 minutes to 2 hours after ingestion and may last 5-8 hours. The average THC levels in MJ were 4% in 1995 and increased to 12% in 2012. However, in recent years with new products such as wax, honey oil, dabs etc that may have concentrations of THC of 40-80% so the effects on the user may be more psychologically and physically intense and effects may include paranoia, anxiety, panic attacks and hallucination. Cannabis containing many of the same toxins and carcinogens as tobacco smoke. Regular smoking of MJ is associated with airway inflammation similar to cigarette smoking and regular use of cannabis alone (without tobacco) may result in symptoms of chronic bronchitis. (Douglas IS et al) There is no conclusive evidence that cannabis smoking is associated with an increased incidence of lung cancer. The best available evidence comes from six case-control studies within the International Lung Cancer Consortium (Zhang LR et al, NASEM). An epidemiologic review of six lung cancer studies concluded that these studies did not support an association of MJ use and lung cancer (Huang Y-HJ et al). A limitation of these pooled studies is the small number of heavy and chronic users of cannabis. The National Academy of Science, Engineering and Medicine (NASEM) expert panel concluded that there is moderate evidence of no statistical association between cannabis smoking and the incidence of lung cancer. There is an increasing body of evidence that cannabinoids have some anti-cancer effects in cell cultures and animal studies. However, there are no convincing clinical trials demonstrating that cannabis is effective in cancer patients.(NASEM) There is insufficient evidence to support the use of cannabinoids in cancer patients, in spite of claims on the web/internet that concentrated cannabis oils can cure cancer. There is evidence that use of cannabinoids are of benefit for treating chronic pain, including neuropathy. Whiting et al performed a meta-analysis of 28 studies that mainly used pharmaceutical grade (Schedule III) cannabinoid based drugs such as nabiximol or nabilone and some smoked or inhaled THC trials. All but one was placebo controlled. The odds ratio was 1.4 of reporting 30% or more improvement in pain with cannabinoids. The NASEM concluded that there is substantial evidence that cannabis is an effective treatment for chronic pain. There have been patient reported outcomes that suggest that cannabis is beneficial for pain, anxiety and depression and may reduce the use of prescription drugs. (Corroon JM et al; Zaki P et al; Anderson SP et al). The NASEM panel concluded stated that there is conclusive evidence that oral cannabinoids are effective antiemetics for treatment of chemotherapy induced nausea and vomiting (CINV). Nabilone and dronabinol are FDA approved drugs for CINV. Good quality studies of inhaled or ingested plant based cannabis for CINV are limited. Most of these randomized trials for CINV were before the use of 5-hydroxytryptamine (5HT3) receptor antagonists. Accordingly, many oncologists would use a 5HT3 antagonist initially. Nabilone or dronabinol may be used for rescue or refractory nausea and vomiting as backup treatment options. Patient reported outcomes have noted benefit from medical marijuana products for nausea and vomiting (Anderson SP et al). The FDA has approved use of dronabinol for human HIV induced anorexia but there is currently insufficient evidence to support or refute the effectiveness of cannabinoids for cancer associated anorexia-cachexia (NASEM). However, cannabis has been reported to increase appetite and patient reported outcomes have again suggested benefit from medical marijuana. In summary, there is no current evidence that smoking MJ results in an increased incidence of lung cancer. However, the landscape is changing rapidly with the legalization of medical and recreational cannabis. This along with the increasing concentration and dose of the available products may result in an increased number of heavy and chronic users. This will require careful follow-up. Other areas of urgent need, as related to this review, for controlled clinical trials include: 1) Do cannabinoids have any role in treatment of cancer? 2) Do cannabinoids have any efficacy in reduction of opioid use or dose? 3) Is there any role for cannabinoids in treatment of cancer anorexia-cachexia. IBS12 CASE-BASED MANAGEMENT OF BRAIN METASTASIS (BM) IN ADVANCED LUNG CANCER PATIENTS: CHANGING THE STANDARDS
MONDAY, SEPTEMBER 9 07:00–08:00

IBS12.01 QUESTIONS TO BE ADDRESSED

M. Guckenberger

University Hospital Zurich, Zurich/Switzerland

Brain metastases develop in relevant numbers of patients through their courses of metastatic non-small cell lung cancer (NSCLC) and are associated with worsening of quality-of-live and survival. Traditionally, outcome was very poor due to the lack of effective treatment options, for the brain metastases but also for extracranial metastatic disease. Recent advances in imaging, local and systemic treatment options have changed the prognosis of patients with NSCLC brain metastases and have challenged traditional treatment strategies. Management of patients with brain metastases today needs a more individualized approach due to the multiple factors influencing the decision making process: patient performance status; number, location and size of brain metastases; presence of symptoms and neurological deficits; presence and extend of extracranial disease; histology and presence of activating driver mutations; available systematic treatment options and their CNS activity; patient preference. From a local treatment perspective, radiosurgery and neurosurgical resection are treatment options, which have shown to improve survival in patients with limited brain metastases. Whole brain radiotherapy is not recommended after radiosurgery and neurosurgical resection; however stereotactic radiotherapy should be added to the resection cavity to improve local metastasis control. The value of radiosurgery without whole brain irradiation for multiple brain metastases is currently under investigation. Whole brain irradiation is today still recommended for patients with multiple and in particular symptomatic brain metastases; whether hippocampal avoidance can reduce the risk of damage to the neurocognitive system is not finally answered. The landscape is currently changing rapidly and fundamentally due to identification of activating driver mutations and the existence of effective targeted drugs. Additionally, treatment with immune checkpoint inhibition has also shown intracranial activity. Consequently, there is in particular a need to identify optimal combined modality strategies of local radiotherapy and systemic targeted drugs and immunotherapy.

IBS12.02 QUESTIONS TO BE ADDRESSED

E. Smit

Netherlands Cancer Institute, Amsterdam/Netherlands

Case-Based Management of Brain Metastasis (Bm) in Advanced Lung Cancer Patients: Changing the Standards. Questions to Be Addressed M. Guckenberger, E.F. Smit Dept. of Radiation Oncology, USZ, Switserland, Dept. of Thoracic Oncology, NCI, The Netherlands. Brain metastases develop in relevant numbers of patients through their courses of metastatic non-small cell lung cancer (NSCLC) and are associated with worsening of quality-of-live and survival. Traditionally, outcome was very poor due to the lack of effective treatment options, for the brain metastases but also for extracranial metastatic disease. Recent advances in imaging, local and systemic treatment options have changed the prognosis of patients with NSCLC brain metastases and have challenged traditional treatment strategies. Management of patients with brain metastases today needs a more individualized approach due to the multiple factors influencing the decision making process: patient performance status; number, location and size of brain metastases; presence of symptoms and neurological deficits; presence and extend of extracranial disease; histology and presence of activating driver mutations; available systematic treatment options and their CNS activity; patient preference. From a local treatment perspective, radiosurgery and neurosurgical resection are treatment options, which have shown to improve survival in patients with limited brain metastases. Whole brain radiotherapy is not recommended after radiosurgery and neurosurgical resection; however stereotactic radiotherapy should be added to the resection cavity to improve local metastasis control. The value of radiosurgery without whole brain irradiation for multiple brain metastases is currently under investigation. Whole brain irradiation is today still recommended for patients with multiple and in particular symptomatic brain metastases; whether hippocampal avoidance can reduce the risk of damage to the neurocognitive system is not finally answered. The landscape is currently changing rapidly and fundamentally due to identification of activating driver mutations and the existence of effective targeted drugs. Additionally, treatment with immune checkpoint inhibition has also shown intracranial activity. Consequently, there is in particular a need to identify optimal combined modality strategies of local radiotherapy and systemic targeted drugs and immunotherapy. From a systemic treatment perspective, it has become apparent that brain metastases may also be sensitive to tyrosine kinase inhibitors against a variety of targets and emerging data suggest that immune checkpoint inhibitors display activity as well. Therefore, in case of asymptomatic brain metastases at diagnosis when the primary lung cancer is characterized by an oncogenic driver, nowadays many would favour initial treatment with tyrosine kinase inhibitors in an effort to delay radiotherapy to the brain as long as possible. Whether symptomatic brain metastases at diagnosis may be managed in a similar manner, especially when refractory to high dose steroids, is less clear. The third generation EGFR TKI (osimertinib) and second/third generation Alk inhibitors (ceritinib, alectinib, brigatinib and lorlatinib) are associated with response rates in the brain in the relapse setting on treatment of first/second generation EGFR TKi's or first generation Alk inhibitor that are not different from extracranial response rates. Thus, also in this clinical situation, systemic treatment plays an important role in delaying radiotherapy – in particular whole brain radiotherapy- as long as possible. It should be noted however, that there are no formal randomized comparisons available of these treatment modalities.

IBS13 HOW TO IDENTIFY AND MANAGE TOXICITY IN STAGE III
MONDAY, SEPTEMBER 9 07:00–08:00

IBS13.01 RADIATION RELATED TOXICITIES IN LOCALLY ADVANCED NON-SMALL CELL LUNG CANCER (LA-NSCLC)

A. Sun

Princess Margaret Cancer Centre, Toronto/Canada

Dr. Alexander Sun, MD, FRCPC Addie MacNaughton Chair in Thoracic Radiation Oncology Princess Margaret Cancer Centre/University of Toronto Lung Cancer Site Group Leader, Radiation Medicine Program Associate Professor, University of Toronto Principal Investigator for PMH – RTOG/NRG Oncology Co-Chair, Lung Disease Site Committee, Canadian Cancer Trials Group (CCTG) Radical radiotherapy is uesd as definitive therapy in locally advanced non-small cell lung cancer (LA-NSCLC), either alone or in combination with chemotherapy and/or surgery. However, definitive doses of radiotherapy are associated with potential toxicity related to the organs at risk (OAR). The major OAR's related to radical radiotherapy for LA-NSCLC include the lung and esophagus. Therefore, we need to be able to identify and manage radiation pneumonitis and esophagitis during and after a course of definitive radiotherapy. For good performance status, unresectable stage III NSCLC, radical radiotherapy is delivered either concurrently or sequentially with chemotherapy to total doses of 60Gy or higher. Although the best outcomes have been obtained with concurrent chemoradiotherapy, higher rates of toxicity have also been observed. With the advent of the establishment of adjuvant durvalumab after definitive concurrent chemoradiotherapy, the management of pneumonitis in particular has become even more of a challenge given the potential overlapping toxicities. For poorer performance status patients, radical radiotherapy may be used alone. For resectable patients with LA-NSCLC, radical radiotherapy can be given concurrently with chemotherapy prior to surgical resection as part of trimodality therapy. In other instances, radical radiotherapy can be given adjuvantly post-operatively for positive margins and can be considered in pathological N2 disease. Prophylactic Cranial Irradiation (PCI) has also been delivered in LA-NSCLC, although mostly in clinical trials as PCI has not been established as part of routine standard of care in stage III NSCLC. In this session, a discussion as well as case presentations will be used to illustrate how to identify and manage the above toxicities in stage III NSCLC. References (max 10) Baker S, Fairchild A. IBS13.02 SURGICAL MANAGEMENT FOR PERIOPERATIVE COMPLICATIONS IN ADVANCED LUNG CANCER AFTER CHEMORADIOTHERAPY

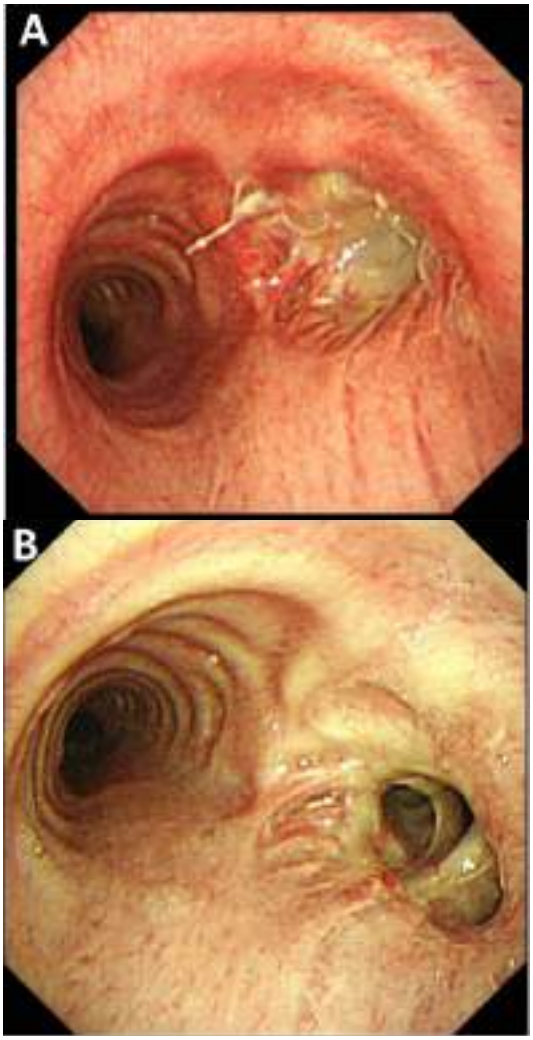
H. Date

Graduate School of Medicine, Kyoto University, Kyoto/Japan

Complete resection of residual lung tumor after induction or definitive chemoradiotherapy may be indicated for selected patients with advanced lung cancer. However, perioperative complication is a great concern. Here, we present videos of four cases requiring surgical intervention for perioperative complications. Case 1 A 59-year-old man was diagnosed with squamous cell carcinoma invading right diaphragm, left atrium and subcarinal lymph node (cT4N2M0). After induction chemoradiotherapy, he was downstaged to cT4N1M0 and underwent right thoracotomy. We realized that the tumor was invading liver through diaphragm. During partial hepatectomy, IVC was injured and massive bleeding occurred. Cardiopulmonary bypass was established and left lower lobectomy with combined resection of diaphragm, liver and left atrium was performed. Case 2 A 50-year-old man was diagnosed with unresectable left upper lobe squamous cell carcinoma invading aorta and #6 lymph node (cT4N2M0). Definitive chemoradiotherapy significantly shrank the tumor. One year later, he was referred to us for salvage surgery. At thoracotomy, we found no fissure between the left upper and lower lobes. The left basal bronchus was accidentally stabled by false recognition of lingula bronchus. The staple lines were removed, and the basal bronchus was reconstructed by end-to-end anastomosis. Then the left upper lobectomy with combined resection of aortic adventitia was performed. Case 3 A 69-year old man was diagnosed with right lower lobe adenocarcinoma with right #2 lymph node metastasis (cT2N2M0). After induction chemoradiotherapy, he underwent uneventful left lower lobectomy with extensive hilar and mediastinal lymph node dissection. He developed radiation pneumonitis and received steroid treatment. On day 52, he readmitted due to sever cough, fever and purulent sputum. Bronchoscopic examination showed left lower bronchial fistula (Figure 1). He underwent urgent right middle lobectomy. The

Case 4 A 55-year-old man underwent a right upper sleeve lobectomy for T2N1M0 squamous cell carcinoma originating in the right upper lobe and developed a symptomatic anastomotic stenosis at two months postoperatively (Figure 2a). He required repeated bronchoscopic dilations to relieve his symptoms, which at 1 year postoperatively were complicated with a perforation of the right middle lobe bronchus. Emergent completion pneumonectomy and auto-transplantation of the right lower lobe were performed. Satisfactory bronchial healing was obtained (Figure 2b).



Keywords: complication, surgery, chemoradiation

IBS14 BEST MANAGEMENT OF EARLY STAGE NSCLC IN ILD PATIENTS
MONDAY, SEPTEMBER 9 07:00–08:00

IBS14.02 IBS14 BEST MANAGEMENT OF EARLY STAGE NSCLC IN ILD PATIENTS

A. Louie

Sunnybrook Health Sciences Centre, Toronto/Canada

Interstitial lung disease (ILD) is characterized by diffuse inflammation and fibrosis within the lung parenchyma.[1]Although a heterogeneous group of diseases, invariably, it is associated with a restrictive defect on pulmonary function testing, and a reduced ability for gas exchange.[2] On imaging, features of ILD can include reticulation, traction bronchiectasis and honeycombing. Interestingly, a diagnosis of ILD is an independent risk factor for the development of lung cancer.[3] Stereotactic ablative radiotherapy (SABR) is a common radical treatment modality for patients with early stage NSCLC and is characterized by its convenience, tolerability, and high efficacy.[4] Given these features, it has been popularized as an attractive option in early stage NSCLC patients with significant medical co-morbidities. Early stage NSCLC patients with co-existing ILD, however, are a high-risk group for any type of treatment, both for treatment-related toxicities and for acute exacerbations of ILD. These toxicities can be severe, and in extreme scenarios, fatal. The focus of this abstract will be on the use of SABR for early stage NSCLC patients with ILD, with an aim to discuss emerging data and future research directions. Despite the generally favorable toxicity profile of SABR, there are an increasing number of reports of serious toxicities in patients with pre-existing ILD. These reports have largely been retrospective in nature, heterogeneous in the radiation doses employed, with findings of extreme ranges in treatment related death rates. Arguments can be made on whether some of these

reports, especially in those with exceptionally high rates of extreme toxicity, confer an element of publication bias. This refers to the phenomenon whereby there is an inclination to report results that are more remarkable (i.e. major toxicity or treatment-related death). Therefore, although it is likely that SABR incurs a greater risk in this setting compared to standard lung SABR cases, the true risk is unclear. To further delve into this issue, our group recently performed a systematic review and meta-analysis of outcomes following several different treatment modalities for early-stage lung cancer patients with ILD.[5] From this initiative, 13 studies assessing outcomes after SABR were identified, and recognizing the caveats of the available data, we concluded that there was a 1 in 4 risk of severe radiation pneumonitis (defined as grade ≥3), and a 15% risk of treatment-related grade 5 toxicity. A specific diagnosis of idiopathic pulmonary fibrosis (IPF) appeared to be associated with the greatest risk, whereby treatment related mortality was 1 in 3, as compared to 14% for non-IPF fibrotic ILD. When considering this potential increased risk, it is important to recognize that the IPF patient population has a significant background risk of acute exacerbations of their disease, with an annual reported range of 5-19%.[6] The Canadian Pulmonary Radiotherapy Investigators group (www.capriclinicaltrials.com) has designed a single arm phase II trial to evaluate the role of SABR in T1-2N0M0 NSCLC patients with co-existing ILD who are not surgical candidates. The trial (clinicaltirals.gov, NCT03485378) is entitled: *Assessment of Precision Irradiation in Early Non-Small Cell Lung Cancer and Interstitial Lung Disease* (ASPIRE-ILD). To our knowledge, this will be the first prospective trial evaluating this clinical scenario, and it is novel in that patients will be stratified using the ILD-GAP score, which is an index that incorporates ILD mortality risk according to Gender, Age and Physiology.[7] The starting SABR dose will be 50 Gy in 5 fractions, and the dose fractionation will be escalated or de-escalated depending on toxicities observed in different cohorts of the trial. The appropriateness of SABR in any, or some of these patients can certainly be questioned in light of the potential serious toxicity. On the other hand, the median survival of untreated stage I NSCLC has consistently been reported to be less than 1 year in various studies.[8] Therefore, the value of treatment would ideally be answered through a randomized controlled trial, however, this is probably unfeasible as patients and physicians alike may be uncomfortable with randomization. Given the inherent risks of both untreated cancer as well as any cancer-directed treatment, we encourage investigators to continue to report on their experiences in this challenging clinical dillemma, whether positive or negative, so that additional research can inform shared decision making. IBS15.01 CURRENT STATUS OF IO IN LUNG CANCER

S. Gettinger

Yale Comprehensive Cancer Center, New Haven/United States of America

Only a decade ago, lung cancer was largely considered a non-immunogenic tumor. The focus of most clinical efforts at the time was development of molecularly targeted agents in hopes to personalize the systemic treatment of lung cancer. Although much has been accomplished over the last 15 years, with regulatory approvals of several targeted agents for EGFR, ALK, ROS1, BRAF and NTRK driven tumors, and emerging targeted therapies for other molecularly defined cohorts (e.g. MET, RET, HER2 driven tumors), the majority of patients with lung cancer do not have readily targetable molecular alterations. Arguably, the most impactful advance in the systemic treatment of lung cancer over the last several decades has been the appreciation and utilization of immunotherapy to attack and control typical lung cancer. Indeed, five- year survival rates from the first phase I trials of programmed death (PD)-1 inhibitor trials (BMS-003 and KEYNOTE-001) in patients with pre-treated advanced non-small cell lung cancer (NSCLC) are an unprecedented 16% (n=578, median duration of response 17 - 39 months), with five- year survival rate from one trial (KEYNOTE-001) evaluating chemo naive advanced lung cancer patients of 23% (n=101, median duration of response 17 months) (ref: PMID 29570421, 31154919). Based on subsequent randomized clinical trials, PD-1 axis inhibitor therapy has become standard first line therapy for the majority of patients with advanced NSCLC (those without readily targetable tumor molecular alterations), either alone (pembrolizumab) if tumor PD- ligand 1 (L1) expression is high (≥ 50%), or with standard platinum doublet chemotherapy if tumor PD-L1 expression is low/ negative/ unknown (pembrolizumab regardless of NSCLC histology; atezolizumab for non-squamous NSCLC) (ref: PMID 30620668, 29658856, 30280635, 2986395). PD-1 axis inhibitor therapy with durvalumab is additionally approved as consolidation therapy for patients with locally advanced NSCLC after receiving definitive concurrent chemoradiation without progression (ref: PMID 30280658). PD-1 axis inhibitor therapy has also shown activity in advanced small cell lung cancer (SCLC), with regulatory approvals of atezolizumab combined with first line etoposide/ platinum chemotherapy, and nivolumab or pembrolizumab as 3rd line therapy (in practice, nivolumab is often combined with ipilimumab after failure of chemotherapy as endorsed by the National Comprehensive Cancer Network) (ref: PMID 30280641, 27269741). Several phase III immunotherapy lung cancer studies are ongoing in the adjuvant and metastatic setting, with additional regulatory approvals anticipated in the coming years. Despite the success with PD-1 axis inhibitors, and tremendous impact on treatment paradigms for lung cancer, most treated patients do not clearly benefit from therapy, and most of those who do respond will ultimately develop resistance with recurrence/ progression of their cancer. Little is known about mechanisms of resistance, and coordinated translational efforts across cancer centers will be required to understand both acquired and primary resistance (to date, we are only aware of two published reports describing potential mechanisms of acquired resistance to PD-1 axis inhibitors in lung cancer; one implicating acquired loss of beta-2 microglobulin with resultant lack of MHC1 expression, the other, loss of tumor specific neoantigens through elimination of tumor subclones or chromosomal loss of truncal alterations) (ref: PMID: 28031159, 29025772). Currently, several trials are evaluating novel immunotherapeutic agents, including other immune checkpoint inhibitors, costimulatory agonists, vaccines, oncolytic viruses and cellular therapies. In most of these trials, patients are not selected by unique molecular/ immunologic characteristics of their tumor. Rather, empiric combinations of therapy (often including a PD-1 axis inhibitor) are generally trialed with tumor biopsies to help understand mechanisms of response and resistance. In clinical practice, a handful of unanswered questions repeatedly surface when treating lung cancer patients with immunotherapy. These include: What is the optimal duration of PD-1 axis inhibitor therapy? *Although there is little data to guide us here, we generally consider treatment holiday after 2 years of therapy without progression. However, PD-1 axis therapy can be continued indefinitely as was done in most registrational trials.* What is the role of immunotherapy in never smokers and those with targetable molecular alterations driving their disease? *There remains pessimism about use of immunotherapy in these populations, with the belief that tumors in such patients are less immunogenic (lower mutational burden with*

less neoantigens). However, there are limited numbers of patients who do respond, and efforts are underway to understand these responses. Novel immunotherapeutic approaches are also being developed. Currently, many thoracic oncologists will reserve PD-1 axis inhibitor therapy until no other standard targeted therapies (or trials evaluating novel targeted therapy) or chemotherapy remain. When should we concede that a patient's tumor is primarily resistant to PD-1 axis inhibitor therapy. i.e., how much time on therapy should be allowed to exclude delayed response or pseudo-progression. *Generally, if a patient's performance status has not deteriorated at the first tumor assessment on immunotherapy (6-8 weeks), many thoracic oncologists will continue therapy for another 6 weeks. If assessment at that time shows further progression, therapy is discontinued.* Should immunotherapy ever be continued with addition of other systemic therapy on progression of disease? *Generally, this is not recommended, unless a patient is having a mixed response or acquired resistance with oligo-progressive disease. That said, there is some rationale here, as PD-L1 may be induced in tumors by subsequent therapy.* Is there any role for consolidation durvalumab in patients with locally advanced NSCLC after concurrent chemoradiation followed by lung resection? *The PACIFIC trial leading to approval of consolidation durvalumab did not include such patients; currently, durvalumab is not indicated after surgery.* Should salvage nivolumab combined with ipilimumab be considered in patients with extensive stage small cell lung cancer after progression on standard chemotherapy plus/ minus atezolizumab. *Although nivolumab plus ipilimumab is not approved for use in the United States as salvage therapy for SCLC, it is occasionally prescribed as endorsed by the NCCN. It is unclear if the combination would have any activity in a patient who failed prior atezolizumab in combination with etoposide/ platinum.*

IBS15.02 DETERMINANTS OF RESPONSE TO ICI

F.R. Hirsch

Mount Sinai Hospital, New York/United States of America

While great promise has emerged with the development of immunotherapy (IT) in lung cancer, we are still struggling with how to select the right treatment to the right patients and how to select the patients, who will benefit from IT. Only 20-30 % of the patients with NSCLC will have a clear benefit from IT compared to chemotherapy alone, and the challenge is to select those patients. PD-L1 protein expression demonstrated by immunohistochemistry (IHC) has been pursuit as primary selection biomarker in the clinical trial development. However, the major challenge for evaluation of PD-L1 and top compare the results from one study to another was the use of different antibodies/assays and processing by the different companies. A comparison of the different PD-L1 assays was performed in the "PD-L1 Blueprint Project", and three antibodies/assays was found to be performing similarly and could be interchangeable (1,2). While higher PD-L1 expression seems to be associated with gradually increased outcome of IT, a tumor proportion score (TPS) ≥ 50% seems to be useful in the choice of IT (e.g. pembrolizumab) monotherapy versus IT plus chemotherapy (CT). The results (PFS/ OS) of IT monotherapy for patients with high PD-L1 expression is not significantly different than for IT+CT, although not directly compared, while for patients with tumors having lower PD-L1 expression, the combination of IT+CT seems better (3, 4). Thus, the predictive role of PD-L1 expression might be different between IT alone and IT+CT. The prognostic role of PD-L1 (e. g. association to outcome without any therapy) is still not clear with conflicting reported outcomes in the literature. Tumor mutation burden (TMB) has in some clinical trials demonstrated to be of predictive value, both based on tissue and plasma (5, 6, 7). In several studies it has been shown that the patient population with high TMB has little overlap with the patient population with high PD-L1 expression (6). Prospective clinical trials arer today performed evaluating plasma TMB as predictive biomarker (b-FIRST). However, also challenges related to TMB reports occur; different assay platforms have been used in different clinical trials, different definitions (e. g cut-offs) have been applied in the definition of high TMB vs low TMB, and also for TMB an comparison of results /assays seems to be needed. Such comparison studies are on-going both in the US (i.e. Friends of Cancer) and in Europe. On this stage, it is not clear whether TMB can replace PD-L1 IHC in treatment decisions; who will benefit from IT or not? Some studies (i.e. CheckMate 227) (8), indicate also that the two predictive assays are not "competing" but complementary. It has been shown that for patients having tumors with low (≤1%)- or no PD-L1 expression, but high TMB a treatment option of combined therapy with nivolumab+ ipilumumab seems justified. There are also conflicting results reported on the prognostic role of TMB associated to no systemic therapy or predictive role associated to chemotherapy alone. Other candidate biomarkers are under investigations and will be discussed. REFERENCES: Hirsch FR et al. IBS16.01 LUNG CANCER SCREENING AND ITS EFFECT ON SURGERY

G. Veronesi

Humanitas Clinical and Research Center, Milan/Italy

The diagnostic revolution started in 1999 when the group of Prof. Henschke in New York published the results of Elcap study showing that Low Dose CT scan had 7 times higher sensitivity than chest-Xray to detect stage I lung cancer in 1000 high risk individuals. Subsequently in 2006 the I-elcap published 80% cancer specific survival rate at 10 years of the 484 patients with a screening cancers detected in 31.000 screened subjects. More evidence was required by before implementing Lung Cancer Screening on a wider scale, and the US randomised controlled trial NLST released data in 2012. The investigators reached the objective of 20% mortality rate reduction in the screening arm so that they stopped the trial and suggested to partecipants of the control arm to be screened.We needed to wait additional 6 years to have the released data of Nelson study, the European largest RCT, which mortality reduction was unexpectedly better than NLST with a mortality reduction 26-39% in men and women at 10 years for the screening arm with LDCT compared to no screening. Despite the evidence is available, in Europe only few countries have started a national implementation. One of the potential obstacle is related to uncertainties on sustainability. In Italy to stimulate a policy maker decision, our group have calculated the potential economical impact to implement LDCT in the population at risk (the analysis was presented at WCLC in Toronto). In collaboration with the Bocconi university we have found one of the lowest ICER for LDCT screening, 3049 for QALY. In Italy the potential target population of LDCT program includes 2.166.000 millions high risk individuals (smokers or former smokers, 55 years or older with 30 packs year smoking history) and 120 milions euros /year is the potential cost to screen all the high risk individuals according to this preliminary CEA analysis. The other obstacle is related to safety of LDCT screening on a large scale outside the academic environment. How characteristic of lung cancer changed with introduction of screening? and which is the impact on surgical approaches? In our experience and other screening programs most cancer cases were diagnosed in stage I with a mean size of 1.6 cm. In addition recall rate was very low, 5-10 % compared to 20-27% on NLST, risk of overdiagnosis was very limited around 10% of screening cancers; Estimated risk of lung cancer due to LDCT radiation exposure was less than 1 out of 108 detected in the worst scenario, false positive cases less than 2 %. It was clear that traditional open lobectomy was an overtreatment and minimally invasive lung sparing resection was required. Different retrospective studies have shown that sublobar resection are adequate oncological operation for very early stage lung cancers (in particular subsolid, slow growing or low suv tumors). More data on this topic will come from the two ongoing randomised trials in Us and Japan comparing lobectomy and segmentectomies for stage Ia and Ib NSCLC. In this scenario among the different types of minimally invasive approaches the robotic technique has recognised a wide diffusion all over the world with a great success due to the indisputable technical advantages including optimal 3D view, increased degrees of freedom, motion scaling, stable camera platform. We described in 2014 the technique and results of robotic approach to afford typical segmentectomies and concluded that robotic system by improving ergonomic, surgeon view and precise movements, may make minimally invasive segmentectomy easier to adoptand perform.

In addition many surgeons find very useful to inject the ICG ev after isolation and resection to better define the intersegmental plane and thus perform a more radical resection according to the technique we described in 2014. In this way many small centrally located tumors with high suspiciousness of malignancy can be treated with a diagnostic and therapeutic resection using MIS and lung sparing procedure. One of the most discussed issue in the treatment of lung cancer is related to extension of lymph node dissection. We analysed a consecutive series of clinical N0 screen detected cancers to identify predictive criteria of nodal involvement and found that in very small (less than 1 cm) or PET negative tumorslymph node dissection can be avoided with no risk of nodal involvement. Major goals of surgical participation in lung cancer screening programs include: 1. Optimization of the management of screen detected nodules; 2. Reduction of false positive rates and surgical diagnosis of benign diseases; 3. Reduction of surgical incision-related trauma; 4.Avoid overtreatment and favor tailored resection; 5. Collect sample for biomarker research for diagnostic and prognostic molecular non-invasive tests; 6. Participate to multidisciplinary meeting with radiologists; 7. Participate in national or international registries for quality control. Henschke, C. I. et al., Early Lung Cancer Action Project: overall design and findings from baseline screening. IBS16 INVASIVE DIAGNOSIS AND SURGERY IN LUNG CANCER SCREENING PARTICIPANTS
MONDAY, SEPTEMBER 9 07:00–08:00

IBS16.02 MINIMALLY INVASIVE LUNG CANCER SCREENING

W. Rzyman

Medical University of Gdańsk, Barcelona/Poland

Lung cancer screening is a challenge for the specialists that are involved in this multidisciplinary venture. There is a huge number of individuals with CT-findings that are non-malignant and a lot of indeterminate pulmonary nodules that are difficult to assess. High sensitivity is required not to overlook early lung cancer but simultaneously acceptable specificity have to be ensured in order to reduce futile invasive diagnostics and treatment procedures related to false positive diagnoses (1,2,3). The experience of the multidisciplinary team and adoption of the specific radiological protocol that is strictly followed is a mainstay of successful lung cancer screening program. Thoracic radiologist is responsible for the reduction of false positive rate to a safe minimum. This goal can only be achieved by strict adherence to the guidelines and protocol for the assessment of nodules. LungRads or volumetry with assessment of volume doubling time should be applied to minimize false positive rate. The multidisciplinary discussion on tumor board meeting of the suspected cases is another element leading to the reduction of unnecessary invasive diagnostics and surgery in non-malignat leasions that produces harm, entails risk of complictions and increases costs (3). In Gdańsk where two screening programs were conducted during last 10 years most harmfull aspects were reduced almost doublefold (tab.1). several studies have shown that by applying an effective diagnostic algorithm together with multidisciplinary discussion of positive cases detected by CT screening, the frequency and extent of surgery for non-malignant disease can be minimized while a high cure rate for individuals diagnosed with lung cancer can be obtained (1,3,4). Mainly radiologists and thoracic surgeons involved in multidisciplinary tumor board have the important responsibility to minimize the risk of useless invasive procedures for benign disease and avoid overtreatment of very early cancers or precancerous lesions (1,3) The proportion of patients that are sent for invasive diagnostic procedures varies between 2-7% and depends on the quality of the screening center. In Gdańsk, although in both programs approximately 3,5% of individuals participating in the screening were sent for the diagnostics, lung cancer detection rate in these groups were 30% and 57% respectively so diagnostic accuracy increased significantly. The invasive diagnostic work –up is based on FNAB and CNB where radiologists play crucial role as in majority of the institutions they perform biopsies. Pulmonary nodules biopsy in the best institutions is performed with 80-90% specificity and sensitivity and reasonably low complication rate. Pneumothorax is among most frequently observed complications requiring pleural drainage in 10-20% of cases. Bronchoscopy, EBUS, EUS and PET-CT are additional tools that completing the diagnosis and staging. Endobronchial navigation bronchoscopy (ENB) is a supplementary method that enhances the diagnostic yield of flexible bronchoscopy from 36-68% to 63-77% depending on the size and location of peripheral pulmonary lesion. This method has great potential in the future treatment of small nodules detected in lung cancer screening programs. Lately two ablation systems are intensively tested that can be applied by ENB. The minimally invasive techniques in the future treatment of screening detected cancers are the only treatment options that could be accepted in this context. The application of ultrasound or radiofrequency ablation by ENB system in the treatment of pure GGO and mixed GGO lesions that are progressing would be the very promising solution. Although lobectomy is still a gold standard in the treatment of stage I NSCLC this dogma most probably is going to be changed in the near future, at least for T1N0 tumors. Many retrospective studies report no difference in overall and recurrence free survival of patients operated with lobectomy and sublobar resection. There are however many studies that are showing conflicting results. In the analysis of 6000 operated stage I NSCLC patients based on national lung cancer registry in Poland Dziedzic et al. have shown significantly inferior overall survival in wedge resection group comparing to lobectomy and segementectomy groups (5). Segmentectomy provides two benefits comparing to wegde resection: allows to obtain a wide resection margin and to perform hilar lymphnode resection. It is however much more technically demanding when VATS procedure is considered. In the presentation the crucial aspects of “minimally invasive” LDCT lung cancer screening will be discussed. IBS17 UNDERTAKING NURSING AND ALLIED HEALTH RESEARCH.. HOW TO SURVIVE IT AND GET PUBLISHED
MONDAY, SEPTEMBER 9 07:00–08:00

IBS17.01 UNDERTAKING NURSING AND ALLIED HEALTH RESEARCH - HOW TO SURVIVE IT AND GET PUBLISHED

K. White

Private Practice, Bexley North/Australia

The nursing and allied health professions include a diverse range of disciplines, such as many different specialist nurses, physiotherapy, occupational therapy, speech and language pathology, dietetics, social work, and others. The foundation of modern health service interventions is that of evidence-based practice, to ensure that patients are receiving interventions that have been proven, through robust research, to provide benefit for the patient. Nursing interventions have a longer history of research underpinning them than allied health. In the allied health professions, there remains a dearth of robust research providing a clear evidence base for interventions routinely used. This presentation will focus on the challenges faced by both nurses and allied health professionals, particularly clinicians, in undertaking research and, once a research study is completed, how to get the research published. This is even more challenging in the general speciality of oncology and within the sub-specialty of lung cancer. The lack of research among nursing and the allied health professions is not a new phenomenon. My unpublished undergraduate thesis for the BAppSc(OT) in 1994 was titled 'The replication of research in the health sciences', investigating the level of replication of research in occupational therapy, physiotherapy, speech pathology and nursing. The aim of this research was to ensure the scientific knowledge base of the interventions being utilised were valid and reliable. The outcome of the research demonstrated a significant limitation in the replication of research, with many interventions being utilised by these professions not having a strong evidence base, or any evidence base at all. Twenty-five years later the scientific base for these professions, as well as dieticians and new and emerging allied health professions, has improved. In the field of occupational therapy most national professional bodies now have a focus on supporting research through funding and the dissemination of research findings. How does a novice clinical researcher go about funding, designing, implementing and publishing a research study? One of the keys for novice researchers is to find an academic or clinical research mentor, who is able to support you in navigating the muddy waters of clinical research. Clinical research is key to ensuring research projects are designed to meet the needs of our rapidly changing clinical environment, emerging clinical areas and interventions. There are many challenges in being a clinical researcher. These include a lack of research competency and training, the pressure of large clinical caseloads, a lack of support from within nursing and allied health departments, as well as at a hospital level, where the priority is primarily for patient intervention, not research. In this presentation I will outline how I navigated my initial clinical research in lung cancer and progressed over time to become an applied public health researcher in cancer control. Throughout this research progression I have had the support of mentors and supervisors while completing higher degrees, as well as clinical champions in my workplaces. I will outline the steps required to develop a research project, including protocol development, practical tips for managing Human Research Ethics and Governance Committee applications, data collection and management. Once your research study is complete what next? Publish or perish remains a key concept for nursing and allied health professionals. While in some health conditions, such as paediatrics, spinal cord injury, and acquired brain injury to name a few, there is a strong body of evidence for allied health interventions, in oncology, specifically lung cancer, a dearth of evidence from the allied health professions continues. There has been an improvement in research in some specific areas of lung cancer management which involves allied health professionals, such as in exercise, rehabilitation, and psychosocial support. However, significant gaps in the evidence base for allied health interventions for people living with lung cancer remain.There has been a growth in nursing research, particularly in lung cancer, but how robust is this research output? Is the nursing profession producing robust RCT studies that inform clinical practice? Internationally, both nursing and allied health professionals may be completing research or quality improvement activities that are building on their evidence base. However, they may not be publishing these important findings. It is critical that the work being done is published and further built on, with ongoing research and investigation, to ensure a robust and evolving evidence base for all nursing and allied health interventions being provided to patients. There continues to be a dearth of research studies by allied health professionals, particularly in the area of oncology and more specifically lung cancer. For our professions to continue to grow in this speciality area and demonstrate our benefit, we need to engage and support clinicians to bring research into their daily clinical practice, to ensure a robust evidence base in oncology, and more specifically lung cancer, is developed.

IBS17.02 HOW TO GET YOUR RESEARCH PUBLISHED

T. John

Austin Health, Olivia Newton-John Cancer Research Institute, Melbourne/ Australia

It is becoming increasingly important for researchers to not only ask and answer questions, but to disseminate the information gained to the wider community. One of the most important and indeed respected means of disseminating information is publish your results in a peer reviewed journal. While this may sound very straightforward, those who have tried to publish their data will be familiar with the frustration with peer reviewers, of rejection without peer review, rejection following extensive peer review or the need to submit a completely revised manuscript. Here I will discuss some of the key principles of getting your paper published, based on my experience as an author, reviewer and associate editor. I will go cover a range of areas from writing a good cover letter, what to include in the paper, to how to respond to reviewers. There are no guarantees to getting your paper published where you want the first time round, but these pointers will hopefully enable you to pick the right type of publication, the right journal and the best way to frame your paper.

IBS18 ESSENTIALS IN BIOMARKER TESTING FOR LUNG CANCER
MONDAY, SEPTEMBER 9 07:00–08:00

IBS18.01 TESTING GUIDELINES IN 2019

M.B. Beasley

Mount Sinai Medical Center, New York/United States of America

Molecular alterations occurring in lung cancer which are either amenable or potentially amenable to treatment with targeted therapies have been identified at an exponential rate in the past decade. Consequently, an increasing number of post-treatment resistance mechanisms have also been identified. Adequate molecular testing is therefore critical for the identification of such alterations for appropriate treatment planning. As such, the first joint CAP/IASLC/AMP molecular testing guidelines were published in 2013 and were expanded in the updated 2018 guidelines. The necessity for this was due not only to the rapid advances in identification of targetable mutations but also to improved technologies with which genetic variants could be identified. Briefly, the 2018 guidelines recommend that, at a minimum, testing for *EGFR* hot-spot mutations as well as *ALK* and *ROS* translocations must be performed. Testing for *BRAF, RET, ERBB2, KRAS and MET* alterations were not recommended as stand-alone assays but were deemed appropriate as part of larger multiplex panels. *EGFR* T790M testing was the only strong recommendation for patients with targetable mutations who relapsed on targeted therapy. The guidelines were recommended for advanced stage adenocarcinomas or tumors with an adenocarcinoma component. Much latitude was left to individual practices in regard to testing early stage cancers and tumors with non-adenocarcinoma histology. European guidelines from ESMO provide similar recommendations regarding *EGFR* and *ALK* testing. In the time since the publications of these guidelines in 2018, the number of therapeutic targets has continued to increase. Additionally, there has been increased focus on neoadjuvant use of targeted therapies. While these neoadjuvant trials primarily focus on *EGFR*, *ALK* and *ROS* abnormalities, some extend beyond this scope to include mutations in genes such as *MET*, which are not part of the 2018 minimal testing criteria. All of these factors contribute to the increasing challenges of providing sufficient testing for optimal

patient care. Coverage of the ever-expanding list of targetable alterations is somewhat ameliorated by the recommendation of multiplexed next-generation sequencing panels (NGS) over single gene testing in order to identify treatment options beyond the minimal recommendations. NGS allows for a larger number of tests to be performed on a smaller amount of material, which is particularly critical given that most patients are diagnosed at an advanced stage and may only have a small biopsy or cytology specimen available as opposed to a resection. While misconceptions remain, cytology specimens are perfectly adequate for molecular testing provided sufficient material is present, an issue which can be a factor in any small biopsy specimen. Molecular testing on cytology specimens is typically performed on cell block preparations; however, results have also been achieved from other types of cytology preparations and supernatant material. In spite of these advances, it is recognized that significant knowledge gaps and limitations exists in regard to testing. As such, a significant number of lung cancer specimens do not undergo appropriate molecular testing. Further, access to testing, debates regarding cost-effectiveness, issues with reimbursement and optimal approaches in resource-limited areas remain a challenge. IBS18 ESSENTIALS IN BIOMARKER TESTING FOR LUNG CANCER
MONDAY, SEPTEMBER 9 07:00–08:00

IBS18.02 TESTS BY NEXT GENERATION SEQUENCING

L. Sholl

Brigham and Women's Hospital, Boston/United States of America

Next generation sequencing (NGS) encompasses a family of technologies that effectively multiplex and digitize nucleic acid sequencing. The major technical platforms used in clinical practice include hybrid capture and amplicon sequencing, either of which can be applied to tumor or cell free DNA testing. Essential steps for any NGS assay include: 1) capture of some or all of the genome; 2) massively parallel sequencing; 3) alignment of the sequencing reads to a reference genome; 4) variant calling and 5) variant interpretation. Each of these steps has a major influence on the assay output, including breadth of coverage (how much of the genome to sequence?), depth of sequencing (how sensitive is the assay?), accuracy, and clinical relevance. In general, DNA hybrid capture assays are optimized for breadth, both in terms of overall genomic real estate (from 100s of genes to the entire genome) and for capturing complex changes such as copy alterations and structural variants. The drawback to the approach, however, is high cost, limited analytic sensitivity, and suboptimal capture and sequencing of highly repetitive regions, leading to poorly-covered or uncovered areas of the genome. Amplicon based sequencing, in contrast, requires a much more focused design. This approach uses PCR to capture the genomic regions of interest and then employs massively parallel sequencing to interrogate each individual PCR amplicon. This approach is lower cost, more sensitive, and faster than hybrid capture, but is best suited for small targeted panels (10s to 100s of genes), is less reliable for detection of copy number changes and rearrangements, and is prone to PCR-related errors. Many of the large academic and commercial NGS panels rely on hybrid capture technology to detect a range of mutations, losses and amplifications, and insertion-deletion/rearrangement events occurring across several hundred genes implicated in human tumorigenesis.[1,2] In addition to revealing the mutational status of characterized oncogenes and tumor suppressor genes, these panels can uncover a host of changes to the DNA representing underlying mutagenic processes or DNA repair defects. For example, mismatch repair deficiency/microsatellite instability is characterized by insertion-deletion events in association with repetitive stretches of DNA and/or certain patterns of nucleotide substitution (C>T changes with an adjacent 3' or 5' guanine). Many laboratories have leveraged existing panel sequencing assays to detect mismatch repair deficiency and are beginning to replace PCR and/or immunohistochemistry screening to identify patients at risk of Lynch syndrome and/or as a biomarker for response to PD-1 inhibition.[1,3] Beyond detection of specific DNA damage signatures, the ability to quantify mutational changes on NGS platforms has given rise to the concept of tumor mutational burden (TMB) and the recognition that this may serve as a biomarker for response to immune checkpoint inhibitors. Attempts to compare TMB values across testing platforms has focused attention on the wide technical and informatic variation intrinsic to different NGS assays that may influence TMB calculation, including gene content, choice of tumor-only vs tumor/normal paired sequencing, germline filtration methods, and unrelated clonal processes (such as clonal hematopoeisis). [4] As a result, identification of a single cutpoint for predicting therapeutic response to immunotherapy is challenging and has driven efforts to standardize NGS panels for TMB detection. [5] While most DNA-based NGS panels in use today are sufficiently sensitive for reliable detection of single nucleotide substitutions (e.g. KRAS G12D; EGFR L858R) or small insertion deletions (EGFR exon 19 deletion mutations), these panels often fall short in detection of large structural variants including rearrangements.[6] Functional rearrangements typically result from gene breakages and fusions occurring within intronic (non-coding) sequences. On a per gene basis, introns tend to be significantly larger than coding exons, which means that an NGS assay designed with cost and sensitivity concerns in mind must have restricted overall intronic coverage. In addition, introns tend to contain a much higher proportion of repetitive elements, thus the tools used for rearrangement detection must be able to discern the presence of these variants despite low sequencing coverage and nonspecific sequence mismatches. In practice, these issues lead to reduced clinical sensitivity for detection of large deletions and rearrangement events. RNA-based NGS platforms, including targeted RNAseq and anchored multiplex PCR, detect the fusion transcript directly, eliminating the need to target introns. Labs may now employ workflows in which a DNA assay is used for mutation and copy changes and an RNA assay is used for rearrangement detection. A substantial minority of DNA sequencing-negative lung cancers may have a fusion detected by an RNA assay, leading some groups to advocate for sequential DNA then RNA testing protocols in driver negative lung adenocarcinomas.[7] NGS is a powerful tool to guide the diagnosis and treatment of patients with lung cancer. Improvements in assay design, chemistry, bioinformatics and variant interpretation will continue to increase its reliability and use across tumor and specimen types. Coordination with experts versed in the limitations of the technology is essential for appropriate implementation in clinical practice. References: 1. Zehir A, Benayed R, Shah RH, et al. IBS19.01 NOVEL RADIOTHERAPY APPROACHES IN SMALL CELL LUNG CARCINOMA – APPLICATIONS TO THORACIC, OLIGOMETASTATIC AND CRANIAL TUMOR CONTROL

A. Bezjak

Princess Margaret Cancer Centre, Toronto/Canada

Radiotherapy (RT) plays a very important role in the management of Small cell Lung Cancer (SCLC), and jointly with chemotherapy can lead to cures in locally advanced SCLC[1]. Advances in RT techniques and understanding of its impact on tumor control are paving the way for a number of novel RT approached in the management of thoracic disease, as well as metastatic disease and brain control in SCLC. Thoracic radiation currently plays a role in extensive stage SCLC[2], particularly in terms of reduction of symptomatic progression of intrathoracic disease. There is room to optimizing the indications, techniques, volumes and perhaps even dose of RT in that setting, and timing with respect to other treatments is worth exploring[3-5]. Whether there is an "oligometastatic" state in SCLC is not clear. One randomized trial of consolidative RT for patients with 1-3 extrathoracic metastases[6] showed worse outcomes if all sites were treated with RT, so at this time we cannot recommend such an approach. However, immunotherapy is now part of systemic management of SCLC and studies have documented an important synergy of RT and immunotherapy[7]. Thus, the question of consolidative RT to areas of either residual disease, or to areas of oligo-progression, should be explored further, particularly if there are improved biological markers to differentiate patients with a lower burden of cancer, or slower natural history of disease. Prophylactic cranial irradiation (PCI) has been more controversial given some mixed evidence of its impact on survival from randomized controlled trials[8,9], but all trials agree that PCI does reduce the risk of brain metastases in patients with SCLC. There are two current approaches to minimizing the risks of PCI – hippocampal sparing[10] and omission of PCI, with MRI surveillance, and perhaps utilization of stereotactic RT if patients present with one or few brain metastases[11]. This approach, which has been of great benefit in reducing the negative impact of brain radiation while maximizing brain tumor control in non-small cell lung cancer, is emerging as a new paradigm in the management of patients with SCLC, although its applicability may be limited. IBS19.02 NOVEL RADIOTHERAPY APPROACHES IN SMALL CELL LUNG CARCINOMA – HAS SABR AND RADIONUCLIDE THERAPY GOT A ROLE TO PLAY?

G. Hanna

Peter MacCallum Cancer Centre, Melbourne/Australia

Novel Radiotherapy Approaches in Small Cell Lung Carcinoma – has SABR and Radionuclide therapy got a role to play? Thoracic radiotherapy has been shown in to increase overall survival when added to systemic therapy in patients with small cell lung carcinoma (SCLC) and M0 stage. The dose, fractionation, treatment time and timing issues have not been fully resolved. A recent study did not show the superiority of 66Gy in 33 daily fractions over 6.5 weeks over twice-daily radiotherapy to a dose of 45 Gy in 30 fractions over 3 weeks twice daily [1]. For stage I non-small cell lung carcinoma (NSCLC), stereotactic ablative body radiotherapy (SABR) has been clearly shown to be superior to conventional fractionation [2]. Given the clear benefit seen in early stage NSCLC, it is postulated that SABR may have a role to play in early stage SCLC. A recent multi-institutional cohort study has reported favourable outcomes in this setting [3]. However, randomised data of equivalence or indeed superiority are lacking. Furthermore, questions remain as the timing and role of systemic therapy and prophylactic cranial irradiation when SABR is used in this setting. In advanced SCLC, many tumors display neuroendocrine clinical and cytological features and many SCLC tumors express somatostatin receptor and this can be imaged using radiolabeled somatostatin analogs such as 68Ga-DOTATATE [4]. Given the uptake by some SCLC tumors of 68Ga-DOTATATE, higher doses of the tracer have been used in an attempt to provide radiolabelled radiotherapy treatment in metastatic disease in what has been described as peptide receptor radionuclide therapy (PRRT) [5]. This molecularly target radiotherapy is a potentially exciting therapeutic approach, but the ideal positioning of such therapy in tumors which are suitable for treatment with PRRT and the safety of PRRT with systemic therapy have yet to be determined. IBS20 ENDOSCOPIC SOLUTION TO IATROGENIC COMPLICATIONS (INTERACTIVE Q AND A)
MONDAY, SEPTEMBER 9 07:00–08:00

IBS20.01 AIRWAY FISTULAS

J. Daniels

Amsterdam UMC, Amsterdam/Netherlands

Introduction Airway fistula as an iatrogenic complication of lung cancer treatments present a particular challenge to the multidisciplinary lung cancer team. It is a rare but very severe complication which requires prompt treatment because of the involved disruption of the natural tissue barriers against infection. Different types of fistulas

exist, the most common airway fistulas that are encountered after lung cancer treatment are bronchopleural fistula (BPF) and tracheo or broncho-oesophageal fistula (T/BEF). These are two very different entities that require their own specific management. *Bronchopleural fistula* BPF is a feared complication after anatomical resection of lung cancer, occurring in 1-4% of the patients [1-3]. Rare causes of BPF in lung cancer patients can include destruction of the airway wall by direct tumor invasion and airway wall necrosis after high-dose radiotherapy. Presenting symptoms can be cough, empyema, persistent air leak and hemoptysis. Significant dyspnea can occur because of increased dead space ventilation if there is a massive air leak. The diagnosis can be made by bronchoscopy and if the bronchoscopist cannot see a fistula, deposition of methylene blue at the site of the stump can help. In case of persistent air leak and no identifiable airway fistula, an alveolar-pleural fistula (more common) should be considered. Imaging techniques such as chest X-ray and CT scan can help to diagnose ensuing pneumothorax and empyema and in large fistulas can sometimes be visualized. The management of BPF can be challenging, especially in complicated empyema, frail patients who have already deteriorated during the postoperative phase and patients that underwent salvage surgery after high-dose radiotherapy [4]. Small BPF (up to 8 mm) without surrounding necrosis can be managed by endoscopically with the help of polyvinyl alcohol sponge and cyanoacrylate glue [5,6]. Larger BPF, presence of airway wall necrosis or failure to close the BPF endoscopically is a reason for surgery. Reconstruction of the stump or anastomosis can be followed by adding a muscle flap to improve perfusion. In case of necrosis, debridement should precede these procedures. Extensive airway necrosis sometimes renders surgical repair impossible. In case of complex empyema, open window thoracostomy can be necessary, especially if more conservative measures have been unsuccessful. *Tracheo-esophageal and broncho-esophageal fistula* T/BEF is a relatively common complication in patients with esophageal cancer (5-15%), but rare in lung cancer patients (1%)[7-10]. Symptoms include cough, especially during intake of food or liquids, infection (bronchitis, pneumonia), recurrent aspiration and weight loss. In patients with lung cancer, the most important causes are malignant invasion of the membranous part of the trachea or bronchi and high-dose radiotherapy with involvement of airways in close proximity to the esophagus (trachea and proximal left main bronchus). The diagnosis can be made with contrast-enhanced esophagography, demonstrating displacement of the contrast into the lung. Bronchoscopy can be used to localize the fistula, to determine its extent, to assess the vitality of the surrounding airway wall and to evacuate aspirated liquids and mucus from the central airways. Immediate treatment is crucial to avoid deterioration of the patient. To minimize further aspiration, oral intake should be eliminated and adequate measures should be taken to minimize reflux and ensure adequate feeding (e.g. gastro-/jejunostomy or total parenteral nutrition). Small fistulas (up to 5 mm) can be treated endoscopically with cyanoacrylate glue or clips. Larger fistulas can be treated with an esophageal stent, airway stent or a combination: double stenting. In case of insufficient effect of a esophageal stent or concomitant airway obstruction, double stenting is preferable and seems to provide better survival than a single stent [11,12]. It is important to realize that pressure on the fragile tissues between both stents can further enlarge the T/BEF. Often multiple endoscopic interventions are required to achieve and maintain adequate palliation. During this presentation the management of airway fistulas will be discussed, with emphasis on the bronchoscopic techniques such as (double) stenting and the application of cyanoacrylate glue. Selection of patients, alternative solutions and specific endoscopic techniques will be important topics. *References* Asamura H, Naruke T, Tsuchiya R, Goya T, Kondo H, Suemasu K. MONDAY, SEPTEMBER 9 07:00–08:00

IBS20.02 AIRWAY STENOSIS

M. Bezzi

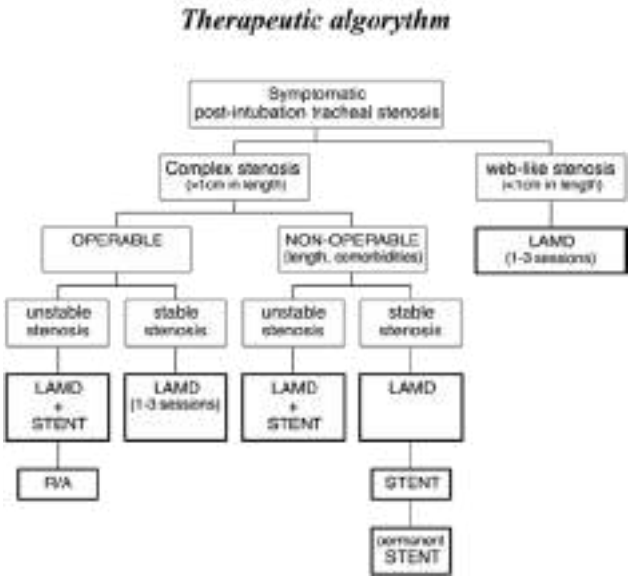
ASST Spedali Civili Brescia, Brescia/Italy

Tracheal stenosis is suspected in individuals with risk factors presenting with signs and symptoms of airway narrowing. The condition may be suspected based on spirometry with a flow-volume loop and CT imaging of the neck and chest but fiberoptic bronchoscopy is required to confirm the presence and severity of tracheal stenosis. The symptoms of tracheal stenosis are similar to those of other conditions so it is important to carefully evaluate patients history. The symptoms of tracheal stenosis typically are wheezing, coughing or shortness of breath, cornage, upper respiratory infections, asthma that doesn't respond to treatment. Benign tracheal stenoses are more commonly the result of an injury to the trachea due to prolonged intubation or tracheostomy but also Infections (tuberculosis), autoimmune disorders such as Granulomatosis with polyangiitisand amyloidosis or radiation therapy to the neck or chest. The morphological classification of airway stenosis includes granulomas, pseudoglottic stenosis, and "true stenosis" divided into web-like and complex stenoses. *Web-like stenoses* are circumferential strictures of the trachea involving the mucosa of a short segment (maximum 1 cm long)without any damage to the cartilages. *Complex stenoses*are sleeve strictures of the trachea more than 1 cm long, often associated with various degrees of cartilage involvement, malacia and inflammation. Several treatment options that can be used for tracheal stenosis depending on the cause, location and severity of the tracheal narrowing. Resection and anastomosis of the involved tract of the trachea is the gold standard treatment. Interventional Pulmonology (IP) offers minimally invasive techniques. Some IP treatment options can provide immediate relief but are considered temporary solutions, while others can provide a better long-term solution. Short-term treatment options for the condition include laser surgery and mechanical dilation with rigid scopes.Treatment options that are generally considered to work long term include stenting and tracheal reconstruction when only a short portion of the trachea is involved. Choice of procedure depends on the exact location and extent of the stenosis, but also on patient age and comorbidities.The most common treatment options for tracheal stenosis include: In 2007 Cavaliere et al. published the results of Laser Assisted Mechanical Dilation in 113 post-intubation tracheal stenoses

Sex	Age(Y)	Cause of stenosis		Type of stenosis	
M 47	50±21 (12-84)	Intuba-tion 38	Tracheot-omy 35	Web-like 13	Complex 60

Tab 1 - Patient carachterstics Therapeutic bronchoscopies were performed using rigid bronchoscopes (Efer, Dumon-Harrel type; FR) and general anesthesia.Endoscopic treatment was based on the use of three main techniques: laser photo-resection (multiple radial incisions), gentle dilation and removable silicon stents.

Fig 1 Web like stenosis, Complex stenosis, Silicon stent



Most web-like stenoses were successfully treated with Laser Assisted Mechanical Dilation (LAMD) alone; among complex stenoses LAMD was sufficient to treat 13 patients (22%), whereas 47 patients (78%) required stent placement: 22 had their stent removed after one year and did not require any further therapy, 13 inoperable patients required permanent stent and 12 were referred to surgery after failure of multiple endoscopic treatments. No permanent complications secondary to endoscopic treatment were observed. Forty-eight patients (66%) obtained a stable, good result with the endoscopic procedure, 13 (18%) required a permanent stent while 12 patients (16%) were referred to surgery. These authors indicate that bronchoscopic treatment of post-intubation tracheal stenoses can be considered a safe first-line therapy, leaving some selected cases and the relapsing stenosis for surgical resection. 1.Shapshay SM, Beamis JF, Jr, Hybels RL, Bohigian RK. IBS21 COMBATING TOXICITY OF IO-CHEMOTHERAPY COMBINATIONS
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS21.01 ENHANCED TOXICITY OF IO WITH CONCURRENT CHEMOTHERAPY

C. Barrios, A. Gelatti

Latin American Cooperative Oncology Group, Porto Alegre/Brazil

Of the more than 18 million new cancer cases seen worldwide in 2018, approximately 2 million (11%) were lung cancer. More importantly, 1.7 million deaths were seen due to the disease, representing 18% of all cancer related deaths. Global age standardized incidence/mortality rates (22.5/18.6) clearly indicate that today, most patients diagnosed with lung cancer succumb to the disease. With the increasing incidence and mortality seen particularly in developing countries lung cancer is one of the most important global public health current challenges. With recent advances seen over the last couple of decades, therapeutic decisions for NSCLC are based not only on disease stage, comorbidities, performance status and histology, but also should consider the mutational and immunological profile of the tumor and obviously each patient's preferences as well. Until recently, for tumors without any identifiable molecular driver, platinum doublets were the standard treatment for advanced disease. In these patients, despite extensive studies trying to improve current results, "old" targeted agents (bevacizumab, cetuximab) added to standard chemotherapy regimens suggested very modest if any benefit at all. Immune check-point inhibitors introduced over the last few years, have revolutionized our treatment approach and stand to change the natural history of the disease. As single agents, immune check-point inhibitors are effective in a proportion of patients, however a large majority either do not respond or develop resistance. On the basis of still very limited knowledge of primary and secondary mechanisms of resistance, combination approaches with other standard therapies and other immunotherapy strategies have been explored. Unfortunately, in most cases, lack of specific information on the molecular interactions between these therapies remains an important barrier. Albeit basically empirically designed, combinations of PD1/PDL1 inhibitors with standard platinum doublets have demonstrated benefits and are apparently increasing the proportion of patients benefiting from single agent immunotherapies. For many years, chemotherapy has been considered as an immunosuppressant. This is clearly the case in some situations depending on the specific agent and the dose being administered. However, in preclinical models, chemotherapy has shown the potential to increase the immunogenicity of cancer cells increasing the release of tumor antigens, attracting DCs, downregulating PDL1/PDL2 in DCs, enhancing tumor cell recognition and lysis and at the same decreasing microenvironment immunosuppressive factors. With the current need of designing rational combinations, it becomes extremely important to recognize that different chemotherapeutic agents have different interactions with the immune system and that addressing these differences is mandatory to achieve the best possible results. So, with these reasoning, it is fair to say that, among the multitude of specific cytotoxic effects of the different available chemotherapeutic agents and regimens it can be hypothesized that the combination of chemotherapy and IO may enhance immune effects. The combination of chemotherapy and immunotherapy (CIT) has attracted attention of clinicians and researchers and has been investigated in multiple clinical trials. Improved efficacy has been seen with these combinations but as expected, toxicity issues have also been observed. In this particular setting, we will address the intriguing question of how combining chemotherapy and immunotherapy may interfere in chemotherapy related adverse events. A recent metanalysis explored this particular issue and collected trial information from 6 randomized studies in the first line treatment of NSCLC patients. Compared with standard chemotherapy, the combination of PD-1/PD-L1 inhibitors with chemotherapy is statistically associated with a 38% reduction in the risk of disease progression, a 32% reduction in the risk of death and increases 1.6 times the probability of achieving an objective response. These results are achieved at the expense of increased treatment-related adverse events. In particular, the combination was associated with an increased risk of developing grade 3 or worse severity adverse events, an increase in treatment related drug discontinuations and an increase in serious adverse events. However, the number of treatment related deaths was similar with both treatments. Importantly, we need to consider that these data, as most of the information we have available form randomized phase III trials reflect the effects in the limited patient populations included in these trials and do not apply to special populations such as elderly patients, patients with

autoimmune diseases, patients with worse ECOG PS (>2), patients with HIV or with hepatitis B/C and patients on chronic use of steroids. RWD and further trials specifically exploring these groups of patients will be essential to better inform the optimal management of these cases. Nevertheless, recent presented information on the long-term benefits of mainly single agent immunotherapy with a proportion of patients with advanced NSCLC surviving in excess of 3-5 years, raises the issue of a clear impact on the natural history of the disease. This has been previously shown in diseases that explored immunotherapy earlier such as melanoma for example. Further research should try to rationally approach combination regimens and to specifically select patient populations that could derive more benefit. At the same time this will help defining and improving the risk benefit relationship of these regimens. *References: Galluzzi L, et. al. IBS21 COMBATING TOXICITY OF IO-CHEMOTHERAPY COMBINATIONS
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS21.02 REAL WORLD TOXICITIES OF RADIATION PLUS IO IN NSCLC

R. Kelly

Baylor University Medical Center, Dallas/United States of America

As the indications for immune checkpoint inhibitors expand in stage III and stage IV non small cell lung cancer, medical and radiation oncologists will need to risk-stratify patients for the development of immune related toxicities most notably checkpoint-inhibitor pneumonitis (CIP) and to differentiate this from radiation induced pneumonitis. Real-world patient data is providing new insights into the epidemiological and clinical characteristics of CIP and emerging data which needs to be validated suggest a higher incidence of CIP approaching 19% in non- trial patients compared to 3-5% reported in clinical trials. A seasonal pattern of CIP with an increase in the number of cases in the Winter months when viral infections are at a high and in patients that may be more susceptible due to existing comorbidities than ECOG 0-1 trial patients need to be further evaluated. Additionally, it appears the risk of developing CIP is histology dependent with a lower risk being seen in nonsquamous lung cancer. A variety of radiographic patterns ranging from organizing pneumonia to ground glass or interstitial patterns are seen and time-to-onset analysis suggest that there may be two differing phenotypes most notably early onset CIP which is high grade and associated with higher mortality and late-onset CIP which is of lower grade and has less mortality. At the present time, no specific radiotherapy-related treatment parameter such as technique (stereotactic body RTor intensity-modulated RT), timing or number of courses have been associated with CIP, however, there is a trend associated with curative-intent radiotherapy compared with palliative intent radiation. Interestingly, the development of non-pulmonary immune related adverse events has been associated with an improved response and overall survival to checkpoint inhibitors. While these phenomena require further investigation it has been suggested that the poor outcomes associated with CIP relate to the fact that hypoxia from pneumonitis is poorly tolerated in patients who already have respiratory compromise as a result of lung cancer and may precipitate multiorgan failure due to decreased oxygenation. The creation of multi-disciplinary teams that have a specific interest in the management of immune related toxicities may help improve patient outcomes due to early identification but a more comprehensive understanding of the underlying biology is needed if we are to refine our existing diagnostic and treatment algorithms to appropriately manage life-threatening complications associated with changing paradigms of care.

IBS22 JTO WORKSHOP: HOW TO GET YOUR MANUSCRIPT PUBLISHED
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS22.02 JTO WORKSHOP: THE LIFE CYCLE OF A MANUSCRIPT

M. Todd

IASLC, New York/United States of America

This session will describe the process of a manuscript from initial submission to final publication. The session will focus on ways that submitting authors can ensure a seamless and timely handling of their manuscripts. Interactions between authors and editorial offices offer insight into common situations and themes. Participants will learn why editorial offices and publishers require what they require. Time will also be devoted to promotion of published work.

IBS23 IBS23 TREATMENT OF NSCLC OMD IN CLINICAL PRACTICE
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS23.01 RADIOTHERAPY OF OMD IN DAILY CLINICAL PRACTICE

R. Komaki-Cox

Baylor College of Medicine, Houston/United States of America

Non-Small Cell Lung Cancer (NSCLC) is the leading cause of cancer related death in the world.1 Analysis of patterns of failure after first-line systemic therapy for metastatic NSCLC suggest that most progression events, either within or outside the central nervous system (CNS), occur only at sites of disease known to exist at baseline, rather than in new sites.2 Once systemic treatment becomes more efficacious, for patients with limited numbers of metastases, ablation of those metastases may be advantageous in terms of cytoreduction or removal of dominant disease sites that may seed other sites in the future. Stage IV disease that is limited to only a small number of sites ("oligometastatic" disease (OMD)) may reflect a more indolent phenotype that could benefit from local ablative therapy (e.g. surgery or radiation) for consolidation, as suggested by some preclinical and translational analyses.3,4 Several retrospective and small prospective trials have suggested that local therapy may be beneficial for patients with stage IV NSCLC presenting with limited metastases .5-8 At MDACC, we have performed a randomized, phase II study (NCT01725165) to evaluate progression-free survival (PFS) after aggressive local consolidative therapy (LCT) versus maintenance therapy or observation for patients with stage IV NSCLC with ≤3 metastases remaining after front line systemic therapy. As secondary aims, we explored: (1) the safety and incidence of high-grade toxicity, (2) overall survival (OS), (3) patterns of failure and the effect of salvage therapy among patients who crossed over to the local consolidation group, (4) time to development of disease at new metastatic sites, and (5) predictors of PFS. Findings of our randomized trial of aggressive LCT followed by standard maintenance therapy versus maintenance therapy alone for patients with oligometastatic NSCLC that did not progress after initial systemic therapy were as follows.10 We found that the PFS time for the standard (maintenance therapy) group was almost exactly as had been hypothesized from prior studies (3.9 months observed vs. 4 months hypothesized), whereas that of the experimental (LCT) group was substantially longer than predicted (11.9 months observed vs. 7 months hypothesized). Notably, our hypothesis was based on retrospective data in which sites of new disease versus sites of known disease could be followed more thoroughly for progression. In addition, time to the appearance of a new lesion was longer for patients in the LCT arm than for in the no-LCT arm (11.9 months vs. 5.7 months, p=0.0497), suggesting that the LCT could be altering the natural history of the disease2, either by limiting the potential for later spread or possibly by altering systemic anticancer immune responses to facilitate longer control of subclinical disease. Our trial used SBRT or surgery for local treatment for the oligometastasis. However more recent trial was done by consolidative radiotherapy for the limited oligometastatic NSCLC showing SBRT(SABR) Prior to the maintenance chemotherapy improved PFG compared to maintenance chemotherapy alone.10 Common oligometastatic lesions we usually treat by radiotherapy are brain, bone, adrenal gland, lung, liver lymph node, mediastinum,

pleura and muscle. Daily clinical practice, we need to use image guided radiotherapy with 4 D simulation. We should use SBRT or SABR to eliminate oligometasis without overlapping previously irradiated area and avoid critical organs. Take home message: 1) We have enough evidence that treating oligometastasis by aggressive local treatment improved PFS and less appearance of new lesions. 2) Patients are able to tolerate local aggressive RT by SBRT (SABR). 3) Need to consider patients with oligometastases to be treated agressibly by SBRT (SABR). 4) Efficacy to improve OS by additional immunotherapy to the SBRT or SABR to the oligometastasis requires a prospective randomized studies in future. IBS23 TREATMENT OF NSCLC OMD IN CLINICAL PRACTICE
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS23.02 ONCOLOGICAL TREATMENT OF OMD IN DAILY CLINICAL PRACTICE

S. Popat

Royal Marsden Hospital, London/United Kingdom

The front line systemic treatment of metastatic non-small cell lung cancer (NSCLC) has changed rapidly over the past 10 years, from the establishment of histology-specific chemotherapy, the introduction of molecular targeted therapies for specific somatic sensitizing gene mutations/fusions, and now the routine use of immune checkpoint inhibitors either as monotherapy or in combination with chemotherapy. Current data suggests that oncogene addicted tumours have little benefit from checkpoint inhibitor monotherapy, and so advanced NSCLC can be functionally categorized into those that are oncogene addicted and ideally treated with molecular targeted therapy – either as monotherapy or in combination with other therapies- or immune sensitive, ideally treated with immune checkpoint inhibitors again as monotherapy or in combination with chemotherapy. At the same time, advances in radiotherapy delivery have meant that small volume metastatic disease can be treated at ablative doses of radiotherapy. How these two modalities should be integrated in patients with oligometastatic disease for optimal survival and minimal toxicities has been debated over recent months. In parallel our understanding of the natural history of different types of NSCLC has become better understood, alongside the phenotypic and genotypic selection pressures put on them by systemic therapy. Thus, recognizing that patients with oncogene addicted disease such as ALK and ROS1 fusions or EGFR mutations have a high propensity to CNS metastases, and that next generation CNS-penetrant kinase inhibitors are optimally used up front, SRS to brain metastases may be deferred and used on demand in case of late progression, effectively withholding whole brain radiotherapy until much later in the patient care timeline. However, trial data to support this decision making is currently lacking and awaited. Understanding that patients with oncogene addicted disease now have a median survival quadrupled to that previously (now in excess of 4 years) with optimal sequencing of kinase inhibitors, allows a more thoughtful way to integrate a more radical approach into those with small volume oligometastatic disease. We therefore now recognize several states of oligometastatic disease, with much of our information and treatment paradigms evolving from the treatment of patients with oncogene addicted disease. Patients may have the now well-known synchronous or metachronous oligometastatic disease state. Moreover, the integration of kinase inhibitors has identified an oligoprogressive disease occurring in around 30% of cases, and the ability to treat such cases with radical radiotherapy or a surgical approach. In such cases, tissue sampling may be required not only to plan the next steps of systemic therapy by tissue genotyping for acquired resistance mechanisms and new molecular target identification, but also for fiducial placement. Another less well defined disease entity is that of oligopersistent disease- defined as small volume radically treatable disease present after the bulk of oligo- or poly-metastatic disease has responded well to initial therapy, with patient series data suggesting a survival benefit for radically consolidating (oligo-consolidation) or optimally debulking in this approach. The integration of immune checkpoint inhibitors has again changed patterns of disease response and progression. Certainly, major durable responders are observed with checkpoint inhibitors alone, and the role of radically consolidating such patients may be debatable given that around 30% of patients with 50%+ PDL1 expression treated with front-line pembrolizumab monotherapy survive 5 years. However, acquired checkpoint inhibitor resistance is common and single centre series have suggested a rate of 30% of patients progressing with oligoprogression, suitable for ablative therapy or resection. In this presentation, I will discuss all these issues, including concerns about toxicities, and duration of therapy, arguing for a consensus on oligo-definitions, and molecular stratification within trials, encouraging enrolment into ongoing clinical trials to quantify the magnitude of benefit afforded by radically treating the oligometastatic state.

IBS23.03 SURGICAL TREATMENT OF OMD IN DAILY CLINICAL PRACTICE

P. De-Leyn, H. Decaluwe

University Hospitals Leuven, Leuven/Belgium

Patients with metastatic non-small cell lung cancer (stage IV) are usually deemed to be incurable and no local aggressive treatment is generally indicated. However, stage IV NSCLC cancer is a heterogeneous group. This is confirmed by the 8 thh TNM NSCLC staging system. Stage M1a are patients with separate tumor nodules (s) in a contralateral lobe, tumor metastatic pleural or pericardial nodule, or malignant pleural pericardial effusion. M1b is single extra thoracic metastatic disease in one organ and M1c are patients with multiple extra thoracic metastasis in one or several organs. Oligometastatic disease is widely recognized as patients with a limited number of controllable secondary lesions. The exact number of metastasis and definition is still debate. Over the last years remarkable advances in chemotherapy strategy and immunotherapy have resulted in substantial survival benefits in patients with stage IV NSCLC. This questions in some patients the need of aggressive treatment of residual or recurrent disease. In literature, there are several studies on the role of surgery in patients with lung cancer and single metastasis in the brain, adrenal or contralateral lung. Most of the evidence is based on small retrospective series that were collected over an extended period of time. More recently, there is some experience with multimodal treatment including surgery in patients with oligometastatic disease and more metastasis also in different organs. There are several prognostic factors. Mediastinal nodal involvement and tumor size are important. In all patients, FDG- PET could be performed. Since prognosis is very small in N2 patients, invasive mediastinal staging (endoscopically or surgically) should be performed before embarking on an aggressive multimodal

surgical treatment of oligometastatic disease. Over the last years, robotic surgery or uniportal VATS is becoming less invasive with less postoperative complications and better tolerance of neoadjuvant or adjuvant therapy. When surgery is part of multimodal treatment of patients with oligometastatic disease pneumonectomy should be avoided.

IBS24.01 IO/CT FIRST LINE ALWAYS

S. Puri[1], J.E. Gray[2]

[1]*H.Lee Moffitt Cancer Center /University of South Florida, Tampa/United States of America,* [2]*H. Lee Moffitt Cancer Center and Research Institute, Tampa/United States of America*

Combination therapy with anti-programed death protein (ligand) 1 inhibitor (PD-1/PD-L1) and platinum-doublet chemotherapy (CT) plus/minus vascular endothelial growth factor inhibition (VEGFi) has recently emerged as the standard first-line treatment for patients with metastatic non-small cell lung cancer (mNSCLC) without a targetable oncogene. The rationale for using the immunotherapy chemotherapy (IO-CT) combination comes primarily from a clinical effort to improve the efficacy of the first-line treatment of mNSCLC by combining two independently active therapies with non-overlapping toxicity profiles. Additional proof-of-principle comes from pre-clinical studies showing synergy between checkpoint inhibitors (CPIs) and CT through platinum mediated immunomodulation of the tumor microenvironment.[1, 2] Several randomized phase II-III clinical trials have evaluated the combination of platinum doublet CT with CPIs for first line therapy of mNSCLC (Table 1). Pembrolizumab (anti-PD-1) plus platinum-pemetrexed was the first IO-CT combination with promising activity in this setting as noted in the phase II KEYNOTE021 trial.[3] This led to further evaluation of the combination in the phase III KEYNOTE189 trial [4] that compared platinum-pemetrexed with pembrolizumab or placebo in treatment naïve patients with non-squamous mNSCLC .The results showed a significant overall survival (OS) benefit with the pembrolizumab combination that was seen irrespective of the PD-L1 tumor proportion score (TPS) and persisted at the updated follow up analysis despite cross over to IO in 54% patients in the placebo-CT arm.[5] Similarly, the KEYNOTE407 trial enrolled untreated patients with stage IV squamous NSCLC, and noted superior outcomes with the combination of pembrolizumab plus carboplatin-(nab) paclitaxel versus placebo-carboplatin-(nab) paclitaxel.[6] These two trials have established pembrolizumab plus platinum CT as the preferred therapy for previously untreated patients with non-squamous and squamous mNSCLC, and both regimens are currently approved by the FDA for histology specific, front-line treatment of stage IV NSCLC. Additional trials have been conducted comparing the combination of atezolizumab (anti-PD-L1) plus platinum- (nab)paclitaxel versus placebo-CT for the first-line treatment of non-squamous (IMpower 130, IMpower150) and squamous (IMpower131) mNSCLC. While results of the IMpower130 study show an OS benefit of treatment with the atezolizumab-CT combination compared to CT alone [7], the IMpower131 trial showed a clear PFS benefit but no significant benefit in OS between the two arms.[8] Interestingly, the potential benefit of adding VEGFi to IO-CT was explored in the IMpower150 trial. This complex, three arm trial compared the combination of atezolizumab, carboplatin, paclitaxel and bevacizumab (ABCP) and atezolizumab, carboplatin, paclitaxel (ACP) to carboplatin, paclitaxel and bevacizumab (BCP) in CT naïve, non-squamous, mNSCLC. The trial also enrolled a subset of patients with EGFR or ALK mutations who had failed standard tyrosine kinase therapies, a population of patients that historically have a poor response to treatment with CPIs and are otherwise excluded from majority of the IO or IO-CT combination trials. The results showed a survival benefit of the four-drug regimen (ABCP vs BCP) in both the EGFR/ALK WT and mutated population, highlighting the potential role of VEGFi in improving response to CPIs, especially in oncogene driven mNSCLC.[9] Coming back to the question "should IO-CT be first line always?" The answer is yes, for the majority of eligible mNSCLC patients with no targetable mutations. mNSCLC is an aggressive malignancy associated with high mortality, and multiple trials have shown that many patients do not have the opportunity of receiving 2nd line treatment.[5,10] Platinum based CT has been the first-line treatment of choice for mNSCLC for many years. In the last decade, IO has revolutionized the treatment of advanced lung cancer. Recent data (Table 1) clearly demonstrates superior and durable clinical outcomes with the combination of platinum-based CT doublets and CPIs compared to CT alone in both squamous and non-squamous mNSCLC. These combinations are safe with little additive toxicity and should be adopted as routine standard of care therapies in the frontline setting, especially in high disease burden and PD-L1 TPS ≤1. However, there is variability in outcomes based on histological subtypes of mNSCLC and the different IO-CT combinations (Table 1). New trial design strategies are needed to determine the benefit of IO-CT versus IO alone, especially in patients with borderline performance status or PD-L1 TPS ≥50%. Additionally, it is also important to determine the subgroup of patients with the highest likelihood of benefit from addition of VEGFi to IO-CT. References 1.Galluzzi L et al. IBS24 OPTIMAL IMMUNOTHERAPY SEQUENCE IN STAGE IV NSCLC
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS24.02 IO FOLLOWED BY CHEMO OR CHEMO FOLLOWED BY IO

B. Melosky

BC Cancer, Vancouver/Canada

For our patients presenting with stage IV advanced NSCLC, the goals of therapy are primarily palliative. These goals need to be carefully balanced to meet the individual needs of each patient: while we want to keep our patients living as long as possible, we also want to provide them with the highest quality of life. Many patients with advanced NSCLC are treated with the combination of immunotherapy and chemotherapy. This comes at a cost of toxicity and may not be the best strategy for long term survival. We need to compare the evidence to determine which agent, immunotherapy or chemotherapy, to use first in patients with stage IV advanced NSCLC without a targetable mutation (wild-type). Immunotherapy followed by Chemotherapy Numerous phase III trials have compared immunotherapy to chemotherapy for patients with stage IV NSCLC. Some of the trials to be discussed include KEYNOTE 024[1], KEYNOTE 189[2], KEYNOTE 407[3], KEYNOTE 042[4], CheckMate 227[5] and MYSTIC[6]. For each trial, the outcomes and side effect profiles will be presented, and the different trials will be compared. OR Chemotherapy followed by Immunotherapy Immunotherapy agents were initially studied after patients progressed on a platinum doublet. Trials to be discussed include CheckMate 017[7] (squamous), CheckMate 057[8] (non-squamous), KEYNOTE 010[9], and OAK[10]. Again, outcomes and side effect profiles will be presented with a view to identifying which patients will experience the greatest benefit from this strategy. Conclusion & Key Points The increasing percentage of long term survivors in lung cancer is unprecedented and strengthens the argument that sequencing is important. While the evidence is clear that immunotherapy is the best choice for patients who express high PD-L1 or have high tumour mutational burden (TMB), evidence is less clear for how to treat patients without these biomarkers.

	IO followed by Chemo	Chemo followed by IO
Biomarkers	PD-L1 expression, high TMB	PD-L1 non-expressors, low TMB, non-selected population
Evidence to support	KEYNOTE 024//042, CheckMate 227, MYSTIC	CheckMate 017/057, KEYNOTE 010, OAK

IBS25 OPTIMAL GGO MANAGEMENT
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS25.01 EASTERN PERSPECTIVE

H. Asamura

Keio University School of Medicine, Tokyo/Japan

The term "ground glass opacity (GGO)" is being used more often to describe the CT appearance of a focal, non-calcified lesion with a slight/moderate increase in CT density. Usually, GGO is characterized on high-resolution CT scan images with a slice thickness of 1-3mm. The CT appearance of GGO is characterized by "focal, transparent" lesion. First, GGO refers to the localized or focal lesion regardless of the multicentricity, and the diffuse ground glass appearance seen for interstitial pneumonitis should be excluded from this category. Second, GGO lesions is well-characterized by a slight/mild increase in CT density, which does not obscure preexisting lung structures such as blood vessels and bronchi. This apperance refers to the CT-transparency. When the shape of the pulmonary vessels in the nodules is not recognized in the nodule, the lesion is no longer considered GGO, and instead is called a "solid" lesion. GGO lesion can be either homogeneous or heterogeneous. The GGO lesions are classified according to the absence/presence of the solid part. In case the GGO lesions are homogeneous, and does not contain solid part, it is called "non-solid GGO" or "pure GGO". In case the GGO lesions contain a solid, cystic, or linear part inside the nodule, it is called "non-solid GGO" or "complex GGO". The solid part is more likely to be located in the center of the nodule, and surrounded by the GGO part, which is a so-called "fried egg" appearance. The solid part might be scant or prominent with various proportions of solid to GGO parts. In the classic, solid tumor, the GGO part has no longer exist within the nodule. According to the recent studies on the relationship between CT appearance and histopathology of GGOs, not all, but considerable portion of these lesions correspond to the preivasive, non-invasive, or early forms of neoplastic growths, especially those on the adenocarcinoma lineage. The clinicopathological entity of these tumors are being established only recently, and it has never been the subject of clinical studies. The histopathology of GGO has been also studied, and they are either neoplastic or inflammatory. A focal inflammation of the lung panrenchyma sometimes presents with GGO on the CT image, and pathologically it is described as "organizing pneumonia". These changes are more likely to be temporary. In contrast, the persisting GGOs are more likely to be neoplastic. According to the WHO histological classification of lung and pleural tumors, GGO lesions are associated with three pathological entities. "Atypical adenomatous hyperplasia (AAH)" is described as a preinvasive lesion, in which slightly atypical tumor cells line the involved alveoli and respiratory bronchioles. Adenocarcinoma in situ (AIS) is an adenocarcinoma with Clara cells and/or type II pneumocytes growing along alveolar walls and without stromal invasion. The important feature of AIS is "non-invasive" growth of the tumor, and therefore this lesion could be considered *in situ* carcinoma. The third category is adenocarcinoma with mixed subtypes, which shows a mixture of the histologic subtypes as well as obvious invasive growth. The *intervention strategy* for GGO lesions are being established very recently, and some of them still need future clincal trials. Several factors are related to the management stragety; the size of lesions, image characteristics (non-solid versus part-solid), and the history of previous lung cancer. Especially, the indolent nature of the small-sized, non-solid GGOs needs to be stressed. For these tumors, the immediate surgical intervention should be rather avoided. Furthermore, the physical condition of the patiets such as age, co-existing medical conditions also must be taken into consideration. When thinking of surgical interventions, the location of the lesion (outer versus inner) is also an iomportant issue from the technical point of view. For tumors located deeply in the lung parenchyma, the sublobar resection is generally amenable because of the lack in the enough surgical margin. *1. Non-solid GGOs less than 15 mm in diameter. These small lesions without any solid part in the nodule termed as non-solid GGO are basically watched carefully with the repeated high-resolution CT. The appropriate intervals between repeated CTs have not been clearly demonstrated. It might rage from 3 to 6 moths. If the overt growth in size or the newly developping solid component is shown, the surgical intervention should be considered. 2. Part-solid GGOs less than 15 mm in diameter. The solid component in the part-solid GGOs represents the fiborotic scar and/or collapse of the lung in which the proliferation of the collagen fibers and actrive gibroblast is generally seen, and thiese findings indicate the features of invasive growth. Therefore, tumors of this category should be resected, The careful watching should be indicated only for the poor physical conditions compromising the surgical resection. However, considering their minimally invasive nature and small size, the sublobar resection could be reasonablly choosed. For these tumors, the segementectomy rather than wedge resection is preferrable. The location of the tumor should be carefully evaluated. When the tumor is located in the inner two thirds of the lung panrenchyma, the segemetal resection shoul be reapected as amenable. The segmentectomy for this location cannot ensure the safe surgical margin. For such locations, the lobectomy, instead of segmentectomy, must be chosen. 3. Non-solid GGOs larger than 15 mm in diameter. As non-solid GGOs of smaller size category, these lesions should not be resected immediately. However, the larger GGOs are known to be more likely to grow faster even if the lesions still do not contain solid part. Therefore, if the lesion persists at least in the same size, after the appropriate follow-up period of 3-6 motnths, these GGOs should be resected. Similarly, the resection should be performed with sublobar resection. 4. Part-solid GGOs larger than 15 mm in diameter. The part-solid GGOs of this size are more likely to be an invasive adenocarcinomas. Especially when the solid part exceeds 50% of the whole area of the lesion, the invasive features become more common. Therefore,* the lobectomy might be better selected as the mode of resection. The evaluation of the hilar/mediastinal lymph nodes should be also performed during surgery.

IBS25 OPTIMAL GGO MANAGEMENT
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS25.02 WESTERN PERSPECTIVE

J. Donington

University of Chicago Comprehensive Cancer Center, Chicago/United States of America

Ground glass opacities (GGOs) are a 21st century diagnostic and therapeutic challenge. These are defined as focal areas of increased attenuation on computed tomography (CT), where visualization of normal parenchyma and pulmonary structures such as airways and vessels is preserved. Prior to the advent of high-resolution thin-slice CT scanning we had little evidence for the wide spread existence of these lesions or their association with adenocarcinomas of the lung. The opacities develop because of reduced volumes of air the alveolar airspaces due to partial by cells as they grow in a lepidic pattern along the alveolar surface, typically, the abnormal cells only occupy a portion of the airspace and therefore consolidation of the lung parenchyma does not occur. GGOs are typically divided into two categories: 1) pure GGOs, which contain no solid component and 2) part-solid GGOs, with both solid and pure ground glass regions. The introduction of CT screening for lung cancer should dramatically increase the number of patients presenting with small nodules and GGOs. Interpretation and management guidelines are essential and several have been developed and updated. They are derived by expert consensus and management recommendations are based primarily on the GGO's size, percent solid component, and number in combination with the patient's baseline risk for lung cancer development. The most prominent guidelines are from the British Thoracic Society[1] and the Fleischner Society[2]. We have a growing understanding of the role of GGOs in the pathogenesis of adenocarcinomas of the lung. A strong correlation exists between CT appearance and the extent of histologic tumor invasion, which is outlined in the IASLC/ATS/ERS Classification of Lung Adenocarcinomas.[3] There exists a continuum from pre-invasive lesions, atypical adenomatous hyperplasia (AAH) and adenocarcinoma in situ (AIS), to minimally invasive adenocarcinoma (MIA), and finally to invasive adenocarcinoma. This has also resulted in a new subclassification of T1 lesions in the 8th edition of lung cancer staging system[4] that includes precise definitions for these pre-invasive and minimally invasive lesions. Although we all agree on terminology to define these lesions radiographically and pathologically, there is less consensus on the ideal management and more specifically when to intervene surgically and what type of resection is best. The Japanese Clinical Oncology Group have served as the leaders in this realm, carrying out a series of prospective trials to define the appropriate extent of resection and lymph node dissection for pure and part-solid GGOs. I believe one of the greatest disparity between eastern and western lung cancer treatment is in the management of small GGOs. The pre-invasive and minimally invasive lesions, those < 2cm and with solid component < 5mm or with consolidation to tumor

ratio < 0.25. Numerous retrospective series and prospective trials from Asia outline the high potential for cure with a limited resection and no lymph node dissection, but most western thoracic surgeons would argue whether if resection is warranted at all for lesions that we reliably know are pre-invasive, or iss surgery for these lesions overtreatment for a "pseudo disease"? It is difficult to put forth the management ideology for the entire western hemisphere, but I believe that the concept of "do no harm" prevails with regard to these small lesions. The western thoracic community has a far greater tendency toward "watching and waiting" than our eastern counter parts. This is based on the understanding that even though these lesions exist within the adenocarcinoma spectrum, only a small percentage will become invasive cancers. Less than 30% of pure GGOs detected in the NELSON trial[5] and only < 2% in the I-ELCAP cohort[6] ever developed a solid component. We also take comfort in the fact that these lesions have slow doubling times >800 days[7], allowing for change in appearance over time to help define the potential for invasion and risk to the patient. Some of the hesitation for rapid surgical intervention in these pre-malignant lesions is because thoracic resections are invasive, even simple wedge resections typically require general anesthesia and a hospital stay and carry a risk for complication especially in the frail or elderly. In addition, the lungs are vital organs, and in that sense quite different from the breast or prostate where we have taken on a much more aggressive approach to the treatment of pre-malignant and minimally invasive tumors. Even in those tumors, we are now investigating de-escalation of treatment protocols and active surveillance for lesions that may never affect a patient's survival. There is also a tendency for multiplicity with GGOs and the potential for many interventions treatments over a patient's lifetime, if each GGO is to be removed. We are in the early phase of our clinical proficiency with GGOs; as our experience and knowledge grows there will likely be a more uniformed approach to intervention, but in 2019, management varies by geography. IBS26 TREATMENT TECHNIQUES FOR LOCALIZED THERAPY IN MALIGNANT PLEURAL MESOTHELIOMA
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS26.01 TREATMENT PLANNING FOR PLEURAL IMRT (IMPRINT)

A. Rimner

Memorial Sloan Kettering Cancer Center, New York/United States of America

We have developed an Intensity-modulated pleural radiation therapy (IMPRINT) technique targeting the entire hemithoracic pleural space including the diaphragm that simultaneously spares the ipsilateral lung, heart, liver, kidneys and abdominal contents was developed.1 It provides an opportunity for safer, less toxic treatments and increased efficacy by enabling higher radiation doses to the tumor target due to a much higher level of dosimetric control and certainty leading to better target coverage than conventional radiation techniques.2 IMPRINT became technically necessary to deliver adjuvant radiation due to the increased use of lung-sparing surgical techniques such as pleurectomy/decortication (P/D) for malignant pleural mesothelioma. Here we describe the contouring and treatment planning aspects for IMPRINT and potential pitfalls. Since developing this technique the clinical delivery of IMPRINT has been shown to be safe and feasible. Our first report in 36 MPM patients with 2 intact lungs showed that hemithoracic adjuvant IMPRINT (50.4 Gy in 28 fractions) could be delivered with a 20% (n=7) ≥ grade 3 pneumonitis risk; 1 patient had grade 5 pneumonitis.1 The median survival in resectable patients was 26 months. A tomotherapy technique was published with similar toxicity outcomes (20% ≥ grade 2 pneumonitis, one fatal case of pneumonitis).3 These encouraging results have led to a 2-institution phase II trial of trimodality therapy using induction chemotherapy with cisplatin and pemetrexed, lung-sparing P/D, and adjuvant hemithoracic IMPRINT.4 Twenty-seven patients were treated and 29.6% developed radiation pneumonitis (6 grade 2; 2 grade 3). Median progression-free and overall survival was 12.4 and 23.7 months, respectively. In resectable MPM patients who received chemotherapy and IMPRINT, 2-year OS was very promising at 59%. A review of the outcomes of trimodality therapy including IMPRINT demonstrated a median OS of 20 months from the start of RT.5 Based on these findings a multi-institutional phase II study is ongoing to demonstrate the safety and exportability of IMPRINT to 5 institutions (clinicaltrials.gov: NCT00715611). All patients' treatment contours and plans are centrally reviewed and revised for uniformity. This will be followed by NRG LU-006, a randomized phase III study of P/D, chemotherapy +/- adjuvant IMPRINT which is planned to open in the fall of 2019. Target delineation of the entire pleural space is a challenging task. The higher precision of IMRT delivery requires detailed knowledge of the intrathoracic anatomy, incorporation of all diagnostic imaging tools available, pathologic findings at the time of surgery, assessment of the respiratory tumor motion using a 4D scan, and image-guided treatment delivery. A systematic review of failure patterns in 67 patients identified areas at significant risk for local failures emphasizing the need for optimization of radiation targeting and experience with this complex radiation technique.6 Increasing experience over time led to fewer marginal failures and decreased toxicity, suggesting the improvement in target delineation and RT planning. Emergence of multiple pleural nodules and pleural thickening were identified as the most common features of local recurrences.7 We have developed a contouring atlas for target delineation for IMPRINT that will be presented. Treatment planning is similarly complex and requires significant experience. Typically fixed-beam angle IMRT is delivered with six to nine coplanar 6 MV beams equispaced over 200-240 degrees around the ipsilateral hemithorax were used. More recently, rotational techniques such as volumetric arc therapy or tomotherapy have been shown to allow for even more effective sparing of organs at risk.3,8 Strict normal tissue constraints need to be applied to avoid serious toxicities, foremost radiation pneumonitis. Most recently we identified an association of radiation dose to the heart and overall survival that has led to incorporation of new dosimetric planning constraints.9 Details about dosimetric constraints will be presented. 1. IBS26 TREATMENT TECHNIQUES FOR LOCALIZED THERAPY IN MALIGNANT PLEURAL MESOTHELIOMA
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS26.03 SURGICAL TECHNIQUE OF PLEURECTOMY/ DECORTICATION

D. Waller

St Bartholomew's Hospital, Barts Health NHS Trust, London/United Kingdom

Lung sparing radical surgery by (extended) pleurectomy decortication has become for many high volume units the surgical approach of choice rather than extrapleural pneumonectomy. However, the persuasive benefits of reduced postoperative mortality must not lead to compromise of the basic intent to obtain macroscopic complete resection of the malignant pleural mesothelioma. While it is naïve to intend to obtain a R0 resection (because of the anatomical relations of the pleura) a R2 resection should be considered a failure of surgical selection or technique. In this presentation I will consider the salient points in a stepwise fashion of the operation that I have learned over a 20 year experience of over 500 such procedures and illustrate each step with images or operative video sequences. 1.*Anaesthetic requirements* – double lumen intubation under general anaesthesia with single lung intubation is a prerequisite. Epidural analgesia is desirable as the extent of pleurectomy does not facilitate paravertebral catheter placement. Preoperative insertion of a large bore oesophageal bougie facilitates intraoperative dissection around the oesophagus reducing the risk of inadvertent injury. 2.*Exposure* – a standard posterolateral thoracotomy through the 6th intercostal space dividing just the latissimus dorsi is usually sufficient. Particularly bulky tumours in either the apex or base should be approached using a two level thoracotomy via the 4th and 8th intercostal spaces. 3.Dissection- in general the mode of dissection is by digital mobilization having found the correct tissue plane by sharp incision. I use electrocautery to divide most tissues. *Parietal pleurectomy* – I begin with the parietal dissection to confirm resectability from the chest wall. Limited chest wall resection of up to 3 ribs is acceptable but larger defects are usually associated with poor prognosis and are not justified by the increased postoperative morbidity. I continue the parietal pleurectomy down to the diaphragm to determine whether phrenectomy can be avoided but then the phrenic nerve must be preserved. The parietal pleurectomy is continued from the apex down to the azygos vein or aortic arch and then over the oesophagus onto the hilum and down to the diaphragm. *Visceral pleurectomy* – Whilst the parietal pleura can be incised over its lateral aspect I prefer to follow the main bronchus down to the pleural reflection. Then open the space beneath it by sharp dissection and then develop the subpleural plane by digital, blunt dissection across each lobe separately. A prior pleurodesis helps in this process as the fused pleural sheet can then be opened by electrocautery down onto a double gloved finger which protects the underlying lung. The stripping of the fused pleural sheet of tumour from the underlying lung parenchyma should continue in two directions away from and towards the oblique fissure. This action is best performed using a swab as a gentle abrasive putting pressure on the pleural sheet rather than the lung. Meticulous technique is imperative to reduce parenchymal damage which will reduce postoperative air leak and hence hospital stay. I find positive pressure ventilation of the underlying lung to be beneficial in providing counter-traction for the pleurectomy. It also allows for early identification and closure of parenchymal tears and sources of air leak. *Lung resection* – there are commonly areas of parenchymal adhesion or frank invasion at the peripheries of the lung at the medial aspect of the upper lobes (particularly the lingula) and the diaphragmatic surface of the lower lobe. Rather than persist in trying to preserve all lung parenchyma at the expense of air leak I have a low threshold for stapled excision of these peripheral strips of lung. Lobectomy is very rarely indicated. *Pericardiectomy* – I prefer to err on the side of resection rather than preservation of the pericardium to ensure macroscopic complete resection (MCR). *Phrenectomy* – Preservation of the diaphragm muscle whilst ensuring MCR is only applicable in the earliest stage lowest volume tumour. Over enthusiastic blunt dissection of a non-existent tissue plane may damage the underlying muscle and increases the risk of postoperative dysfunction or even herniation. As above I prefer to err on the side of resection to ensure MCR. This may require near total phrenectomy in higher volume tumours with dissection into perinephric fat in the most bulky. We have not found that this aggressive policy towards phrenectomy increase intra-abdominal disease progression, the "seeding" theory. *Lymph node dissection* – as with non small cell lung cancer the importance of accurate intraoperative nodal staging cannot be overemphasized. However, there is not as yet a formally described systematic method. I do adopt the standard method as for lung cancer resection but also, noting the different lymph node drainage of mesothelioma, incorporate dissection of the internal mammary, periphrenic and intercostal (where visible) nodes. 4.*Reconstruction Pericardium* – an absorbable mesh is used to create a non restrictive "sling" to prevent postoperative cardiac herniation. A few interrupted sutures into the pericardial resection margin are used whilst carefully observing for any haemodynamic compromise (particularly on the left) from a patch that is too tight. *Diaphragm* – I prefer a bio-absorbable material to potentially reduce the risk of persistent perioperative pleural sepsis. Secure, non-absorbable interrupted sutures are inserted into the diaphragmatic resection margin over the posterior and medial aspects. This may require direct insertion into chest wall if no diaphragm remains. Anteriorly, the patch is fixed with interrupted pericostal (non-buttressed) nonabsorbable sutures. 5.*Closure* Prior to closure in standard fashion careful attention is paid to *aerostasis* with suture closure of leaks and spraying of aerosolized tissue sealant over the lung surface. Meticulous *haemostasis* is imperative aided by the local application of haemostatic patches to the parietal surface. Prophylactic clipping of the *thoracic duct* is advisable to reduce the risk of postoperative chylothorax. 6. *Postoperative* To reduce the problem of persistent postoperative air leak, 3 large bore intercostal drains are connected to suction to bring the lung surface to the rib cage and the patient is extubated as soon as possible to reduce the damaging effects of positive pressure ventilation.

IBS27 CHESTWALL TUMORS
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS27.01 ENDOSCOPIC TREATMENT OF UNRESECTABLE MANAGEMENT OF CHEST WALL TUMORS (EXCEPT STERNUM)

G. Rocco

Memorial Sloan Kettering Cancer Center, New York/United States of America

The principles to surgically manage chest wall tumors vary according to the origin of the tumor (primary vs secondary), the pre-existing conditions of the chest wall (previously operated, irradiated or infected) and the available materials for reconstruction (1). Primary chest wall tumors require resection with at least 4 cm margin as well as careful removal of the periosteum/perichondrium of the remaining rib segments (1 to 2 cm) which may harbor the cancer-cells filled lymphatics responsible for early recurrence (2,3). As a rule, the uppermost and lowermost ribs around the primary tumor including the intercostal muscles need to be removed. For tumors located posteriorly in the first three to four ribs, reconstruction may be avoided albeit the extravasation of pleural fluid in the subcutaneous tissues may be a source of complication and affect the patient's perception of a successful result (1,2). To ensure consistent intrathoracic physiology and avoid lung herniation through anterior and lateral chest wall defects, especially if larger than 1 rib with the upper most and lowermost intercostal spaces, reconstruction is advisable (2,3). Secondary tumors can present as solitary soft tissue or bony metastases requiring localized resection or can infiltrate the chest wall in continuity (3). The latter is the case of T3/4 lung cancer which needs to be resected en-bloc with the chest wall, keeping the line of resection at least at 2 cm from the edge of the infiltration (3). The reconstructive materials to be used are represented by time-honored rigid and soft meshes (Vycril, Polypropilene, Marlex, PTFE) which can still be effectively used for primary reconstruction in the absence of complication factors, such as redo procedures, previously irradiated or infected fields (1,4,5). More recently, new materials have been introduced in the clinical practice, namely, new generation titanium plates, acellular collagen matrices, Poly-4-hydroxybutyrate (P4HB), and, cryopreserved homograft of cadaveric origin (1). These materials present a common advantage of being biocompatible, amenable to modeling and incorporable into the host without the need to remove them should local infection complicate the postoperative period (1). However, all of these prosthetic materials need to be covered with viable tissue, ie, muscle flap, fat and omentum since direct exposure to skin may cause wound seroma or breakdown (1). New perspectives are provided by obtaining adequate biomimesis in the reconstruction of large chest wall defects through 3D printing from CT chest wall templates (6). However, the choice of the reconstructive materials is still a matter of surgeon's preference, resource availability, and costs (2). Apart from some important exceptions (ie, Ewing's sarcoma),

primary chest wall tumors may be chemo- and/or radioresistant (7). The resort to a multimodality approach (ie, chemoradiotherapy followed by surgery) for the involvement of the bony as well as the neurovascular structures at the thoracic inlet has been associated to significantly improved survival rates (8). While the role of adjuvant treatment for non-Pancoast T3N0-1 lung cancer invading the chest wall is established, the recent literature identifies promising survival advantage in administering induction treatment in this selected subset of patients (9,10). IBS28 MANAGING SIDE EFFECTS FOR BETTER QUALITY OF LIFE
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS28.01 THE USE OF DIGITAL MEDICINE FOR SYMPTOMS MANAGEMENT IN LUNG CANCER PATIENTS

R. Navon

Sheba Medical Center, Ramat Gan/Israel

Lung cancer is one of the most common cancers affecting both men and women. Lung cancer is associated with high symptom burden and psychological distress. As a result, lung cancer patients' family caregivers also show high rates of distress. In addition, the common treatments, radiation and chemotherapy, may have severe side effects. Both treatments disrupt normal daily living activities and diminish well-being. Hence, symptom management in lung cancer patients may lead to improvements in various aspects, such as: quality of life, emotional stability and supportive environment. Additionally, the prolonged longevity of lung cancer patients nowadays significantly increased the burden of symptom management on the health system. Therefore, the need to optimize symptom management is of great significance. Contemporary technology enables the use of digital medicine, to provide information and interaction with patients in order to improve symptom management. It can help in overcoming several barriers and in reducing the health system's costs. For example, gathering information about the patients' needs may help health care providers to adjust and improve the services according to the principles of personalized medicine; frequent automated digital reminders may improve patients' collaboration during treatments. Patients' confusion and uncertainty that may lead patients to avoid consulting about symptoms, can be prevented by using on line follow-up regarding these symptoms. Enhancement of the care provided to people with cancer can be translated into reduction in symptom prevalence and/or burden and, possibly, reduction in unnecessary hospital admissions, hospitalization days, or clinic visits. A particular population which may benefit from the use of digital medicine is patients from rural areas. These patients lack accessibility medical services. Inaccessibility causes delays in diagnosis, treatment, and follows up, as well as unavailability of advanced care including multimodality treatment options and enrollment in clinical trials. Computer-based systems which employ interactive telecommunication technology have a great potential for a revolutionary impact on healthcare delivery by expanding accessibility and reducing costs. This is particularly true for those using computer-controlled telephony known as interactive voice response technology. This presentation will bring conclusions from several digital medicine symptom management programs, and emphasize lessons which can be learned from their results and possible directions for the future.

IBS28.02 PALLIATIVE CARE FOR IMPROVED QUALITY OF LIFE; IT'S NOT END OF LIFE CARE (HOSPICE)

N. Mitrea

Transilvania University, Brasov/Romania

Since 1967, when the first Hospice has been opened by Dame Cicely Sounders (founder of St. Christopher's Hospice, London, England), and palliative care has been blended with hospice, several definitions have been given to palliative care and hospice terms. In 1997, the palliative care definition by Field and Cassel was short and simple: "palliative care is seeking to prevent, relieve, reduce or soothe the symptoms of disease or disorder without effecting a cure". The current most common references for palliative care definition is the World Health Organization's, 2002: "*Palliative care* is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." (Sepulveda et al., 2002). Variations in defining palliative care have recently caused controversies among professionals in the multidisciplinary teams, as it is now the case with the definition given by International Association for Hospice and palliative care: "Palliative care is the active holistic care of individuals across all ages with serious health-related suffering due to severe illness, and especially of those near the end of life. It aims to improve the quality of life of patients, their families and their caregivers." (IAHPC, 2018). Even more controversies are surrounding the term Hospice as confusion exists regarding the differences and overlaps between hospice and palliative care. In this presentation several definitions of terms will be discussed, including palliative care, quality of life, hospice and death. In order to better illustrate the case, the principles of palliative care will be remembered: holistic care, objective of care = improved quality of life, affirms life and regards death as a normal process, doesn't hasten or postpone death, patient in the center of care and families as units of care, care provided by a multidisciplinary team, bereavement support for families. Some suggestions will be made for aligning to the reality of living a finite life and for the acceptance of the universal mystery of death. Palliative care and hospice need to be destigmatized and promoted among both, the general public and the healthcare professionals, in order to be early on integrated in the trajectory of a serious disease progression. For this reason, the bow tie model of 21st century for palliative care - the enhanced model, will be described. In conclusion, palliative and hospice are about: quality of life, being human, meaningful relationships, control of pain and other symptoms, respect for the dignity of the person, growing throughout the trajectory of the disease. The take home message is valuable for all of us: "*You matter because you are you. You matter to the last moment of your life, and we will do all we can, not only to help you die peacefully, but to live until you die.*" (Dame Cicely Saunders) References: Field, M.J., & Cassel, C.K., (1997). *Approaching death: Improving care at the end of life* (Report of the Institute of Medicine Task Force). Washington, D.C.: National Academy Press. IAHPC. *Global Consensus based palliative care definition*. (2018). Houston, TX: The International Association for Hospice and Palliative Care. Retrieved from https://hospicecare.com/what-we-do/projects/consensus-based-definition-of-palliative-care/definition/ Sepulveda, C., Marlin, A., Yoshida, T. & Ulrich, A. (2002). *Palliative Care: The World Health Organization's global perspective*. Journal of Pain & Symptom Management, 24(2), 91-96.

IBS29 HOW TO SUCCESSFULLY RUN A MULTIDISCIPLINARY TUMOR BOARD
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS29.01 CAN A MULTIDISCIPLINARY TEAM MEETINGS IMPROVE LUNG CANCER SURVIVAL?

K. Fong[1], E. Stone[2], B. Page[1]

[1]*University of Queensland, Chermside/Australia,* [2]*St Vincent's Hospital Sydney, Darlinghurst/Australia*

Multidisciplinary team (MDT) management for lung cancer has been increasingly introduced globally with the aim of improving outcomes for patients. This is reflected by the recognition that lung cancer MDT management is the standard of care in some countries The proponents of MDT care note the perceived benefits of MDT care to all stakeholders, including the patient, their clinicians and the general population. On the other hand, there are potential disadvantages associated with MDT lung cancer care, particularly the costs of setting up the service, the time commitment from the clinicians involved and possible delay to treatment. Observed obstacles to implementing effective MDT management include inadequate infrastructure and organisational/administrative support, lack of enabling technologies, incomplete specialist representation and low attendance by some MDT disciplines, inadequate case preparation and sub-optimal quality information for decision making. The organisation and performance of MDT lung cancer varies round the world and even within countries. This heterogeneity may affect the effectiveness and quality of MDTs such that quality assurance for MDT is essential. This talk will identify the eidence for the effects of lung cancer MDT care on patient centred outcomes including survival in the context of unparalleled improvements in the range of therapeutic options currently available for lung cancer.

Keywords: Lung cancer, Survival, MDT care

IBS29 HOW TO SUCCESSFULLY RUN A MULTIDISCIPLINARY TUMOR BOARD
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS29.03 QUALITY CONTROL

T. Murgu

University of Chicago, Chicago/United States of America

Lung cancer diagnosis and therapy have progressed within the recent years due to significant advancements of bronchoscopic techniques for diagnosing intrathoracic adenopathy and peripheral lung lesions, radiotherapy and surgery techniques, molecular targeted therapeutic agents and immunity checkpoint inhibitors. Published evidence suggests that multidisciplinary team presentation (aka tumor board) in lung cancer has the potential to improve long-term outcomes. Clinical guidelines recognize the importance of multidisciplinary meetings in the optimal care of lung cancer patients. Evidence suggests that dedicated lung cancer tumor boards lead to increased treatment utilization rates and improved survival outcomes for patients with lung cancer. Lung cancer tumor boards also allow for education and promotion of specialty services. This is especially relevant in the fast pace of modern medicine wherein technological and drug therapy advances lead to changes in the structure of traditional lung cancer tumor board and continuously challenge our approach to managing patients suffering from lung cancer. In this session, we will describe each of these issues with reference to our own experiences and literature considerations pertinent to: Selecting needle-based or surgical techniques for obtaining a cytohistologic diagnosis from the primary tumor and/or mediastinal or hilar lymph nodes Managing potential candidates for curative surgical resection; a lung cancer tumor board should include at least a thoracic surgeon specializing in lung cancer, medical oncologist, radiation oncologist and pulmonologist Managing patients with clinical stage I and II NSCLC, even if the patients are considered for nonsurgical therapies such as percutaneous ablation or stereotactic body radiation therapy Managing patients with lung cancer who require multimodality therapy (i.e. in patients with discrete N2 involvement by NSCLC identified preoperatively) Coordinating the optimal approach to obtaining and processing biopsy/cytology specimens to provide expeditious diagnostic and molecular results.

IBS30 RISK ASSESSMENT IN CT SCREENING
TUESDAY, SEPTEMBER 10 07:00–08:00

IBS30.01 RISK ASSESSMENT TO ESTABLISH SCREENING PROGRAMS: THE AUSTRALIAN POINT OF VIEW

A. Mcwilliams[1,2]

[1]*University of Western Australia, Perth/Australia,* [2]*Fiona Stanley Hospital, Perth/Australia*

Australia has a multicultural community of 25 million people. (1) The ethnic background of Australians is predominantly Caucasian (83.6%) with 5.2% Chinese ancestry and 2.8% Indigenous Australian in 2016 census data.(1) It has one of the lowest current smoking rates in the world with only 14% of people >18 years being current smokers in 2017-2018.(2) Despite this, lung cancer remains the greatest cause of cancer death for women and men and is the fourth leading cause of all deaths in Australia. (2,3) Lung cancer cases continue to increase due to a variety of reasons including our growing and ageing population and the lag time between the tobacco epidemic and lung cancer occurrence.(4) Lung cancer rates in Indigenous Australians are approximately double compared to non-Indigenous Australians.(4) Overall, the majority of lung cancer in Australia is attributable to tobacco exposure but 20% of lung cancer occurs in never smokers.(4) There are known gender differences with ~90% of lung cancer in men attributable to tobacco exposure but only ~75% in women. (4) Other occupational exposures play an important role in lung cancer in Australia, with asbestos being one of the most important toxins contributing to lung cancer incidence.(1) A large longitudinal screening program in asbestos exposed individuals (>1700 participants) is ongoing in Western Australia, the Asbestos Review Project. The project has been utilising low dose chest computed tomography (CT) screening since 2012. Lung cancer rates in this cohort are similar to a high-risk smoking cohort despite lower tobacco exposures. The use of current screening enrolment criteria (USPSTF/NCCN) would have resulted in most lung cancer cases being missed. (5) Population based screening programs in Australia have been implemented for cervical, breast and bowel cancers but currently there is no national screening program for lung cancer. A proposed screening program must meet the Australian Screening Framework established in 2008 and be endorsed by the Standing Committee on Screening and the Australian Health Minister's Advisory Council. (6) In their last published statement in 2015, implementation of a national program has not been supported.(7) The definition of the appropriate population to screen and the likely uptake of screening requires further evaluation in the Australian population.The reduction in mortality from lung cancer screening only occurs in those at high risk so the delineation of this cohort is crucial for minimisation of harm and a cost-effective program. (8) International work evaluating various risk prediction models to define the population that would most benefit from lung cancer screening have been published. (8,9) The performance of one of the most well validated models, the $PLCO_{M2012,}$ has been retrospectively evaluated in the Australian population in a subset of the 45 and Up study.(10) In this large longitudinal cohort, 95 882 ever smokers, >45 years were included in the analysis. The predictive power of the $PLCO_{M2012}$ risk model was assessed compared to other potential lung cancer screening enrolment criteria (NLST, USPSTF). This study showed that the risk model, although derived from a North American population, performed equally as well in the Australian population. It would reduce the proportion of ever smokers >55 years, potentially eligible for screening to ~29%. However, only 2% of the cohort were of Asian ancestry and 1.6% Indigenous Australian. The PLCO risk prediction model has been utilised prospectively in the PanCanadian study and further prospective validation is ongoing in Australia, Canada and Hong Kong in the International LungScreen Trial (ILST). The further refinement of a risk prediction model incorporating occupational/environmental carcinogen exposures such as asbestos and ethnicity is needed to further improve risk assessment for lung cancer screening. IBS30.03 RISK ASSESSMENT TO ESTABLISH SCREENING PROGRAMS: THE CANADIAN POINT OF VIEW

S. Lam

BC Cancer Agency, Vancouver/Canada

Risk Assessment to Establish Screening Programs: The Canadian Point of View Stephen Lam MD, FRCPC BC Cancer Agency & University of British Columbia, Vancouver, Canada The Canadian Task Force on Preventive Health Care (CTFPHC) supports screening with low dose computed tomography (LDCT) of the chest to decrease lung cancer mortality.[1] The Task Force recommends annual screening up to three consecutive years in high risk adults aged 55-74 years with at least a 30 pack-year smoking history, who currently smoke or quit less than 15 years ago. Pilot LDCT screening program or studies are being conducted in Canada to help determine how to best implement organized lung cancer screening for people at high risk at the population level. Based on emerging data that suggests both the CTFPHC and the US Preventive Services Task Force (USPSTF) age and pack-years selection criteria[2] are suboptimal and that risk prediction tools such as the PLCOm2012 are more sensitive with better positive predictive power to identify ever smokers who will develop lung cancer with a lower number needed to screen to prevent one lung cancer death and are more cost-effective, [3-8] pilot studies in Canada adopt the PLCOm2012 risk prediction tool to select high risk ever smokers for LDCT screening. A prospective study is being conducted in newly diagnosed lung cancer patients in the Greater Vancouver area. In 1,076 patients, 37% were never smokers reflecting the foreign-born ethnic distribution. Of the 683 ever smokers, 60% met the PLCOm2012 model 6-year risk ≥1.5% screening criteria while only 39.5% met the USPSTF screening criteria. The International Lung Screen Trial (ILST), a multi-center prospective trial in Canada (British Columbia, Alberta), Australia, Hong Kong, and the United Kingdom, offer screening to ever smokers age 55 to 80 years if they meet the USPSTF criteria or the PLCOm2012 model 6-year risk ≥1.5% criteria. Participants receive two annual screens and are followed for six years for lung cancer outcomes. Interim results in 4,863 participants with 101 lung cancers showed that PLCOm2012 identified 26.6% more lung cancers than USPSTF criteria (99% of all lung cancers versus 78% with USPSTF). However, PLCOm2012 screened 9.9% more people than USPSTF criteria. If 2% six-year lung cancer risk threshold were used for screening selection criteria as is currently used in the Cancer Care Ontario Pilot, PLCOm2012 would be 12.7% more sensitive identifying 88.1% of lung cancers while screening 11% fewer people compared to USPSTF criteria. A 1.7% six-year lung cancer risk threshold would be 24.1% more sensitive identifying 97% of all lung cancers while screening only 1% more people than USPSTF criteria. The 1.7% threshold may be a better screening selection criterion. The worldwide burden of lung cancer is significant and projected to rise during the coming years especially in East Asian countries, namely, China, Japan, South Korea and Taiwan because of the large population size, high stable incidence rates in male and significant upward trends in females many of whom are never smokers.[9] With global migration and increasing number of new Canadians who are diagnosed with lung cancer are from Asian countries such as in Vancouver, better lung cancer risk assessment tools need to be developed that take into account ethnicity and other environmental exposures such as outdoor and household air pollution exposures.[10] Risk prediction tools may be perceived by some to be more complex to use than age and pack-years. The web based PanCan risk prediction tool, a precursor to the validated PLCOm2012 model, was tested in both English and French in 8 centers across Canada from coast to coast.[7] The tool was found to be simple to use and took approximately 5 minutes to administer over the telephone. Similar experience was found with the web based PLCOm2012 risk assessment tool for enrollment into the International Lung Screen Trial and the Cancer Care Ontario pilot screening program. Risk assessment can be readily done by a navigator or a physician for enrollment into lung cancer screening programs as part of the shared decision process. IBS31.02 NOVEL DRUG ACCESS: DREAM VERSUS REALITY

R. Dziadziuszko

Department of Oncology and Radiotherapy, Medical University of Gdansk, Gdańsk/Poland

The number of targeted agents registered for treatment of non-small-cell lung cancer (NSCLC) has increased exponentially over last decade as a result of improvements of molecular biology, clinical pharmacology, and clinical research. Molecularly defined subsets of NSCLCs are now recognized from the perspective of these improvements, which directly affect survival of large unmber of NSCLC patients. These innovations are associated with exponential increase of costs to health care, resulting in inequalities among, and often within, countries and societies. Landscape of access to innovative drugs and novel approaches to maximize the access to new therapies will be presented from European perspective.

GR01 WHETHER AND HOW TO ADAPT TREATMENT OF NSCLC OLIGOMETASTATIC DISEASE TO...
SUNDAY, SEPTEMBER 8 13:30–15:00

GR01.01 DEFINITION AND MINIMAL STAGING IN OLIGOMETASTATIC DISEASE

A.M. Dingemans

Erasmus Medical Centre, Rotterdam/Netherlands

Oligometastatic non-small cell lung cancer (NSCLC) is perceived as a separate entity of metastatic NSCLC with limited metastatic potential and possibility of long term survival when treated with local radical treatment[1-3]. However, uniform definition of oligometastatic NSCLC does not exist. We showed in a recent systematic review (21 papers) that the number of metastasis, allowed in the definition of oligometastatic NSCLC, varies between 1 and 8, in only 2 out of 21 papers > 5 metastasis were allowed[4]. This has led to an European Organisation on Research and Treatment of Cancer (EORTC) – Lung Cancer Group (LCG) initiative to formulate a consensus definition of synchronous oligometastatic NSCLC. A pan-European multidisciplinary consensus group was established. Results from the systematic review, a European survey and real patient cases were taken into account when. It was concluded that the definition of synchronous oligometastatic NSCLC is relevant when a radical treatment is technically feasible for all tumor sites with acceptable toxicity, that may modify the disease course leading to long-term disease control. Based on the review, a maximum of 5 metastases and 3 organs is proposed. Mediastinal lymph node involvement is not counted as a metastatic site[5]. In addition staging with PET-CT and imaging of the brain is mandatory. This is in line with the advice of the EORTC-imaging group[6]. The eligibility criteria of recent and ongoing clinical trials in this setting will be discussed in this presentation. 1. Gomez D, Tang C, Zhang J, et al. SUNDAY, SEPTEMBER 8 13:30–15:00

GR01.03 NODAL STATUS OF THE PRIMARY DISEASE?

D. Ball

Peter MacCallum Cancer Centre, Melbourne/Australia

Oligometastases from non-small cell lung cancer (NSCLC) can be classified as synchronous, which are diagnosed at the same time as the locoregional disease, or metachronous, developing after (successful) treatment of the locoregional disease. The title of this presentation implies that the nodes are present at the time of treatment, so the focus will be restricted to the treatment of synchronous oligometastases. In the absence of a universally accepted definition of oligometastatic disease we will assume that the term can be used where there are up to five metastatic sites. Nodal involvement as a prognostic factor in patients with oligometastatic disease. The earliest reports of attempting to improve survival outcomes for patients with limited metastastic disease were in patients with brain metastases either by resection (1) or by resection or stereotactic radiosurgery (2). Five year survivors were observed, vindicating aggressive treatment in this subset of stage IV patients with NSCLC, but patients with regional node involvement appeared to have worse survival than patients with N0 disease. This was confirmed in a subsequent large multicentre individual patient data meta-analysis reported by Ashworth et al of 757 patients who were treated with ablative treatments to all sites of disease (3). Factors that were important for survival in the meta-analysis were metachronous versus synchronous and histology (favouring adenocarcinoma) as well as N stage. Using recursive partitioning analysis, Ashworth et al were able to group patients with synchronous metastases into an intermediate risk group with N0 disease and a 5 year survival of 36.2% versus a high risk group with N1 or N2 disease and a 5 year survival of 13.8%. Why should regional node status be a prognostic factor in patients who already have distant metastatic disease? Most likely it is because nodal involvement is a surrogate for the volume of metastatic disease that may have been underestimated in the pre-PET era. Is regional nodal involvement a contraindication to an aggressive approach? Although Hu et al (2) recommended against an aggressive approach to the locoregional disease in patients with stage II or III NSCLC, the fact that 3 year survivors were observed in their cohort and 5 year survivors in the meta-analysis suggests that it is an option that should be discussed considered. in a retrospective study by Flannery et al if the thoracic disease was not treated definitively, survival at 5 years was 0% compared with 34.6% for surgical resection or chemoradiation (P < 0.0001) (4). Patients with N0 or N1 disease (grouped together) had longer survival than patients with N2 or N3 disease, but this was not statistically significant. A prospective phase II trial treated patients with up to 5 oligometastatic sites with chemotherapy followed by chemoradiation to the primary and involved nodes plus SABR or high dose radiotherapy (60 Gy in 30 fractions) to the metastases was associated with a median survival of 28 months, but there was no difference in survival whether nodes were or were not involved (5). Does nodal status influence whether locoregional disease should be treated by surgery, SABR or (chemo)radiotherapy? This will depend on the patient's fitness for surgery, and the anatomical extent and location of disease. We have no evidence to support any one strategy. We use the same principles to select treatment to the locoregional disease as if there were no oligometastatic disease present. In the Ashworth meta-analysis, surgical management of the primary was a favourable prognostic feature with a hazard ratio of 0.74 (95% CI: 0.55 – 1.00) on univariable analysis, but not on multivariable analysis (3). In the first randomized trial in patients with NSCLC oligometatases the use of ablative treatments did improve disease free survival in patients with NSCLC who had up to 3 metastases and no evidence of progression after systemic therapy.(6) In this small trial, nearly all patients had synchronous oligometastases. Treatments used for the primary disease after first-line systemic therapy included surgery, stereotactic ablative body radiotherapy (SABR) and chemoradiation. Any involved regional nodes were regarded collectively as one "oligometastatic site". There was no significant difference in progression-free survival comparing patients with N0-1 disease versus N2-3. Conclusion Where a patient has synchronous oligometastatic disease that is amenable to ablative therapy, definitive treatment to the primary site and any involved regional nodes taking into account the patient's general condition and disease stage is a reasonable option, regardless of nodal stage. GR01.04 THE RATIONALE FOR LOCAL CONSOLIDATIVE THERAPY IN ONCOGENE-DRIVEN, OLIGO-AND POLY-METASTATIC NSCLC

J. Heymach

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Immunotherapy with PD-1/PD-L1 checkpoint blockade has transformed the management of metastatic NSCLC. These agents are now commonly used as the first-line systemic therapy, either as monotherapy or in combination with chemotherapy, for most patients with metastatic disease who do not have driver mutations in *EGFR* or *ALK*. While this represents a major advance, the majority of NSCLC patients do not have an objective response to PD-1/PD-L1 blockade (Borghaei et al., 2015; Fehrenbacher et al., 2018; Vokes et al., 2018). The molecular determinants of an immunologically inert phenotype are incompletely understood, although it is often associated with a lower tumor mutational burden (TMB) and/or low tumor PD-L1 levels. In addition to TMB and PD-L1, other genomically-defined subgroups have been identified with distinct responses to immunotherapy. LKB1 or EGFR mutant NSCLC subgroups have been characterized for presenting an immunologically inert (or "cold") phenotype with relative depletion of T-effector cells and have been associated with lack of response to immunotherapy. However, other subgroups that are defined by genomic alterations in BRAF or POLD1/POLE genes have been associated with enhanced immunotherapy responses in NSCLC. Patients with *EGFR* and *ALK* alterations, which represent 10-15% of total lung adenocarcinoma, were found to have an ORR of 3.6%, with lower PD-L1 and TIL infiltration (Gainor et al., 2016). EGFR mutant patients have also been associated with lower response to immunotherapy in NSCLC (Gainor et al., 2016). Using clinical specimens from the PROSPECT resected NSCLC cohort, we conducted immunohistochemical immune profiling (n=94). EGFR mutant tumors expressed significantly lower levels of PD-L1 and granzyme B (GZMB). We evaluated mRNA expression and observed increased TGFB3 in EGFR mutant tumors and decreased GZMB. Moreover, EGFR mutant tumors displayed decreased T cell clonality compared to EGFR wild-type tumors. To determine the potential impact of different oncogenic drivers on immunotherapy responsiveness, we conducted a retrospective analysis from the MD Anderson GEMINI database. This analysis confirmed that EGFR mutant patients had shorter PFS (1.8m) and ORR (6%) to PD-1/PD-L1 checkpoint blockade than EGFR wild-type patients. KRAS mutant tumors are highly heterogeneous in their response to targeted agents and immunotherapy. We identified that genomic alterations in three genes: *STK11/LKB1*, *TP53*, and *CDKN2A* defined biologically distinct KRAS mutant subgroups with distinct immune profiles. LKB1 loss was associated with greater sensitivity to agents enhancing energetic, proteotoxic, or replicative stress such as HSP90 and PARPi (Skoulidis et al., 2015). LKB1 loss was also associated with a distinct immune phenotype with lower levels of PD-L1 and other checkpoint molecules, IFN-γ signaling and lower T-cell infiltration. Using KRAS-mutant GEMMs or syngeneic GEMM-derived cell lines, we observed that LKB1 knockout (KO) recapitulated these features in immunocompetent mice. In collaboration with Foundation Medicine, we assessed 924 patients with metastatic NSCLC. To control for TMB, we only analyzed those with intermediate/high TMB levels. The top two genes associated with lower PD-L1 levels were *STK11*/LKB1 and EGFR. *STK11*/LKB1 alterations were also the most strongly associated with a shorter duration of time on PD-1/PD-L1 blockade (Skoulidis et al., 2018b). Among KRAS mutant LUAC patients, LKB1 mutant tumors were associated with lower response to immunotherapy in three independent retrospective cohorts and the randomized phase III Checkmate 57 study (Skoulidis et al., 2018b). This group did not have a significantly lower TMB than the overall cohort, but did have lower PD-L1 levels. LKB1 mutant tumors were associated with shorter PFS and OS on immunotherapy, even in the PD-L1 positive LUAC population regardless of KRAS status. Our preliminary analysis indicates that loss of LKB1 is associated with resistance to combined chemotherapy and pembrolizumab but not associated with worse outcomes after adjuvant chemotherapy (Skoulidis et al., 2018b), suggesting it is not merely a prognostic marker. To validate this finding our group recently has studied the impact of LKB1 mutations on clinical outcomes of non-squamous NSCLC patients treated with chemo-immunotherapy. Consistent with our previous data, LKB1 genomic alterations were associated with inferior clinical outcomes in NSCLC patients treated with chemo-immunotherapy with response rates comparable to those reported for chemotherapy alone (Skoulidis et al., 2018a). BRAF is mutated in 2% to 4% of lung adenocarcinoma (Planchard et al., 2016), and approximately 1-2% of lung tumors harbor the BRAF V600E mutation, which results in activation of the MAPK pathway to promote cell proliferation. BRAF V600E mutation status has been reported to predict sensitivity to the combination of trametinib and dabrafenib, MEK and BRAF inhibitors respectively in lung adenocarcinoma (Noeparast et al., 2016) but it is not much known about the effects of this mutation in driving immunotherapy response. We analyzed BRAF mutant patients that were treated with PD-1/PD-L1 checkpoint inhibitors in our GEMINI database and we compared with patients bearing classic EGFR mutations (exon 19 deletions + exon 21 L858R), EGFR exon 20 mutations (no T790M included), and HER-2 mutations. The analysis reported that BRAF mutant tumors display an increased TMB and that patients with BRAF mutations presented an improved PFS when treated with PD-1/PD-L1 checkpoint inhibitors compared with patients bearing other driver mutations. Further studies on co-mutational status and TMB in these genomicaly-defined groups are ongoing to address potential underlying mechanisms associated with these findings. In addition to BRAF mutations, alterations in DNA repair and replication machinery genes including DNA polymerase epsilon (POLE), polymerase delta 1 (POLD1), and mutS homolog 2 (MSH2) have also been identified in patients that presented with durable clinical benefit to PD-1 blockade therapy. These studies suggest that genomic biomarkers identify subgroups of NSCLC with different responses to immunotherapy and, presumably differing mechanisms of immune modulation. Integration of genomic biomarkers such as STK11/LKB1 in addition to established immune biomarkers such TMB and PD-L1 expression is likely to provide useful information for predicting response to immunotherapy as well as a framework for the development of tailored immunotherapy approaches.

SUNDAY, SEPTEMBER 8 13:30–15:00

GR01.05 SITE OF OLIGOMETASTASES

P. Van Schil

Antwerp University Hospital, Belgium/Belgium

The concept of oligometastatic disease representing patients with only a few or "oligo"metastases, is a relatively new entity in thoracic oncology and surgery [1-2]. Most probably, an intermediate state exists between patients with locoregional disease without distant metastases and those with multiple metastatic involvement in one or more distant organs. The International Association for the Study of Lung Cancer (IASLC) adopted this concept and in the

8th Tumor-Node-Metastasis (TNM) edition a new category was introduced representing those patients with a single metastasis in a single distant organ, currently M1b involvement [3]. These patients belong to stage IVA, as well as patients with contralateral malignant nodules. In contrast, multiple metastases in a single or multiple distant organs are currently described as M1c disease, and they are grouped together in the new stage IVB category. In the IASLC database patients with clinical stage IVA disease had a median survival time (MST) and 5-year survival rate of 11.5 months and 10%, respectively, in contrast to 6.0 months and 0% for patients with stage IVB disease [4]. No consensus exists on the precise definition of oligometastatic disease. For this reason the European Organisation of Research and Treatment of Cancer (EORTC) created a task force to propose a definition of synchronous oligometastatic disease based on consensus by thoracic oncology experts [5]. A maximum of 5 metastases and 3 organs is proposed. Diffuse serosal metastases (meningeal, pericardial, pleural, mesenteric) as well as bone marrow involvement are not accepted as specific site as these cannot be treated with radical intent. Is the specific organ involved important in management and prognosis of these patients? Patients with contralateral lung nodules, brain, bone and adrenal metastases are mostly reported in literature as these organs are quite accessible for local ablative treatment by surgical excision or stereotactic radiotherapy. For patients with bilateral / contralateral tumor nodules introduced in the IASLC prospective database by the electronic data capture (EDC) system, MST was 12 months, quite similar to patients with ipsilateral pleural/pericardial effusion. Although the numbers were quite small, for those patients with a single adrenal metastasis introduced by EDC, MST was 6.5 months, for a single bone metastasis 12.6 months, and for a single brain metastasis 12.1 months [3]. These survival times were significantly better than those for patients with multiple lesions at a single site. In general, most survival data are from retrospective series with an inherent selection or publication bias. For this reason, the EORTC decided not to consider the specific organ involved but this may change when more prospective data become available. Are there any predictive factors for survival in patients with oligometastatic disease? In an individual patient data meta-analysis of 757 patients with 1-5 synchronous or metachronous metastases from non-small cell lung cancer (NSCLC), predictive factors were synchronous versus metachronous metastases, N stage and adenocarcinoma histology [6]. Surgery was the most frequently used treatment, as well for the primary tumor as for the metastatic involvement. Low-risk patients had metachronous metastases, the intermediate risk group presented with synchronous metastases and N0 disease, and the high-risk group with synchronous disease and thoracic lymph node involvement. So, adequate lymph node staging should be performed in every patient [7]. May combined modality therapy including locoregional ablative treatment by stereotactic radiotherapy or surgery improve prognosis in patients with oligometastatic disease? A recent landmark trial investigated the role of local ablative therapy in patients with stage IV NSCLC with three or fewer metastases remaining after first-line systemic therapy [8]. In this multicentre, controlled phase II study 49 patients were randomized between local consolidative therapy group consisting of surgery, radiotherapy or a combination with the aim of ablating all residual disease, and maintenance treatment which was chosen from a predefined list of regimens approved by the Food and Drug Administration (FDA). Primary endpoint was progression-free survival. Secondary outcomes were overall survival, safety and tolerability, time to progression of previous metastatic lesions, time to appearance of new metastatic lesions, and quality of life. Most frequent metastatic sites were brain, bone, adrenal gland, pleura and metastatic lung lesions. Significantly longer progression-free and overall survival rates were noted in the local consolidative therapy group than in the maintenance treatment group. Time to the appearance of a new lesion was longer among patients in the local consolidative therapy group than among patients in the treatment group. Survival after progression was also longer in the local consolidative group [8]. Regarding specific management of oligometastatic disease related to the site of involvement, the European Society of Medical Oncology (ESMO) recently published clinical practice guidelines for metastatic NSCLC including oligometastatic disease [9]. In the presence of a solitary metastatic site on imaging studies, efforts should be made to obtain a cytological or histological confirmation of stage IV disease. Stage IV patients with one to three synchronous metastases at diagnosis may experience long-term disease-free survival following systemic therapy and local consolidative therapy (high-dose radiotherapy or surgery). Because of the limited evidence, these patients should be discussed within a multidisciplinary tumor (MDT) board and inclusion in clinical trials is preferred. Although operative risk is low and long-term survival may be achieved, current evidence for surgery in oligometastatic disease is limited, and the relative contribution of surgery versus radiotherapy as local treatment modality has not been established yet. Solitary lesions in the contralateral lung should, in most cases, be considered as synchronous secondary primary tumors and, if possible, treated with curative-intent therapy [9]. Finally, even salvage surgery may be considered in highly selected patients with oligometastatic disease to improve long-term outcome [10]. REFERENCES 1. Pfannschmidt J. Lung Cancer. 2010;69:251-8 2. GR02.01 HOW CAN WE INCORPORATE EXERCISE PRACTICES INTO PATIENT'S LIVES?

C. Mathias

NOB/ Grupo Oncoclinicas, Salvador/Brazil

Physical activity is any movement using skeletal muscles. There have been over 16 studies examining physical activity and lung cancer risk, 12 cohorts and four case-control studies have examined the association between physical activity and lung cancer. When stratifying by study design, the pooled risk reduction amongst the 12 cohort studies is 23%, and amongst 4 case-control studies, a pooled risk reduction of 38%[1]. Among In a meta-analysis of 11 studies comparing highest versus and lowest levels of leisure-time physical activity, including odds ratios from studies in which the association between physical activity and cancer prevention was adjusted for smoking intensity: moderate-intensity physical activity was associated with a statistically significant risk reduction in lung cancer incidence, OR=0.87 (95% CI: 0.79–0.95), and vigorous-intensity physical activity was associated with a statistically significant risk reduction in lung cancer incidence, OR=0.70 (95% CI: 0.62–0.79). During exercise, particularly moderate-intensity aerobic exercise, T-cell populations transiently, NK cell populations and activity, and neutrophil quantity and activity transiently rise[2]. Exercise or physical activity haves a profound effect on macrophage physiology, including phagocytosis, chemotaxis, metabolism and anti-tumor activity. In murine models of acute exercise, peritoneal macrophage phagocytosis was increased *in vitro*, relative as opposed to sedentary conditions[3]. Although these effects are transient during an acute bout of exercise, the repetitive effects may produce a cumulative (training) effect. Chronic bouts of physical activity have been associated with an inverted 'J-curve' such that optimal immune function is achieved with moderate-intensity physical activity and sedentary and vigorous-intensity below optimal immune-system function. Physical activity is also a useful adjunct to improve the deleterious sequelae experienced during cancer treatment including fatigue, muscular weakness, deteriorated functional capacity, and many others. There is a growing base of evidence that suggests engaging in exercise, such as brisk walking, yields fewer symptoms and side effects during treatment and retards delays the rate at which physiologic systems are affected[4]. The mechanistic models hypothesized that includes pathways relating to sex hormones, metabolic hormones, inflammation and adiposity, immune function, oxidative stress, DNA repair, and xenobiotic enzyme systems. During cancer treatment, deconditioning of the cardiovascular and pulmonary system is common and is associated with diminished levels tolerance to of physical activity. However, it appears that the adaptive capacity of the cardiorespiratory system to exercise training remains intact during treatment. Among In a meta-analysis of 17 high-quality studies, aerobic fitness—a marker of cardiorespiratory function—improved significantly in cancer survivors during treatment over the exercise intervention period. Muscle Ffatigue and muscle weakness are also common sequelae of cancer treatment, but may be amenable to exercise training. A meta-analysis of randomized controlled trials concluded that both upper body and lower body strength improve as a result of exercise training during cancer treatment, with d=0.39 (95% CI:

0.12–0.65), and *d*=0.24 (95% CI: 0.07–0.41), respectively[5]. Strength improvements in the absence of muscle hypertrophy suggest that the adaptations resulting from strength training may be largely attributable to neural adaptations from better motor unit activation (recruitment, discharge rate), synchronization, and cross education. Neural adaptations occur early on in aduring a strength training program and may explain strength improvements in most short-term training studies. Mmoderate intensity activity may optimize immune activity and promote an anti-inflammatory state. Several biomarkers of immunologic function and inflammation exist including neutrophil and lymphocyte counts, natural killer cell activity, C-reactive protein, IL-6, IL-10, and TNF- alpha. It remains unclear what benefits exercise may have on immune system function after cancer treatment[6]. Despite the large volume of studies examining muscular strength among cancer survivors during treatment, few studies have examined the role of strength training among those with cancer cachexia[7]. It is interesting, Interestingly, given the success of resistance training among cancer survivors, to increaseincreasing upper and lower body strength that use of this modality among cancer survivors with cachexia is not more commonly studied. Despite the favorable profile of physical activity along the cancer continuum, many research gaps still exist. Elucidating the optimal dose of physical activity necessary to maximize the reduction in cancer risk of cancer and the optimal dose of physical activity necessary to improve specific physiologic systems, or treatment-specific side effects is warranted. In July 2010, an expert panel from the American College of Sports Medicine reviewed current studies of exercise training and cancer survivorship and released a roundtable consensus statement, concluding that exercise training is "safe during and after cancer treatments and results in improvements in physical functioning, quality of life, and cancer-related fatigue"[8]. Incorporation of exercise practices should, therefore, be advised and stimulated to prevent lung cancer, decrease treatment related side effects, rehabilitate survivors and possibly help during the cachexia period. Interaction between medical oncologists, thoracic surgeons, pulmonologists, physical therapist and sports medicine experts is mandatory for an optimal design of needed trials that will answer several opened questions related to this topic. GR02.02 WHAT IS THE BEST MANAGEMENT OF TARGETED THERAPY TOXICITY?

G. Goss

The Ottawa Hospital, Ottawa/Canada

Over the past decade, the discovery of oncogenic driver mutations in NSCLC and the subsequent advent of targeted therapies against these genomic alterations have significantly altered the management of adenocarcinoma of the lung for a significant proportion of patients. While most oncogenic driver mutations are rare, some exist in up to 50% of specific demographic groups, and together, oncogene-driven disease represents the majority of adenocarcinoma cases (1). Targeted therapies permit directed anti-neoplastic efficacy, with less systemic adverse events than chemotherapy. However, these agents are not without their own unique toxicities that must be managed for optimal drug compliance and therapeutic benefit. This talk will focus on the management of toxicities resulting from the targeting of aberrant pathways and common driver mutations in adenocarcinoma of the lung. We define targeted agents as pharmaceutical interventions directed specifically at one or more of the actionable genomic alterations that result in oncogenic phenotypes (proteins, signalling, etc.). Given the breadth of agents to be tested in this indication, the primary focus of the talk will be on approved (versus experimental) and commonly used agents, including small molecules and antibodies, but not antibody-drug conjugates. Genomic alterations to be addressed include at minimum the ERBB family of genes, KRAS, ALK, ROS-1, PI3K, VEGF and BRAF. For each agent directed against one of these aforementioned alterations, we will approach management of toxicity by contrasting the normal function of the pathway with adverse events associated with inhibition of this pathway. The management of the most frequent and serious adverse events of the pathway blockade will be the focus of the presentation. In conclusion, targeted therapies have had a profound impact on progression-free survival in a significant proportion of patients with metastatic adenocarcinoma of the lung, however they can be associated with a unique set of significant toxicities. The appropriate management of these toxicities may often determine whether a patient derives benefit or not from a targeted therapy, as toxicities can impact dose, frequency of delivery and compliance. Moving forward, increasing the specificity of targeted genomic alteration blockade is required to limit unwanted effects on wild-type proteins. The future of targeted therapy mandates that we devise newer agents with minimal toxicity. 1. Cancer Genome Atlas Research Network. Comprehensive molecular profiling of lung adenocarcinoma. GR02.03 WHAT IS THE BEST MANAGEMENT OF IMMUNOTHERAPY TOXICITY?

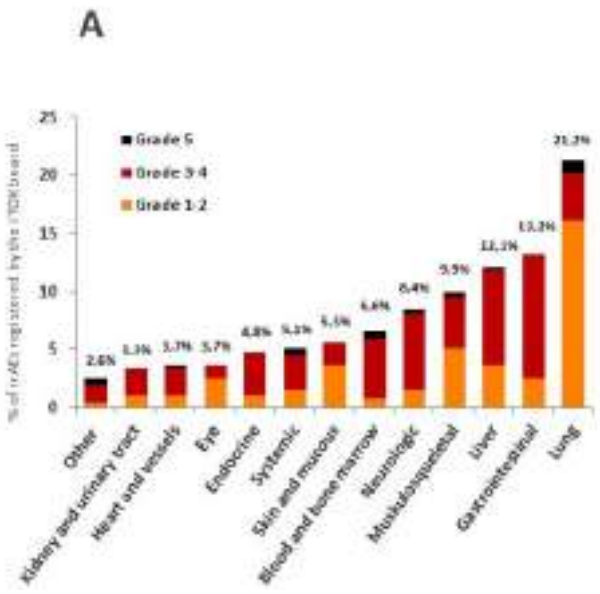
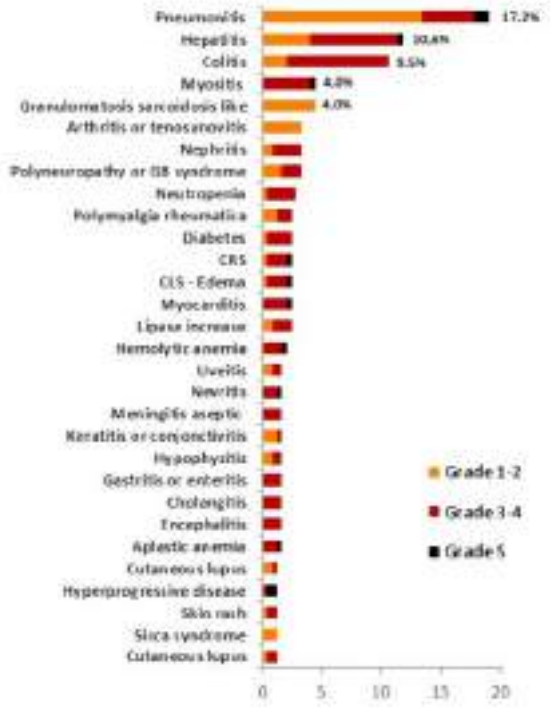
J.-M. Michot

Gustave Roussy Cancer Campus, Villejuif/France

Introduction. The consultations and advices of the organ specialists for immune-related adverse events (irAEs) management can be of great help. The oncologist who uses the immune-checkpoint inhibitors (ICIs) should in his clinical practice be surrounded by different organ specialists that will support him in the management of irAEs[1-3]. Although guidelines provide detailed algorithms for the management of irAEs[4-6], few studies have assessed the real-life medical need of the oncology community. We propose here to report the activity of the immunoTOX assessment board to point the medical needs of oncologists in real life. Patients and methods. Organization of the immunoTOX assessment board. The ImmunoTOX assessment board is an academic group of physicians based at Gustave Roussy, Villejuif and at Paris-Sud University AP-HP Hospital, bringing together physicians specialized in the management of immunological toxicities[1]. Are present oncologists, pharmacovigilance pharmacists, internists and various specialists from expert bodies in the management of immunological toxicities (dermatologist, nephrologist, gastroenterologist, cardiologist, rheumatologist, hepatologist, neurologist, ear nose and throat specialist, ophthalmologist, hematologist, lung specialist and endocrinologist) Results. Over the period studied, 398 requests were sent to the immunoTOX board, for 356 patients. The median time between the occurrence of irAE and the immunoTOX board discussion was 35 days (IQ 13-72). The main requests to the immunoTOX board were about a diagnostic opinion on the relationship between immunotherapy and the side effect (n = 148, 37% of cases), followed by an opinion on the possibility of reintroduction the ICI in a patient after previous irAE (n = 109, 27% of cases), followed by an opinion about the management of a complex immunological toxicity (n = 100, 25% of cases), and by the possibility of starting an ICI in a patient with comorbidities (n = 41, 10% of cases). A certain or probable or possible causal relationship between immunotherapy and side-effect was found in 273/356 (77%) of patients. Among the 273 irAEs investigated, the main organ categories were distributed in the lung (n = 58, 21.2%), the gastrointestinal tract (n = 36, 13.2%), the liver (n = 33, 12.1%). %), musculoskeletal (n = 27, 9.9%) and nervous system (n = 23, 8.4%) (*figure 1A*).





The question of retreatment was 27% of the requests addressed to the immunoTOX board. The question of retreatment involved the possibility of resuming immunotherapy after prior irAE, which was grade 1-2 in 49% of cases and grade 3-4 in 51% of cases. The immunoTOX board gave a favorable recommendation for retreatment with caution for use in 65% of cases, a notice for maintaining temporary hold in 15% of patients, and a notice in favor of permanent discontinuation in 20% of cases. The requests question of the possibility of initiation of immunotherapy in a patient with comorbidities was one in ten. In patients with comorbidities, the immunoTOX board was in favor of initiating immunotherapy and recommended a precaution for use without formal contraindication in 93% of cases. Conclusion. The Immunotox board highlights the prominent real-life medical needs in the field of management of immunological toxicities. Questions rely mainly on toxicities affecting lung, digestive tract, hepatic and neuro-muscular system. When discussing a readministration or initiation of ICI in patients with autoimmune comorbidities, the Immunotox board was generally not opposed to give immunotherapy. A model of multidisciplinary management with oncologists working in close collaboration with organ specialists may guarantee to the patient the access to the ICI. This report will provide a basis of medical needs to define future strategies in prospective clinical trials of immunological toxicities management. GR02.04 IMMUNOTHERAPY: HYPERPROGRESSION AND TREATMENT BEYOND PROGRESSION

D. Gandara

UC Davis Comprehensive Cancer Center, Sacramento/United States of America

The tidal wave of checkpoint immunotherapy (CPI) over the last few years has both opened up a myriad of new treatment options for patients with lung cancer. There are many unique aspects of these PD-1- and PD-L1-directed therapies, turning oncologists into both immunologists and endocrinologists, to better manage a large variety of immune related adverse events. This presentation with address two other aspects of CPI which currently remain both poorly understood and controversial: Hyperprogression/Fast Progression and Treatment Beyond Progression. Hyperprogression/Fast Progression (HPD/FP): A phenomenon of accelerated tumor growth, termed hyperprogressive disease (HPD), has been reported in patients receiving checkpoint inhibitor therapy. HPD has been defined as a ≥ 2-fold increase in tumor growth rate (TGR) from baseline to first evaluation, by comparison with pre-treatment Alternate criteria describing rapid progression on CPI therapy have also been described. Whether HPD is unique to CPI remains unclear, as do associated predictive factors. We developed an alternative approach termed fast progression (FP), in order to study this phenomenon retrospectively in prior Phase III trials of CPI. In addition to CT-confirmed rapid early tumor growth, FP includes early death due to PD from cancer. Using these FP criteria, we analyzed data from the Phase III OAK study, demonstrating equivalent rates of FP with atezolizumab versus docetaxel. However more patients met criteria for FP by TGR increase with atezolizumab. Further, FP was not associated with previously reported predictive factors. This presentation will update those results as well as other new data regarding the HPD/FP phenomenon. Treatment Beyond Progression (TBP): Cancer immunotherapy may alter tumor biology such that treatment effects can extend beyond radiographic progression. This effect explains the discordance between relatively modest response rate/progression free survival and more impressive overall survival in multiple CPI trials in advanced NSCLC. Presumptive benefit of TBP with CPI therapy has been observed in multiple tumor types including melanoma, renal cancer and NSCLC, leading the FDA to call for randomized trials designed to study this phenomenon. We studied TBP in the Phase III OAK trial of atezolizumab versus docetaxel, and reported that post-PD efficacy was consistent with a positive benefit-risk profile of atezolizumab TBP in patients performing well clinically at the time of PD. INSIGNA, a recently activated joint ECOG-SWOG Phase III study, is the first prospective trial to include an arm evaluating TBP. This presentation will discuss the biologic rationale for TBP with CPIs and detail other recently published data.

GR03 PROBLEM AREAS FOR THE NEXT WHO CLASSIFICATION OF LUNG CANCERS
MONDAY, SEPTEMBER 9 15:45–17:15

GR03.01 HIGH GRADE NEUROENDOCRINE TUMORS

M.G. Papotti

University of Torino at Città della Salute Hospital, TORINO/Italy

The four-tier WHO 2015 classification scheme of lung neuroendocrine neoplasms (NEN) includes morphologically and clinically heterogeneous conditions (1). High grade tumors typically encompass large and small cell neuroendocrine carcinomas (LCNEC and SCLC, respectively). The survival of these two types of poorly differentiated NENs is similar and significantly different from that of the well differentiated carcinoid tumors. Thus their appropriate classification is a clinically relevant exercise. While the morphological features of classical SCLC and those of low grade carcinoids allow to easily take these two tumors apart, the correct classification of some atypical carcinoids and of LCNEC is less straightforward. In fact, morphology alone may not be sufficient to identify the various histotypes (that still represent the most relevant prognostic parameter in NENs), and to specifically classify aggressive forms into the group of high grade carcinomas. Even immunophenotype profiling may fail to some extent and only the more recent genetic data have been able to better stratify variations within each single histological type (as recognized by the current WHO criteria). According to such criteria (1), high grade neuroendocrine (NE) carcinomas are defined as malignant tumors made of large or small cells having a solid, diffuse (or more rarely irregularly organoid) growth patterns, with extensive necrosis and a mitotic index exceeding 10 per 10 high power fields. This definition fits for a relatively wide group of tumors, whose clinical behavior is not perfectly overlapping. In particular, while SCLC are invariably associated to a high mitotic rate and high grade cytological features including classical salt&pepper chromatin pattern, LCNEC belong to a grey area that merges with atypical carcinoids on the one side (having intermediate values of mitotic index), and with SCLC on the other (with the occurrence of combined small and large cell NE carcinoma variants). Immunophenotypic markers are not always useful for accurately stratifying NENs. In fact, chromogranin A, synaptophysin and CD56 are generally expressed by the majority of NENs, though with a different intensity and distribution (for example, SCLC may be negative or only focally reactive for chromogranin, but invariably expresses synaptophysin) (2,3). Some transcription factors such as TTF1 and hASH1 are usually intensely positive in high grade tumors, both LCNEC and SCLC, as opposed to carcinoid tumors, that are generally not reactive (with the possible exception of some peripherally located spindle cell carcinoids). The proliferation index, as defined by Ki-67 immunohistochemistry, was proposed as an effective complementary tool to identify different prognostic subgroups, although its use is not officially accepted by the WHO classification with the exception of a differential diagnostic role in small biopsy specimens (1). Indeed, high grade tumors have a much higher mean Ki67 index compared to carcinoids (mean values of 60-80% versus 2-8%). For this reason, the integration of Ki67 data with the two official morphological parameters (necrosis and mitoses) proved effective in a proposed grading system (4). The spectrum of aggressive NENs is unfortunately complicated by the existence of combined NENs, having areas of brisk proliferation admixed with a relatively quiescent tumor cell population. In addition, rare cases have been demonstrated to progress from well differentiated carcinoid to high grade NE carcinomas. The relationship between low and high grade NENs is further supported by the observed heterogeneous genetic profile of high grade tumors, namely LCNEC. Apart from the original detection of the carcinoid-specific MEN1 mutations in a small fraction of "morphological" LCNECs, and of two other different groups of LCNEC, one related to SCLC and the other associated to a genetic signature of non small cell lung carcinomas (5,6), recent comprehensive genomic and transcriptomic analyses of 75 LCNEC identified two molecular subgroups, labeled "type I LCNEC" (having bi-allelic TP53 and STK11/KEAP1 gene alterations, and a NE profile with ASCL1 high / DLL3 high / NOTCH low), and "type II LCNEC" (enriched for bi-allelic inactivation of TP53 and RB1 genes, reduced NE markers, ASCL1 low / DLL3 low / NOTCH high, upregulation of immune-related pathways) (7). In this latter study, some genomic alterations were shared with pulmonary adenocarcinomas and squamous cell carcinomas. In a more recent study (8), the reverse approach was used, starting from a series of carcinoid tumors. With the aim of a full molecular NEN characterization by integrative analyses of genomic, transcriptomic, and methylome data, three molecular groups were identified: clusters A through C were enriched by typical carcinoids (TC), atypical carcinoids (AC) and LCNEC, respectively. Interestingly, the latter cluster also included a subgroup of six "morphological" ACs, here designated "supra-AC" that were molecularly similar to LCNEC, thus supporting the postulated link between the low and high grade lung NENs. Therefore, misclassification is common between AC and LCNEC, due to the existence of "carcinoid-like" LCNEC (5,7), possibly resulting from the evolution of a well- into a poorly differentiated NEN (9), as also reported in thymic LCNEC (10). In conclusion, the correct classification of high grade lung NENs is in general easily obtained in conventional forms of oat cell SCLC and of highly atypical and proliferating LCNEC. Conversely, the separation is more subtle in the presence of the rare intermediate (grey zone) cases, standing between AC and LCNEC, that probably correspond to the recently proposed category of "G3 NE Tumor" in the pancreas (11) and the gastrointestinal tract (expected in the next WHO classification of digestive system NENs). GR03 PROBLEM AREAS FOR THE NEXT WHO CLASSIFICATION OF LUNG CANCERS
MONDAY, SEPTEMBER 9 15:45–17:15

GR03.02 ADENOCARCINOMA

A. Nicholson

Royal Brompton and Harefield NHS Foundation Trust, London/United Kingdom

Many of the limitations in the WHO 2004 classification for adenocarcinomas (confusion over the term bronchioalveolar adenocarcinoma, usage of the term "mixed pattern" and no classification for small biopsy/cytology specimens) were addressed in the 2011 IASLC/ATS/ERS multidisciplinary classification, [1] and this proposal was adopted by the 2015 WHO classification with minor changes.[2] Adenocarcinoma in situ, minimally invasive adenocarcinoma, lepidic predominant adenocarcinoma and invasive mucinous adenocarcinoma have now replaced the term "bronchioloalveolar adenocarcinoma", with subsequent TNM staging changes to use invasive size for T factor size.[3] However there remains significant interobserver variation between pathologists in relation to the point at which invasion starts, indicating that tighter definitions of distinguishing a lepidic pattern from other invasive patterns are needed, especially in areas where these disagreements have a clinical impact. Interobserver agreement between pathologists has been shown to be much better for distinction of invasive patterns (acinar, papillary, micropapillary, solid). Accumulating data supports the 2015 WHO proposal that the cribriform pattern be regarded as a pattern with adverse prognostic significance. It is also proposed that micropapillary be expanded to include a filigree, as well as classical, pattern. One of the most important needs is for pathologists to better recognize the morphologic spectrum of the micropapillary pattern which is often underestimated. Several publications suggest prognostic groupings as lepidic, acinar/papillary and solid/micropapillary as a stratification, and these have been shown to predict response to adjuvant therapy.[4] This leads into the issue of grading of resected adenocarcinomas and the presence of more aggressive histological patterns as a minor component. The histological feature termed "spread through airspaces" or STAS has been shown to be a poor prognostic factor for all major histologic types of lung cancer, including adenocarcinoma where it is frequently seen. There is considerable evidence that the presence of STAS carries prognostic significance, [5,6] in particular in relation to non-anatomic resections, but there remains a need to identify where STAS begins and artefactual dissemination of tumour due to handling and processing of specimens ends.[7] A tighter definition and evidence of international reproducibility is needed. While subtyping of histological patterns is well established in non-mucinous adenocarcinomas, mucinous adenocarcinomas are less well characterised. Various patterns of mucinous differentiation have been proposed, as well as assignment of histologic patterns in similar

fashion to non-mucinous ADCs although only invasive mucinous adenocarcinomas (IMA) and colloid adenocarcinomas currently have specific subgroupings.[2] This proposal has proved to be well founded given the specific molecular features and behaviour pattern of IMAs,[8] although again work is required to refine prognostication. More data is also required tumours with mixed mucinous and non-mucinous areas. Resections are increasingly occurring after neoadjuvant therapy, with there is already a need to assess these in a structured fashion.[9,10] Work is ongoing within the IASLC Pathology Committee to propose a method for classification in this clinical scenario. The 2015 WHO classification saw a seminal change in its structure, in that a classification system was proposed for biopsies and cytology specimens, rather than solely resections. In addition, a major theme utilized in the 2015 WHO classification was a multidisciplinary approach incorporating surgery, imaging, oncologic respiratory medicine, molecular biology as well as pathology. which needs to be maintained into the discussions of future classifications.[1] This approach must remain and will likely need to be enhanced, given the revolution in molecular and immunologic characterisation of tumours, especially adenocarcinomas, and all these new clinically relevant findings will need to be part of pathologic reporting for the ensuing decades. The relative importance and structure of morphologic, immunohistochemical, molecular and immunologic data will need to be incorporated into a system that is appropriate not just for the most advanced cancer centres where all data are available but for laboratories and diagnostic services in underserved countries where morphologic features may be the only ones available. GR03.03 PLEOMORPHIC CARCINOMAS

A. Borczuk

Weill Cornell Pathology, New York/United States of America

The category of sarcomatoid carcinoma in lung cancer classification is composed of five tumor types - pleomorphic, spindle, giant cell, carcinosarcoma and blastoma. While these are all relatively rare tumors, the pleomorphic carcinoma category is the most common of this group. Pleomorphic carcinomas are defined as combinations of adenocarcinoma, squamous carcinoma or large cell carcinoma with a spindle or giant cell element. It may be that spindle or giant cell examples, while diagnostically more challenging, represent variants of similar histogenesis but with complete mesenchymal transformation. Small cell carcinoma in a pleomorphic carcinoma is exceedingly rare. These tumors are often bulky tumors at presentation, with a propensity for central necrosis. Historically, this tumor is highly aggressive and treatment refractory. The histology of this tumor type includes correct identification of a malignant spindle component morphologically, or a giant cell component. While nuclear pleomorphism is an aspect of the tumor, the degree of nuclear enlargement, multinucleation and the presence of emperipolesis all distinguish giant cells of pleomorphic carcinoma from nuclear enlargement in high grade tumors. Immunohistochemistry has be helpful in identifiable a cytokeratin positive spindle or giant cell component. The use of zinc finger E-box binding homeobox1 (ZEB1), a protein involved in epithelial-mesenchymal transition to identify spindle or giant cell component of these tumors, both in small samples and resections, is emerging. Molecular alterations have also been linked to pleomorphic carcinomas. The tumors harbor mutations in KRAS as well as a higher rate of MET exon 14 skipping mutations. This is generally confined to cases with an adenocarcinoma component. TP53 mutations are also frequent. The molecular mechanisms of pleomorphic carcinoma with a squamous only epithelial component remain to be characterized. It has been proposed that MET exon 14 mutations may be targetable using agents such as crizotinib. In addition, these tumors show an elevated rate of high positive PDL1 immunoreactivity which may offer immunotherapy option in these patients. The relationship between large cell carcinoma and new entities such as SMARCA4 deficient carcinoma/sarcoma and the category of sarcomatoid carcinoma remains unclear. Greater elucidation of the molecular underpinning of sarcomatoid carcinoma categories may help clarify the place for these entities within the classification of lung cancer.

GR03.04 MOLECULARLY-DEFINED THORACIC MALIGNANCIES (NUT, SMARCA4 AND OTHERS SARCOMAS)

A. Yoshida

National Cancer Center Hospital, Tokyo/Japan

Classification of tumors has been traditionally based on clinical and histological findings, with each entity often being characterized by molecular genetic changes. However, a few recently described tumor entities are defined by specific genetic abnormalities, and three such tumors are discussed here with a particular emphasis on their nosologic controversy. [NUT carcinoma] NUT carcinoma is a poorly-differentiated aggressive carcinoma with frequent squamous differentiation. NUT carcinoma harbors *NUTM1* rearrangement by definition, with the most common fusion partner being *BRD4* (~70%) and uncommon partners including *NSD3* and *BRD3*. NUT carcinomas typically involve organs along the midline, such as the head, neck, and upper aerodigestive tract in young patients; however, a broader range of patient age and tumor sites exist. Recently, *NUTM1* rearrangement has been reported in a small number of malignant tumors that lack epithelial differentiation, some of which show an undisputable phenotype of sarcoma. Tumors with *CIC-NUTM1* fusion are the best known and their histological and transcriptomic similarities to *CIC-DUX4* sarcomas suggest their relatedness with CIC sarcomas. Other *NUTM1*-rearranged sarcomas are highly heterogeneous, both histologically and genetically, including fusion partners such as *BCORL1*, *MXD1*, *MXD4,* and *MGA*. Interestingly, *MGA-NUTM1* sarcomas have been repeatedly documented in the thoracic cavity of adults. More recently, *NUTM1* rearrangement has been discovered in benign and malignant skin adnexal tumors. *NUTM1* rearrangement is therefore no longer a signature of a single entity NUT carcinoma, and phenotypic correlation is critical for diagnosis. [SMARCA4-deficient thoracic sarcoma (DTS)] SMARCA4 is a core catalytic subunit of the SWI/SNF chromatin remodeling complex. SMARCA4 deficiency in thoracic tumors primarily occurs in association with carcinomas, accounting for 5–15% of lung adenocarcinomas and up to 30% of large cell and pleomorphic carcinomas. These carcinomas typically affect smoking men and are more common in poorly differentiated TTF1-negative tumors that are wild-type for *EGFR* and *ALK*. SMARCA4- DTS is a recently recognized sarcoma type with fewer than 60 cases reported to date. SMARCA4-DTS most commonly occurs in young to middle-aged

adult men (median, 40 years old) with heavy smoking exposure and presents as large tumors in the thoracic cavity. SMARCA4-DTSs are aggressive, and the median survival is 4–7 months. Histologically, the tumors consist of diffusely infiltrating large dyscohesive epithelioid cells with relatively monotonous nuclei and prominent nucleoli, similar to proximal-type epithelioid sarcoma. Rhabdoid cells are seen in a subset of cases. By definition, all cases are deficient in SMARCA4 immunohistochemically because of inactivating *SMARCA4* mutation. SMARCA4-DTS is different from SMARCA4-deficient lung carcinoma with respect to demographics (younger), clinical outcome (worse), histological features (more dyscohesive), immunophenotype (frequent positivity for CD34, SOX2, and/or SALL4, and negativity for claudin-4), and gene expression profiles. Interestingly, some SMARCA4-DTS tumors tested have frequent C:G/A:T transversion mutations and mutations in *TP53*, *KRAS*, *KEAP1*, and/or *NF1*, a shared profile with smoking-associated lung adenocarcinomas. The question has thus been raised whether these sarcomas might represent a dedifferentiated form of lung carcinoma. Nonetheless, an epithelial component has not been reported in any of the documented SMARCA4-DTS cases. Furthermore, most examples are not centered in the lung, and some entirely lack lung parenchymal involvement. [Primary pulmonary myxoid sarcoma (PPMS) with *EWSR1-CREB1*] PPMS is a rare low-grade lung sarcoma of young adults often presenting as an endobronchial mass. The tumor consists of multinodular myxoid growth that is populated by corded or reticular proliferation of spindle and/or epithelioid cells. These tumors often coexpress vimentin and epithelial membrane antigen and harbor *EWSR1-CREB1* fusion. Tumors with a similar histological appearance have recently been reported in various soft tissue and visceral sites, including the brain, by the names of myxoid variant of angiomatoid fibrous histiocytoma (AFH) and intracranial myxoid mesenchymal tumors, which harbor *EWSR1* fusions with genes encoding one of the CREB family transcription factors (*ATF1*, *CREB1*, or *CREM*). Primary pulmonary AFHs have been reported, with some showing myxoid features. Although PPMS is recognized in the WHO classification of the lung as a distinctive tumor, a significant overlap in histology and genetics, albeit several differences, may suggest a close relationship between PPMS and myxoid AFH.

MONDAY, SEPTEMBER 9 15:45–17:15

GR03.05 GRADING OF NSCLCS - PROBLEMS AND SOLUTIONS

A. Moreira

New York University School of Medicine, New York/United States of America

Background Tumor grading has been a traditional component of the pathologic evaluation and in many organ systems, tumor grading offers guideline to therapy and patient management. The latter has not been applied to NSCLC. However, considering the new advances in therapy modalities for NSCLC and advances in adenocarcinoma classification, it is now clear that there are different types of adenocarcinomas and these tumors should not be treated the same way. The 2015 WHO classification of pulmonary adenocarcinoma based on the predominant histological pattern has consistently been found to correlate with prognosis. There is broad agreement that the five histological patterns (lepidic, acinar, papillary, solid and micropapillary) are important prognostic indicators. Recent studies have proposed the inclusion of a number of additional pathologic features (the role of secondary patterns, non-traditional pattern such as cribriform and complex glandular patterns, nuclear grade, mitotic counts, presence of spread through alveolar space (STAS), and necrosis.) that also have prognostic value. The addition of these histological features to the predominant pattern could offer greater refinement of a grading scheme. Supplementing the classification of lung adenocarcinomas with an objective grading system will help define prognostic groups that could benefit from the changing landscape of emerging management and treatment options. Contrary to adenocarcinoma, there has been little advancements in the histological prognostic indicators in squamous cell carcinoma of the lung. Isolated reports have suggested that the presence of tumor budding into the stroma is the sole indicator of poor prognosis. Keratinization, which has been traditionally used to grade these tumors, does not appear to have prognostic value. However, a systematic evaluation of prognostic markers in these tumors have not been carried out. A summary of the current efforts in squamous cell carcinoma will be discussed. The IASLC pathology panel has proposed a systematic study to evaluate a set of histological criteria that have been described as prognostic indicators in adenocarcinoma aimed at establishing an objective grading system of invasive lung adenocarcinoma. Design A multi-institutional study involving well-annotated multiple cohorts of stage 1 adenocarcinomas with at least five years of follow up were evaluated. Annotation included an estimate of the percentage for each histological pattern present for each case; nuclear grade, cytology grade; and mitotic counts with pattern hot-spot association, presence of STAS, and necrosis. A cohort of 284 cases was used as a training set. Univariate analysis was performed to identify significant associations of histological features with recurrence-free survival and overall survival. ROC curve analysis was used to select the best model based on combinations of several features and its association with disease recurrence or death of disease. The results were validate on independent cohorts of 212 cases. Results Review of the literature showed that there are many variation in the classification and definitions on non-traditional patterns. In our cohorts, cribriform and complex glandular patterns followed similar curve as traditional high grade patterns (solid and micropapillary), therefore these non-traditional pattern were defined as patterns of high grade in the model. Another are of variation is the percentage of high grade pattern that can influence outcome. Therefore, the cut-off for a high grade pattern associated with recurrence or death of disease was also established in the training cohort and correspond to 20%. Therefore, amounts smaller than 20% of high grade pattern did not influence outcome. In the training cohort (n=284) all parameters tested, predominant patterns, mitotic count, nuclear grade, cytological grade, and STAS (but not necrosis) were found to have significant prognostic value on a univariate analysis. A Baseline Model composed of Age + Gender + Race + Type of surgery + Pathological Stage; showed an AUC of 0.673. In an attempt to improve this curve, histological parameters were added to the model. The addition of only the predominant pattern to the baseline increases the AUC to 0.698. A model based on the combination of predominant pattern paired with the second predominant pattern was found to have the highest AUC (0.765), followed by a combination of predominant pattern plus worse pattern (AUC=0.74). Addition of other histological features (nuclear grade, mitotic count, STAS etc.) did not significantly improve the model. Similar results were found in the validation set (N=212). The combination of the two

most predominant patterns showed an AUC = 0.763, followed by a combination of predominant + worse pattern with AUC = 0.766. Addition of other histological features did not show improvement of the model. There was no statistical difference between the models using the two most predominant patterns and the predominant plus worse. There was good reproducibility scores for the 2 models Conclusion Our results suggest that an objective grading system for pulmonary adenocarcinoma is possible. Considering that there is no significant differences between a model that accounts for the 2 most predominant pattern and another composed of the predominant plus worse pattern. The IASLC pathology panel proposes the later to be used, because pathologists traditionally grade tumors by the worse component. Therefore, histologic assessment of the predominant pattern and worse pattern, would represent the most parsimonious and prognostic grading system for stage I lung adenocarcinomas. The use of the model in two other independent cohorts of adenocarcinomas (stages 1-3), as well as a reproducibility study will be discussed.

PC01.01 SETTING THE STAGE: TENSION BETWEEN PATIENT SAFETY, SCIENTIFIC PURITY AND PATIENT INCLUSION

J. Sands

Dana-Farber Cancer Institute, Boston/United States of America

Clinical trials are important to the process of better understanding the therapeutic potential of new drugs while also serving as treatment options for individuals seeking the best possible treatment. When writing protocols, we think about how best to determine the effectiveness and side effect profile of the treatment being studied. This can lead to more limited eligibility in an effort to reduce complications not related to the disease or drug. When seeing patients in clinic, we think about how best to treat each individual, which can lead to preferring less strict eligibility. These two perspectives can sometimes seem to be at odds. How do we best define eligibility in a way that both provides scientific rigor while also providing the trial as an option to as many people as possible? This session sets the stage for an in-depth discussion of these 2 important aspects of clinical trials and how to strike the ideal balance for enrollment eligibility criteria. As part of this introduction, a highlight of the process of drug development through different phases of clinical trials from "pre-clinical work" to phase 3 studies is helpful. The following is a general structure. Any prospective drug must demonstrate compelling results at one phase to then be studied in the next phase. This starts with lab studies and often treatment of mice with prospective drugs. Any studies before treatment of humans is called "pre-clinical." When results in this setting are promising, treatment in humans starts with phase 1. In this setting the focus of the study is to find the most appropriate dose, and there are often multiple diagnoses allowed for enrollment within that one study. The strategy for dose finding generally includes starting treatment for a few individuals at a low starting dose. After verifying tolerability, another group starts treatment on the study at a higher dose and so on. Less commonly, studies will allow dose increases for each individual that is tolerating the lower dose with ongoing disease control. Dose escalation often continues until finding the "maximum tolerated dose." Although the side effects of the drug often weigh heavily in determining the dose for further study, responses to the treatment are certainly considered. After determining a dose for future study, this drug may enter a phase 2 study. In this phase, many more individuals are treated at the determined dose, and the effectiveness of the treatment is studied within a specific clinical setting. Results that suggest efficacy often lead to a phase 3 study, which includes randomization to the new drug, or the standard of care treatment, within a specific clinical setting. Although placebo is sometimes utilized, all individuals should get at least the best known therapy. For example, KEYNOTE-189 enrolled individuals with metastatic nonsquamous, non-small cell lung cancer (without sensitizing EGFR or ALK mutations) to the standard of care first line chemotherapy, pemetrexed and a platinum, with randomization to also include either pembrolizumab or placebo. Although people received placebo, it was given along with the chemotherapy, as was pembrolizumab. This introduction is followed by two related session. One is focused on crafting trials to allow more broad enrollment with the acknowledgment of trials as a treatment option. The other is focused on trial development with full attention toward scientific rigor and study of the drug. A discussion of the balance of these goals follows.

PC01.02 REAL WORLD RESEARCH GROUPS - ROS1DERS

M. Hennink

Longkanker Nederland, Groningen/Netherlands

Reinventing Clinical Trials *Merel Hennink* Lung cancer research has made great progress in the last decade. Discovery of more treatable mutations have paved the way to more treatment options. We are moving away from a "one-size-fits-all" chemotherapy towards personalized medicine. (1) However, these developments require accurate diagnostics to identify the right treatment options. Furthermore, as a common cancer like lung cancer is split into rare subgroups, it also poses additional challenges. Rare mutations in NSCLC (for instance ROS1) result in small patient populations for trials and less bio-materials for research. The main question here is how to navigate this changing landscape. The ROS1ders – a community The ROS1 rearrangement was first described in 2007 and occurs in about 1% of patients with NSCLC. Of the estimated 1.5 million new cases of NSCLC worldwide each year, approximately 15,000 may be driven by oncogenic ROS1 fusions.(2) In 2015, little was known about the ROS1 rearrangement and only a single drug was available to treat the disease. Also in 2015, a group of ROS1 positive lung cancer patients formed an international community on social media, The ROS1ders, allowing them to connect with each other. Through social media, patients are becoming increasingly engaged, and discussing the diagnostic and treatment options available in their countries or hospitals. In addition, these national and global online communities, where information is shared, can highlight (inter)national disparities in treatment access. *Treatments* Crizotinib is currently the only FDA- and EMA–approved agent for the treatment of *ROS1*-rearranged NSCLC. Unfortunately several healthcare systems across the world have difficulty with reimbursing the drug due to lack of data from randomized clinical trials (UK, South Africa, Canada, New Zealand). In Canada, Real World Data from the ROS1 Facebook group helped in the approval process. "The Committee expressed that they were impressed with the patient input of 259 ROS1 positive patients and caregivers from 32 countries who supported the use of crizotinib. Overall, from the perspectives of patients with ROS1-positive NSCLC, they value a chance to extend their life and spend more time with their families by having a treatment that is effective, and improves their symptoms and outcomes."(3) Global ROS1 initiative – from advocacy to active research The ROS1ders transitioned from advocacy to active research in the past few years. Reaching out to academic cancer centers, they strove to increase the amount of cancer models available to stimulate ROS1 research. The Global ROS1 Initiative is a partnership connecting researchers, patients, caregivers, and physicians worldwide. Patients who have an upcoming biopsy contact the national study nurse, and can choose to donate extra material to generate a cell line, a patient-derived xenograft (PDX) mouse model, or both. The goal is to create models and data accessible to all researchers. All models and characterization data will be made available as an open access database to researchers and collaborators. The Global ROS1 initiative has already generated four cell lines at the University of Colorado, and three PDX mouse models are in development. Patients are in the driver seat!(4) Europe *Diagnostics* Testing is essential to select the right treatment. Nevertheless, systematic diagnostic testing for ROS1 in metastatic NSCLC is not yet included in the European Society of Medical Oncology recommendation, but only suggested. (5) In Europe, access to molecular testing and new medicines differs between individual countries, even within the same country. In the Netherlands, a retrospective study in all patients that tested negative for EGFR and KRAS, showed an increase in ROS1 testing between 2013 (10%) and 2017 (61%) (6). Given the demonstrated added value of patient-driven organizations, both for patients and research, we need a more systematic testing for ROS1, in order to offer effective treatment to more ROS1 patients and strengthen our international community. *ROS1 patients as research partners in Europe* The Global ROS1 Initiative requires streamlined protocols to be successful. Currently, European ROS1ders cannot donate tissue for a variety of reasons. Therefore, a pan-European collaboration should be implemented, that centralizes expertise on the small number of potential tissue donations. In this network, tissue processing should be centralized in a single lab, and the resulting data and models could be distributed to collaborating partners. However, the setup of such network is very difficult, in part due to national differences in legislation. Furthermore, although we are a European Union, patients are not really united, and bringing together the European ROS1ders

is not an easy task. We deal with language, boundary and policy issues. Due to European public health systems, all responsibility is given to doctors. Most patients see less benefit in getting informed and organized. Data protection laws and less use of social media make it more difficult to connect patients. Next, the number of non-governmental organizations supporting lung cancer patients is small - in particular in Europe. And finally, fundraising activities are rather uncommon in Europe. Overall these aspects make it harder for patient advocates to make a difference. As such, international networking and solidarity become even more important. In the Netherlands, www.stichtingmerelswereld.nl was founded to raise awareness and accelerate research. As a result, research on drug resistance has been initiated in cell lines and PDX mouse models. In parallel, drug resistance is also studied in France and Germany. Combining these individual studies might result in a 1+1 equals 3 scenario. We strive to unite our national voices to influence European policies and use our European voices to connect national studies. *Understanding the role of personalized medicine* https://www.lungcancer.org Jessica J. MONDAY, SEPTEMBER 9 11:00–12:30

PC01.03 REAL WORLD RESEARCH GROUPS - ALK+ GROUP

L. Olson

www.outlivinglungcancer.com, Lowell/United States of America

There is a natural tension inherent to clinical trials—between scientific rigor and a participant's hope that an experimental therapy shall prove effective. However, it is important to never lose track of the reason for clinical trials. To quote Dr. Richard Pazdur, Director of the FDA's Oncology Center of Excellence, 'We have to understand that the clinical trials are here to serve the patients. The patients are not here to serve the clinical trials.' (1) The decision to enroll in a clinical trial—particularly phase I where both maximum tolerable dose and the safety profile are being ascertained—is not a casual one. Generally the prospective participant has exhausted traditional therapies. With the emergence of actionable mutations and targeted therapies, the paradigm for participation is evolving. It is foreseeable that a participant can have a response to a therapy measured not only in months but in years. And when progression does occur, that same participant may enroll in yet another clinical trial. For many patients with advanced lung cancer, clinical trials now offer the best option for therapeutic treatment. It is critically important to find the balance between advancing medical research and extending individual lives. To this end, exclusion criteria need to be reevaluated. A patient who is desperately ill is often willing to tolerate a far higher degree of risk. Arguments for exclusion criteria fail to take into account the fact that this is a representative population; should the drug receive FDA approval, this will be the consumer profile. (2,3) It is also vital to understand the burden that clinical trial participants take on. First, financial. There is an overriding misperception that participation in a clinical trial is cost free. In reality, it is often only the experimental therapeutic that is provided free of charge. Clinical trials are procedure rich—from pharmacokinetics to additional scans/MRIs/EKGs/biopsies. In most cases a participant's insurance is billed for these procedures, resulting in quickly maxed out deductibles and added copays. More frequent visits to the site of the trial require additional time and travel on the part of the participant. Transportation, lodging and meals are often the responsibility of the patient. There are lost wages, for either the patient or their caregiver or both. Often there is also the burden of childcare. The financial toll adds to the high degree of stress that a patient and their families are already living under. It also means that clinical trials are an option only for those with both the financial means and a solid support system in place. As economically distressed families are unevenly distributed among minorities, the clinical trial population is not representative. Not only does this mean there is an inherent disparity in access to clinical trials, it also impacts the science, as clinical trial participants in an ethically diverse country such as the US are overwhelmingly caucasian. In addition, it is important to point out that healthy volunteers to clinical trials are almost always compensated for both their time and even small things that are typically not covered in a clinical trial for oncology patients—such as parking. (4,5,) And then there is the physical toll upon a patient. Excessive scanning, multiple biopsies, exhaustion associated with additional visits to the site. "When you begin to look at a trial from the patient's perspective and consider the complexity of the trial and what we are asking them to do, is it any wonder that so many patients are refusing to participate? And is it any wonder why so many patients choose to withdraw from a clinical trial?" (6) As accrual is an ongoing issue in clinical trials, it is imperative for both the sake of patients as well as medical science, that the voice of the patient be heard. Patient reported outcomes (7) often fail to capture the actual experience of a trial participant. Rather than being the one size fits all that is commonly handed to participants at each visit now, why not write the PRO with the assistance of actual participants? Humans, unlike their rodent counterparts in the lab, are sentient beings. Potentially a wealth of anecdotal information is being lost simply because no one thinks to ask. Clinical trials cannot happen without the cooperation of human participants. That cooperation is referred to as compliance. A patient who is noncompliant risks ejection from a trial. This creates a relationship that is inherently unbalanced. It is possible to address both accrual and the needs of the participant if clinical trials become truly patient centric. To do so one must consider the burden of participation. A clinical trial should be viewed as an opportunity, albeit one that is not risk free. Lessening the burden and removing some of the barriers to participation will better address the needs of both patients and the field of medical research. 1. PC01 REINVENTING CLINICAL TRIALS
MONDAY, SEPTEMBER 9 11:00–12:30

PC01.04 LUNG CANCER PATIENTS SHOULD HAVE BETTER ACCESS TO CLINICAL RESEARCH: RELAX THE ELIGIBILITY CRITERIA

J. Freeman-Daily[1,2]

[1]*The ROS1ders, Mountain View/United States of America,* [2]*GrayConnections.Net, Federal Way/United States of America*

Clinical trials are essential for improving treatment of cancer patients. However, only 2%-3% of adult cancer patients participate in clinical trials, and many trials close because they do not enroll enough patients. Others are slow to accrue patients, which prolongs the time required to obtain results. Those trials that meet accrual goals often have cohorts that don't reflect the demographics or performance status of the real-world population of patients who have the disease. Why do trials have trouble enrolling enough patients? Some of the significant barriers to clinical trial participation stem from over-

restrictive trial eligibility criteria. Unger et al (2019) found 21.5% of patients did not enroll in a clinical trial because they were not eligible. A Kaiser Permanente study of non-small cell lung cancer patients found 80% of the patients were not eligible for two NSCLC treatment studies. Trial eligibility must balance opposing factors. It must be narrow enough to ensure the effect of the treatment can be determined, yet broad enough that the population of patients is meaningful. Researchers often use "common" eligibility criteria without giving due consideration to how those criteria may impact trial recruitment and the real-world applicability of their study. A population of younger patients with no health issues other than lung cancer might make it easier to identify the effect of the experimental treatment, but this population gives no real insight into how the treatment affects the typical population of lung cancer patients (which has an average age of 71). Recommendations to modernize eligibility criteria have been recently published by a joint effort of the American Society for Clinical Oncology and Friends of Cancer Research, as well as the US Food and Drug Administration and the National Cancer Institute. The recommendations include relaxing restrictions on brain metastases, minimum age, HIV/AIDS, organ dysfunction, and prior and concurrent malignancies while ensuring patient safety. Other aspects of a trial may cause patients to decide not to enroll even if they meet the eligibility requirements. Locations of trial sites might require the patient to travel, yet the patient might not be able to afford time or cost of travel, or their insurance might not cover treatment at any trial site. The trial protocol may prohibit certain previous treatments, or require weeks of washout from previous tyrosine kinase inhibitor (TKI) treatments (which raises the possibility of TKI flare). Preliminary evidence shows that relaxing trial eligibility requirements could result in a greater number of patients becoming eligible for clinical trials. Harvey et al (2019) conducted a retrospective study of 10,500 CancerLinq records of patients with lung adenocarcinoma. They found 47.7% of patients were excluded from clinical trials by traditional exclusion criteria (no brain metastases, no other malignancies, and creatinine clearance greater than 60 mL/minute), while only 1.5% of patients were excluded by the ASCO-Friends recommended expanded criteria that removed these restrictions. Relaxing clinical trial eligibility while maintaining safety is in the best interest of the patient. Patients are not for clinical trials. Clinical trials are for the patient. PC02 COMBINING WITH CHEMO: OLD SCHOOL IS NEW AGAIN
MONDAY, SEPTEMBER 9 14:00–15:30

PC02.02 TKIS SHOULD BE GIVEN WITH CHEMO

R. Rosell

Germans Trias i Pujol Science Institute, Badalona, Barcelona/Spain

TKIs Should Be Given with Chemotherapy. This is an open question, with some pros and cons, mainly due to the complexities of chemotherapy activity regarding genetic alterations. However, there are several promising hints that the combination could be useful, but not all chemotherapeutic drugs prove beneficial. This information will be provided in the presentation. Resistance to erlotinib and, in general, to any generation of EGFR TKIs, is heterogeneous and requires the comprehensive dynamic molecular profiling of the tumor with either tissue, liquid biopsies, or both. Before the development of the third-generation EGFR TKIs, at the time of progression to erlotinib or gefitinib, patients were successfully treated with chemotherapy [Sequist et al Sci Trans Med 2011]. The alternation of chemotherapy and EGFR TKIs merits revisiting. The intercalation of erlotinib with chemotherapy has shown a median PFS of 16.8 months in EGFR-mutant NSCLC patients [Wu et al Lanect Oncol 2013]. The most salient biological concept to re-address the contribution of chemotherapy in EGFR-mutant NSCLC is the fact that nuclear cyclic GMP-AMP (cGAMP) synthase (cGAS) expression suppresses DNA repair and, therefore, can enhance the activity of EGFR TKIs. Preclinical data strongly favors this model, showing that etoposide or other chemotherapeutic drugs can promote the translocation of cGAS to the nucleus by phosphorylation of cGAS on the tyrosine residue 215. In the nucleus, cGAS is recruited to double stranded breaks, interacting with PARP1. The cGAS-PARP1 interaction jeopardizes the generation of the PARP1-Timeless complex and suppresses homologous recombination [Liu et al Nature 2018]. The fact that cGAS transcripts are increased in NSCLC is of clinical interest, indicating that cGAS could be a new biomarker involved in the response to immune checkpoint inhibitors [Gui et al Nature 2019]. Multilayer research sheds light on potential safe and active combinatory therapies in EGFR-mutant NSCLC and many therapeutic approaches converge in the complex signaling pathway crosstalk. Perhaps tumor heterogeneity is not the major difficulty and the mechanisms of resistance are more dependent on the capacity of tumor cells to re-wire and re-program the signaling pathways that they use to grow and migrate [Karachaliou et al EBioMedicine 2018]. Epi-transcriptomics are also involved in resistance to EGFR TKIs (Figure) [Zanconato et al Nat Med 2018]. Several chromatin regulators have emerged as druggable targets, including bromodomain-containing protein 4 (BRD4). BRD4 interacts with YAP1, and Bromodomain and Extra-Terminal motif (BET) inhibitors impair the expression of YAP1 direct target genes, including AXL, FST1 and aurora A [Zanconato et al Nat Med 2018]. We have recently reported that the combination of EGFR TKIs with barasertib, an aurora kinase B inhibitor, illustrates a strong antiproliferative activity in a broad panel of EGFR-mutant resistant cell lines [Bertran-Alamillo Nat Comm 2019]. DNA repair modulators may be associated with resistance to EGFR TKIs. In our original study of erlotinib in EGFR-mutant NSCLC [Rosell et al NEJM 2009], we explored the role of DNA repair genes on the treatment outcome. Among several transcripts examined, breast cancer type 1 susceptibility (BRCA1) gene mRNA surfaced as relevant in the repair of erlotinib-induced DNA damage through an H2A histone family member X (H2AX)-independent pathway [Rosell et al Clin Cancer Res 2011]. Normally, DNA damage repair involves a homologous recommendation, through H2AX [Wang et al Science 2007]. Patients with low BRCA1 mRNA expression had significantly longer PFS than patients with high BRCA1 mRNA levels, and BRCA1 levels were an independent predictor of PFS in the Cox-multivariate regression analysis. Finally, turning off the DNA damage checkpoint after DNA repair involves the removal of phosphorylated H2AX from the chromatin, followed by its replacement with canonical H2A. This exchange of phosphorylated H2AX for H2A is mediated by facilitates of chromatin transcription (FACT) (Figure). The ability of FACT to remove phosphorylated H2AX from the chromatin is inhibited by PARP1 [Rosell et al Clin Cancer Res 2011]. A novel class of drugs, curaxins, act as a chromatin trapping of the FACT, suppressing simultaneously NF-κB signaling and promoting activation of p53 [Gasparian et al Sci Trans Med 2011]. The combination of erlotinib with curaxins, or FACT inhibitors, like CBL0137 [Lindner et al Cancer Res 2018], may be a significant advance in the field of EGFR-mutant NSCLC therapy.

PC02 COMBINING WITH CHEMO: OLD SCHOOL IS NEW AGAIN
MONDAY, SEPTEMBER 9 14:00–15:30

PC02.03 IO SHOULD BE GIVEN AS A SINGLE AGENT

J. Brahmer

Johns Hopkins Sidney Kimmel Cancer Center, Baltimore, Baltimore/United States of America

Programmed cell death 1 (PD-1) checkpoint pathway inhibitors have greatly changed the treatment paradigm for advanced stage non-small cell lung cancer (NSCLC). Durvalumab is approved for use as a single agent after chemotherapy combined with radiation for stage 3 NSCLC.(1) Pembrolizumab is approved for use in the first line treatment setting for advanced NSCLC not amenable to radiation for patients whose tumor has a tumor proportion score (TPS) of 1% or greater in the United States.(2) For patients whose tumor has a TPS of ≥ 50%, it is approved for use in the first-line treatment setting in multiple countries throughout the world.(3) However, PD-1 checkpoint blockade combinations, either anti-PD1 or anti-PD-L1 antibodies, with chemotherapy regardless of PD-L1 status have shown benefit as well. (4,5,6) Single agent immunotherapy (IO) has several advantages. Cost of combination therapy is an issue. While these PD-1 pathway blocking antibodies are expensive as single agents, combining them with chemotherapy adds to the cost, time in infusion, and adds chemotherapy related side effects. So, if patients can, single agent immunotherapy is still preferred, particularly in a population i.e. TPS ≥ 50% who is more likely to benefit compared to chemotherapy. Some would say the same is true for patients with TPS ≥ 1, but here the data for single agent IO compared to combinations with chemotherapy is mixed. While trials comparing this scenario, i.e. comparing single agent PD-1 antibody compared to chemotherapy plus IO, head to head have not yet been done, it is hard not to do cross trial comparisons as seen in table 1. Clearly though, chemotherapy and IO combinations have increased objective response rates regardless of PD-L1 TPS status where response rates range from 57.9%-62.1%.(4,5,6,7,10) While combinations with chemotherapy show increased response rate regardless of PD-L1 TPS, chemotherapy can have deleterious effects on the immune system. (8) Chemotherapy can alter immune function by causing lymphopenia. Steroids, added to chemotherapy regimens to prevent allergic reactions and control nausea, can suppress pro-inflammatory cytokines and impair Natural Killer (NK) cell function and dendritic cell differentiation or activation. Taxanes specifically can cause inhibition of T-cell and NK-cell activation. Thus, these combinations may prevent immune activation and suppress immune memory. Duration of response in single agent IO in the first line treatment setting is 16.8-20.2+ month.(9,2,3) The duration of response in the IO plus chemotherapy patient population is 7.7-11.2 months.(4,5,6) The data from the chemotherapy IO combinations is too immature to know what the potential five-year survival is compared to the impressive 23.2% 5 year survival rate of the initial trial of pembrolizumab in the treatment-naïve setting(Keynote 001).(9) Immunotherapy, particularly PD-1 pathway checkpoint antibodies, have drastically changed the treatment landscape for advanced stage lung cancer patients. Single agent pembrolizumab particularly in patients with TPS ≥ 50% lung cancer results in an impressive long term survival that is not seen with chemotherapy alone. Combining immunotherapy agents with chemotherapy increases disease response but long term survival outcome data and duration of response is immature. Table 1 – Overview of Results in NSCLC PD-L1 TPS ≥ 50% patient population

PC02 COMBINING WITH CHEMO: OLD SCHOOL IS NEW AGAIN
MONDAY, SEPTEMBER 9 14:00–15:30

PC02.04 IO SHOULD BE GIVEN WITH CHEMO

L. Paz-Ares

Hospital Universitario 12 Octubre, Madrid/Spain

Lung cancer is the leading cause of cancer death worldwide. Non-small-cell lung cancer (NSCLC) accounts for almost 85% of all cases. The prognosis of NSCLC patients remains quite unsatisfactory due to the frequent advanced disease stage at diagnosis and the relatively low efficacy of the available systemic treatments. Of note, over the las few years significant progress as inhibitors of programmed death-1 (PD-1) and its ligand PD-L1 have proven to be effective therapies in metastatic NSCLC lacking sensitizing *EGFR* or *ALK* mutations, initially in pretreated patients. Subsequently, in metastatic NSCLC patients with PD-L1 expression of at least 50% on tumor cells, upfront pembrolizumab improved median progression-free survival (PFS) and overall survival (OS) compared to standard platinum-based chemotherapy. However, patients with a tumor proportion score (TPS) of 50% or greater represent only some 30% of those with NSCLC, and progression during the first three months is frequent in one third of the cases. To enhance the immune response through PD-1 inhibition, several studies have combined the potential immunogenic effects of cytotoxic chemotherapy with immune checkpoint inhibitors (ICPI), particularly of some chemotherapy regimens such as those pemetrexed-based. The first study that gave some important information regarding the efficacy of combining IO and chemotherapy was Keynote 021, randomized phase II trial of carboplatin plus pemetrexed with and without pembrolizumab. It showed significantly better response rates (RR) and longer PFS with the addition of pembrolizumab to chemotherapy. Over the last two years at least 6 other phase III clinical trials with pembrolizumab (KN 189 and KN 407) have showed the benefits of combined chemotherapy plus IO therapy in terms of PFS and OS (HR 0.49-0.64). Consistent data have been achieved on atezolizumab trials, although the magnitude of the OS benefit (HR 0.78-0.93) have been somehow lower. Randomized studies with nivolumab, durvalumab and avelumab are expected to be reported in the near future. Chemo-immunotherapy combinations are associated with the expected toxicities of chemotherapy and IO on their own. At present, for patients with tumors with TPS >50%, there are no comparative trials of IO monotherapy (e.g. pembrolizumab) as compared to chemotherapy. Across trial comparisons may support the use of IO monotherapy for most of cases. Chemo-IO regimens may be considered for patients requiring rapid responses (e.g. symptomatic patients) or those with aggressive disease. In patients, whose tumors express PD-L1 in 1-49% of cells, chemo-IO combinations are seen as the best treatment options. Of note, in the IMPOWER 150 trial, patients with EGFR/ALK aberrations also benefitted from the addition of atezolizumab to the paclitaxel/carboplatin/bevacizumab regimen. In patients with tumors with negative expression of PD-L1 the benefits on PFS were more debatable but the pembrolizumab-based combos, and to some extend those with atezolizumab, resulted in prolonged survival. The value of certain genomic aberrations (e.g. Keap or LKB1) or low tumor mutational burden (TMB) as a predictive tool in this setting needs further validation. In addition, the results of several ongoing combination studies (CheckMate-9LA, POSEIDON) investigating two and four drug regimens of PD-(L)1 plus CTLA-4 inhibition with/without chemotherapy are eagerly awaited and will reveal further knowledge of efficacy and tolerability in this setting. PC03 ADJUVANT THERAPY FOR RESECTED NSCLC HARBORING EGFR MUTATION, CHEMOTHERAPY OR TARGETED THERAPY
MONDAY, SEPTEMBER 9 15:45–17:15

PC03.01 PROS

W.-Z. Zhong

Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangzhou, P.R.China/ China

Lung cancer is so far the leading cause of cancer death worldwide. Complete surgical resection remains the most effective approach for patients with early-stage non-small cell lung cancer (NSCLC). Patients with completely resected stage I NSCLC could have a 5-year survival of ~80%, whereas it fails to ~30%. Since 2003, adjuvant chemotherapy became the standard of care showing 4% absolute 5-year survival benefit compared to surgery alone [1]. Following randomized control trials revealed similar results [2-4], yet limited survival benefit, low therapeutic completed rate plus high toxicities rate may somehow hinder its clinical applicability. In the past decade, targeted therapies had achieved tremendous success in oncogene-driven advanced NSCLC showing both high efficacy and low toxicities [5]. As a matter of course, targeted therapy had its baby steps in early-stage NSCLC. However, no positive results were found in these trials which should probably be blame for large proportion of stage IB patients and incorrect detection methods for *EGFR*mutation. Besides, conservative trial design without head to head comparison could not fully address toxicities issues caused by chemotherapy. Precise target population seemed to be an essential key point to adjuvant targeted therapies and ADJUVANT as well as EVAN trial came into being [6, 7]. Although overall survival (OS) was not mature enough to measure, significantly prolonged disease-free survival (DFS) was observed in both trials along with better tolerability. Indeed, questioning around adjuvant targeted therapy has never been adjourned such as the optimal duration of targeted therapies, study design and lack of OS data. Ross et al brought up with an informative comment for ADJUVANT trial bringing the concept of MRD (molecular residual disease) into adjuvant treatment [8]. Based on the ctDNA testing after standard of care adjuvant chemotherapy, patients of high risk of recurrence will be given further treatments while observation for the others. It highlighted the significant role of discriminating beneficiaries from adjuvant targeted therapies instead of simply providing more efficient treatment modalities. Previous biomarker-based studies regarding adjuvant treatment among different tumor types [9, 10] had provided inspirational examples, and as well shown clinical feasibility and urgent need for personalized adjuvant treatment after complete surgical resection. For ADJUVANT trial, we established a comprehensive signature of genetic-features (MEDUSA) to guide personalized adjuvant treatment in EGFR-mutant stage II-III NSCLC. Results would be unleashed in upcoming ESMO meeting. Through utilizing multi-omics data, we could predict whether additional treatments, adjuvant chemotherapy only or observation would be adequate for each individual and provide optimal sequential treatments. Further translational researches and corresponding trials regarding resectable NSCLC should decipher the issues. Fortunately, several trials regarding dynamic monitoring postoperative ctDNA or genomic profile of primary cancer to guide sequential treatments are ongoing and the results should be expected.

	Study	Regimen	Sample size	Population	IB ratio	Median follow-up	DFS	5-year DFS	OS	5-year OS	complete rate

J. Patel

University of Chicago, Chicago/United States of America

Surgery remains the cornerstone of treatment for early-stage non-small cell lung cancer (NSCLC). However, despite undergoing potentially curative surgery, patients with stage I, II, or IIIA NSCLC are at substantial risk for recurrence and death from lung cancer. Adjuvant cisplatin-based systemic therapy has conclusively been proven to decrease the risk of recurrence and improve overall survival outcomes. EGFR tyrosine kinase inhibitors have been proven to be the superior first-line treatment for EGFR-mutant advanced NSCLC. Several trials have shown superior progression-free survival and fewer side effects compared with doublet chemotherapy in advanced disease. Given that EGFR-TKIs are more active than platinum-based doublet chemotherapy in patients with advanced EGFR mutant lung cancer, there has been substantial interest in bringing these agents to earlier disease states.There are several clinical trials evaluating the effect of EGFR-TKIs as adjuvant treatment. Despite improvements in disease free survival, to date, none have demonstrated statistically significant improvements in overall survival. Moreover, multiple questions regarding duration of therapy and appropriate TKI remain unanswered. More survival data are needed before one can recommend adjuvant TKIs for all.

MONDAY, SEPTEMBER 9 15:45–17:15

PC03.03 FUTURE STRATEGIES IN EARLY STAGE EGFR-MUT NSCLC

V. Papadimitrakopoulou

Department of Thoracic/HN Medical Oncology, MD Anderson Cancer Centre, Houston/United States of America

EGFR tyrosine kinase mutations occur in approximately 10% of advanced non-small cell lung cancer (NSCLC) Western patients and in 30% of Asian patients. *EGFR* tyrosine kinase inhibitors (i.e., gefitinib, erlotinib, afatinib, icotinib, dacomitinib and, recently, osimertinib) are superior to chemotherapy in patients with advanced *EGFR*+ lung cancers and have become the standard first-line treatment for NSCLC patients harbouring those specific mutations (1-5). Despite this, definitive trials of EGFR-TKIs as adjuvant treatment of EGFR-mutant early stage NSCLC are few and controversial. Improving outcomes with targeted adjuvant therapy and specifically overall survival remains a challenge in the management of radically resected NSCLC. As shown by the addition of the antiangiogenic agent, bevacizumab to adjuvant chemotherapy in the E1505 trial (6). The first prospective data to suggest that adjuvant targeted therapy may indeed alter the disease course for early-stage NSCLC were from the SELECT and RADIANT trials (7, 8), in addition retrospective analyses also showed promising results in improving DFS in stage I-III EGFR mut+ NSCLC and a potential OS benefit. The results of the ADJUVANT/CTONG1104 study (9), a randomized open-label phase III trial in completely resected (R0) stage II–IIIA (N1-N2) EGFR-mutant NSCLC (defined as exon 19 deletion or exon 21 Leu858Arg) comparing 4 cycles of standard adjuvant Cisplatin and Vinorelbine or 24 months of the EGFR-tyrosine kinase inhibitor (TKI), gefitinib revealed significantly longer median DFS in the gefitinib arm than in chemotherapy arm, while OS was not mature. Several questions remain including: A) the patient subset with early stage disease that may derive the most benefit B) the optimal duration of adjuvant TKI therapy C) the degree of toxicity and associated adherence to therapy over long periods of time and finally D) the cost of therapy. Phase 3 prospective trials remain necessary and several are under way, including the ALCHEMIST study, using erlotinib and the ADAURA study using Osimertinib. Finally use of neoadjuvant targeted therapy (10) and chemotherapy may offer distinct advantages in eliminating micrometastatic disease prior to surgery and clinical trials using this approach are planned or ongoing and will be discussed. PC04 IS CHEMOTHERAPY NECESSARY FOR ADVANCED NSCLC PATIENTS WITH PD-L1 50% OR MORE?
TUESDAY, SEPTEMBER 10 11:30–13:00

PC04.01 PRO: CHEMOTHERAPY IS NECESSARY

M. Garassino

Fondazione IRCCS Istituto Nazionale dei Tumori, Milan/Italy

As first-line therapy single agent pembrolizumab showed better outcomes than chemotherapy (CT) in patients with NSCLC and PD-L1 expression ≥50% [1]. Recently has been published another phase 3 trial in which patients with aNSCLC with an expression of PD-L1 ≥1%, treated with pembrolizumab as single agent, results in better overall survival (OS) than CT in first-line, mainly in subgroup with PD-L1 ≥50% [2]. After the approval and subsequent use of pembrolizumab as single agent in first-line in NSCLC with PD-L1 ≥50%, in 2018 several phase III trials explored the combination of immunotherapy agents (pembrolizumab and atezolizumab), with no regards of PD-L1 status, in association with standard CT, gaining better outcomes than CT alone in first-line NSCLC [3-8]. A matter of debate is what we have to do in patients with PD-L1 ≥50% due to the absent comparison between combination therapy and ICI as single agent and similar results in 1-year OS among these treatments [1,3-4]. So, why should we suggest the use of combination over ICIs as single agent in patients with PD-L1 ≥50% in first-line? First of all, we can see that trials of combination therapy report benefit with CT plus ICI across all PD-L1 subgroups, with a greater magnitude of benefit in patients with PD-L1 ≥50% with no regards of kind of drugs used (either CT and ICI) and histology (squamous or non-squamous) [3-8]. This magnitude of benefit is supported from an higher objective-response rate (ORR) in patients treated with combination therapy over ICI as single agent in subgroups of patients with PD-L1 ≥50% [1-4], suggesting combination therapy as best choice even in patients with highly symptomatic disease with the purpose of obtaining a fast shrinkage of tumor. Analyzing Kaplan-Meyer curves of single agent trials [1,2], you can observe that there is a violation of proportional hazard assumptions. We can see a crossing of the curves within first 3-6 months suggesting us that there's a subgroup of patients who have a worse prognosis when treated with single agent immunotherapy over CT. This worse prognosis could be

possibly partially due to a phenomenon called hyperprogressive disease [9], a quicken tumor growth during treatment with ICIs in NSCLC irrespectively of the line of therapy. If we look at Kaplan-Meyer curves of all combination studies, we can see that the combination of CT plus ICI abrogates the crossing curves [3,4,6,8], probably overcoming hyperprogessive disease with the addiction of CT by modulating tumor microenvironment. In subgroups of patients with liver and/or brain metastases, generally considered at worse prognosis, combination therapy demonstrates a benefit. In a retrospective analysis of KEYNOTE189 [10] were evaluated outcomes of patients with brain and/or liver metastases. In this analysis the addiction of pembrolizumab to CT grants a benefit over CT alone either in progression-free survival, OS and ORR in patients with liver and/or brain metastases. Another evidence of benefit in patients with liver metastases in combination therapy was seen in IMpower150, in which the addiction of atezolizumab to bevacizumab plus CT seemed to add something even though there's a bias due to the use of bevacizumab [5]. In advanced NSCLC treated with ICI as single agent [1,2] we see a lower benefit in non-smoker than in current or former smoker patients, whilst in combination studies this difference isn't seen regardless kind of drug and histology [3,6-8]. Even gender may be a possible reason to choose combination instead of ICI as single agent. As we previously do for smoking habit, we indirectly compare trials with single agent and with combination. We can see that in KEYNOTE024 there's a stronger benefit using pembrolizumab in males over females. This reported benefit for male patients is lost in combination treatment, with slight better outcomes in women instead, with no regards of drugs used and histology [3,4,6-8]. Finally, basing on preclinical evidences, we know that the combination between CT and ICIs may enhance the immune system activity due to immunological effect of cytotoxic agents through the expression of PD-L1 on the surface of tumor cells, the depletion of myeloid-derived suppressor cells and T-regulatory cells and the augmentation of the presentation of antigens by cancer cells [10]. At the state of the art the aim of our discussion remains an unanswered question but based on what we previously said, at least in patients with high tumor burden, in never smokers, we suggest CT plus ICI as first-line in aNSCLC with PD-L1 ≥50%.This could allow us not to lose patients in the first six months of treatment. PC04 IS CHEMOTHERAPY NECESSARY FOR ADVANCED NSCLC PATIENTS WITH PD-L1 50% OR MORE?
TUESDAY, SEPTEMBER 10 11:30–13:00

PC04.02 CON: ICI IS ENOUGH

M. Reck

Lung Clinic Grosshansdorf, Airway Research Center North (ARCN), Member of the German Center for Lung Research (DZL), Grosshansdorf/Germany

The implementation of anti PD-1 / anti PD-L1 checkpoint inhibitors has completely changed management of patients with advanced non-small-cell lung cancer (NSCLC). On the way to an individualized use of these agents a correlation between the PD-L1 expression on tumor cells and immune cells and efficacy of immunotherapies could be demonstrated across different agents and treatment lines. In particular a clear correlation between survival and PD-L1 expression on tumor cells (TPS-score) has prospectively been evaluated and validated for the anti-PD1 antibody pembrolizumab defining a TPS score of =/> 50% as a predictor for enhanced outcome by pembrolizumab and showing impressive 4 and 5 year overall survival rates for untreated patients with a TPS-Score of =/> 50% of 48% and 29.6% respectively (1,2). Two prospectively randomized phase III trials confirmed the superior efficacy of pembrolizumab monotherapy with a significant prolongation of overall survival compared to platinum based chemotherapy in untreated patients with a TPS-score of =/> 50% (3,4). Recently the concept of combining immunotherapies with chemotherapies has demonstrated superior efficacy compared to chemotherapy patients with advanced NSCLC independent from the PD-L1 expression and the question appears, whether such a combination would also be the preferred treatment for the selected group of patients with a TPS-score of =/>50%. Analysing this question a couple of points need to be addressed: First of all this important question has never been addressed appropriately in a prospective trial and in none of the combination trials a immunotherapy monotherapy arm was part of investigated schedule. Therefore all assumptions remain subjective and exploratory. Second: We have seen a dramatic improvement of survival expectation together with a relevant prolongation of treatment duration by the adaption of immunotherapies in management of advanced NSCLC. Therefore tolerability, symptom control and quality of life become essential parameters for feasibility of treatment. Across all chemo-immunotherapy combination trials the frequency of CTC grade 3-5 treatment related adverse events (TRAEs) was substantially higher compared to the pembrolizumab monotherapy arms. In particular in an updated report of the Keynote 189 trial the frequency of TRAEs grade 3-5 was 71.9% for the combination of pembrolizumab and chemotherapy compared to 17.8% in the Keynote 42 trial and 31.2% in the Keynote 24 trial leading to a treatment discontinuation rate of 33.6% compared to 9% and 13.6% in the Keynote 42 and 24 trial (4,5,6). Considering the symptomatic efficacy ICI monotherapy has shown a clinical relevant improvement of symptoms during treatment compared to chemotherapy assessed by the QLA-C30 GHS/QOL score together with a substantial prolongation of time to symptom deterioration in the Keynote-24 (7). This unique pattern of symptomatic efficacy, which clearly reflects the patient related impact of anti tumor therapy has so far not been to that extent for the combination trials. Third: Besides the impressive activity demonstrated by the use of first line chemo-immunotherapy combinations we are confronted with the rapidly emerging clinical problem, that we suffering effective and tolerable post progression treatment opportunities. So far no specific treatment approaches are available and mostly we are ending up with the use of limited effective docetaxel +/- an antiangiogenic agent. In contrast a first line ICI monotherapy offers the opportunity of a post progression full dosed platinum based combination treatment with clearly higher efficacy compared to docetaxel alone. Fourth: Currently the most appropriate endpoint to assess efficacy of immunotherapies remains to be determined and we have seen in various trials that response and PFS might not be the optimal endpoints. In contrast it is general accepted the survival represents the most eminent and meaningful endpoint. Looking on the survival results of the different trials the differences in follow up periods need to be taken into account leading potential differences in the assessment of survival times. However respecting the lack of prospective randomised trials it appears that no benefit in survival in particular long term survival could be generated by the addition of chemotherapy to immunotherapy in the group of patients with a TPS-score =/> 50%. In an exploratory analysis of the Keynote 189 trial the 2 year OS rate for patients with a TPS-score =/> 50% was 51.9% for the combination of chemotherapy and pembrolizumab

compared to 51.5% and 44.7% for pembrolizumab monotherapy in the Keynote-24 and -42 trial. Furthermore also the Hazard ratios were comparable across the trials (HR 0.59 for Keynote-189 compared to HR 0.63 and 0.69 in Keynote-24 and -42). In summary ICI monotherapy represents the preferred new highly effective and well tolerable first-line treatment opportunity in untreated patients with a TPS-score of =/> 50%. Addition of chemotherapy is associated with poorer tolerability and in particular long-term tolerability. Ongoing research might define the few patients, where tumor control cannot be achieved by ICI monotherapy. 1. TUESDAY, SEPTEMBER 10 14:30–16:00

PC05.01 ICIS FOR PATIENTS WITH INTERSTITIAL PNEUMONIA

T. Kato

Kanagawa Cancer Center, Yokohama/Japan

Interstitial pneumonia (IP) or pulmonary fibrosis (PF) is one of the most common and poor prognostic comorbidities with lung cancer, and also known as a risk factor of treatment related pneumonitis. Around 10% of patients are diagnosed concomitant IP/PF at the time of cancer diagnosis. The prognosis of lung cancer patients with IP/PF has been reported to be poor, because 5-20% of those receiving chemotherapy experienced exacerbation of IP/PF, and some of them are mortal. Median overall survival time of these patients with stage IV non-small cell lung cancer is around 10 months, which is 2 months shorter than patients without IP/PF. In spite of risk of acute exacerbation, chemotherapy including platinum doublet or monotherapy are considered as the standard treatment for the patient with IP/PF because of a certain level of efficacy. Not only chemotherapy, other types of cancer treatment including radiotherapy, surgical resection, and targeted drug also induce acute exacerbation of pre-existing IP/PF occasionally. Targeted small molecules including EGFR-TKIs are reported to have higher risk of acute exacerbation of pre-existing IP/PF, and some surveillance reports that existence of IP/PF is a most significant risk factor related to emergence of treatment related pneumonitis. Immuno-checkpoint inhibitors (ICI) now play an important role in lung cancer treatment, and as immune related adverse event, immune mediated pneumonitis is considered that should be paid most attention because of its high frequency and potential lethality. Regarding to ICI, relation between pre-existing IP/PF and treatment related pneumonitis is not clear, so far. Because of relationship to smoking history, higher level of microsatellite instability (MSI), and tumor mutation burden (TMB), these are associated with favorable efficacy, ICI also may have some role in treatment strategy for the lung cancer patients comorbid with IP/PF. A phase II trial of nivolumab for pretreated NSCLC patients with IP/PF, in 18 pretreated NSCLC patients with mild idiopathic IP, showed 36% of response rate and a 56% of 6-months progression-free survival rate in mild idiopathic IP. Two grade 2 pneumonitis were observed, and both are improved by corticosteroid treatment. In this session I will try to review ICI treatment for patients with IP/PF and also discuss about their clinical adaptation for clinical practice.

PC05.02 ARE ICIS EFFECTIVE FOR POOR PERFORMANCE STATUS PATIENTS WITH ADVANCED NSCLC?

F. Grossi[1], C. Genova[2]

[1]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milano/Italy,* [2]*IRCCS Ospedale Policlinico San Martino, Genoa/Italy*

The management of non-small cell lung cancer (NSCLC) in patients with poor performance status (PS) has always been a challenging task. Until the last decade, platinum-based chemotherapy has been the main therapeutic approach to NSCLC, and is retaining a major role in patients without actionable oncogenic drivers and low expression of programmed death protein ligand 1 (PD-L1). However, patients with poor PS are generally excluded from combination-based regimens and from enrollment in novel clinical trials [1]. While immunotherapy with immune checkpoint inhibitors (ICIs) has become a cornerstone in the management of advanced NSCLC, data regarding its role in ECOG PS=2 patients are generally limited; indeed, the most relevant phase III randomized controlled trials involving ICIs in advanced NSCLC have excluded ECOG PS=2 patients, resulting in a general lack of recommendations from international guide-lines [2]. The currently available information on this specific population has been collected from a handful of clinical studies, all of them involving patients receiving ICIs in second or further lines. In the phase II CheckMate 171 trial, 98 ECOG PS= 2 previously treated patients with squamous NSCLC received single-agent nivolumab; in the preliminary data, the safety profile of nivolumab and the objective response rate (ORR) in ECOG PS=2 patients were globally similar to the overall population, while median overall survival (mOS) was lower, as expected due to the prognostic effect of PS [3]. The phase III-IV CheckMate 153 trial, designed to assess safety of nivolumab in pre-treated NSCLC patients, showed similar results, but notably, in patients with ECOG PS=2, a significant improvement in symptom burden was observed [4]. An additional source of data for unfit NSCLC patients treated with ICIs is represented by expanded access programs (EAPs), in which real-life patients received nivolumab before its registration. In the largest EAP (Italian nivolumab non-squamous NSCLC cohort), 108 pre-treated ECOG PS=2 patients received nivolumab; the independent negative prognostic role of ECOG PS on survival was confirmed, while no safety issues were observed [5]. In contrast with the previous studies, the PEPS2 trial was specifically designed to assess the role of pembrolizumab in a population of previously treated NSCLC patients with ECOG PS=2. The study is currently ongoing, although the data reported so far encourage the use of pembrolizumab in this population; moreover, PD-L1 tumor proportion score appeared to be associated with survival [6]. In conclusion, while the well-known prognostic effect of poor performance status is observed during administration of ICIs, the safety profile and the activity of these agents make immunotherapy a feasible strategy for treating unfit NSCLC patients, especially when single-agent ICIs are administered, although limited outcomes in terms of survival are to be taken into account when choosing whether to offer active antineoplastic treatment to unfit patients or not; since ECOG PS=2 represents a wide range of patients, this choice needs to be made on an individual basis. Notably, a limit of the aforementioned data is represented by the lack of comparison with chemotherapy in controlled randomized studies; to fill this gap, some ongoing trials are being conducted: more specifically, the IPSOS trial is designed to enroll patients who are unfit for platinum-based chemotherapy and randomize them to atezolizumab vs. single-agent chemotherapy [7], while another trial (NCT02581943) is designed to compare pembrolizumab alone or in combination with low-dose carboplatin-paclitaxel [8]; finally, the eNERGY trial is designed to compare ipilimumab-nivolumab with a carboplatin-based doublet in ECOG PS=2 patients [9]. The availability of data from these and similar studies will provide additional insights on the role of ICI in unfit NSCLC patients.

Study	Regimen	ECOG PS=2 patients (% of global population)	Results in ECOG PS=2 (results in global population)
CheckMate 171 (phase II)	Nivolumab	98 (12%)	TRAEs= 46% (50%) Grade 3-4 TRAEs= 6% (12%) mOS= 5.4 months (9.9) ORR= 11% (14%)

PC05.03 ICIS FOR PATIENTS WITH IMMUNE-RELATED COMORBIDITY

R. Pirker

Medical University of Vienna, Vienna/Austria

Immune checkpoint inhibitors have recently been established as standard therapy for patients with advanced NSCLC. However, data on immune checkpoint inhibitors are limited for special patient populations such as elderly patients, patients with poor performance status and patients with immune-related comorbidity (1). Major clinical trials excluded patients with active autoimmune diseases requiring systemic steroids, patients with systemic immunosuppressive treatment, patients with interstitial lung disease or history of pneumonitis requiring systemic steroids, and patients with chronic viral infections (e.g. hepatitis, HIV). Patients with immune-related comorbidity include patients with autoimmune diseases, patients with organ transplants, patients with end-stage renal disease and patients with chronic viral infections. Data on the efficacy and safety of immune checkpoint inhibitors are limited for these patients and mainly based on patients with melanomas and only few patients with lung cancers. Immune checkpoint inhibitors could result in unacceptable immune activation in patients with pre-existing autoimmune diseases (1). Based on a literature report, exacerbations of autoimmune symptoms occurred in about 1/3 of patients who had been treated with these drugs (1). Therefore, great caution with regard to the use of these drugs in patients with autoimmune diseases is mandated. Patients with organ transplants have been excluded from clinical trials because of the concern of potential organ rejections. Nevertheless, few reports are available on immune checkpoint inhibitors in patients who had undergone prior organ transplantations (2-8). A recent overview (4) reported on 19 patients with the following characteristics: median age 59 (14-77) years, 74% males, melanoma (n=11), cutaneous squamous cell carcinoma (n=3), NSCLC (2) and hepatocellular ca (n=2), and duodenal cancer (n=1). Median time to start of checkpoint inhibitors after organ transplantation was 11 (range 1-25) years. Patients were treated with nivolumab (53%), ipilimumab (26%) or pembrolizumab (21%). Most patients received low dose prednisone. Graft rejections occurred in ten patients (7/12 kidney, 2/5 liver, and 1/2 heart transplants), particularly among patients who had been treated with anti PD-1 antibodies. Median time to rejection was 21 (range 5-60) days. Among nine patients without rejections, four had immune-related adverse events (hepatitis, colitis, pneumonitis, and dermatitis). A clinical benefit was seen in 57% of patients. This overview indicated that treatment with immune checkpoint inhibitors is associated with a high rate of transplant rejections. A high rejection rate was also reported by others (5). A retrospective analysis of patients with liver transplants indicated transplant rejections in two out of seven patients undergoing treatment with PD-1 inhibitors for hepatocellular carcinomas (n=5) and melanomas (n=2) (8). Taken together, patients with solid organ transplants have a clinically relevant risk of transplant rejection when treated with immune checkpoint inhibitors. Little information is available for patients with impaired renal function including end-stage renal disease (1, 9). In a report on three patients undergoing hemodialysis, immune checkpoint inhibitors resulted in a partial response in one patient and in stable disease in two patients (9). The toxicity was acceptable except grade 2 pneumonitis in one patient. Based on a literature review, 10 out of 13 patients undergoing hemodialysis responded to immune checkpoint inhibitors. Grade 3-4 immune-related adverse events occurred in three patients. The authors concluded that immune checkpoint inhibitors may not be contra-indicated in patients undergoing hemodialysis but may result in significant toxicity (9). Patients with chronic viral infections, especially hepatitis C, appear to have little risk of treatment-related increases in adverse events and, therefore, may be treated with immune chekpoint inhibitors under careful monitoring (1). Although our knowledge on immune checkpoint inhibitors in patients with cancers is rapidly expanding, we still need more information on the efficacy and safety of these drugs in patients with immune-mediated diseases. Data in the real-world setting would be of particular interest. The gathering of these data could be facilitated by establishing registries on national and international levels. Until further information on the safety of these drugs will become available, immune checkpoint inhibitors should be administered with great caution and only after a careful risk benefit assessment in patients with immune-related comorbidity.

PC05.04 ICIS FOR ELDERLY PATIENTS WITH ADVANCED NSCLC

H. Borghaei

Fox Chase Cancer Center, Philadelphia/United States of America

Immunotherapy with checkpoint inhibitors has changed the treatment landscape of many cancers. In the management of patients with non-small cell lung cancer the introduction of immunotherapy as a single agent or in combination with chemotherapy has led to significant improvement in survival and response rates in many patients but not all. I will discuss the role of this approach in the treatment of the elderly patient population with non-small cell lung cancer. I will examine the available data related to clinical efficacy and toxicity of these treatments and hope to delineate a potential role for the continued use of checkpoint inhibitors in the elderly patient population.

MS01.01 BIOLOGICAL MECHANISMS OF RESISTANCE

J. Gainor

Massachusetts General Hospital, Boston/United States of America

Immune checkpoint inhibitors targeting the programmed cell death 1 (PD-1) axis have transformed the management of non-small cell lung cancer (NSCLC). Despite the dramatic and sometimes durable activity of these agents, a majority of patients will progress on therapy.[1] Patients who experience a de novo lack of response to initial therapy are deemed as having primary (intrinsic) resistance. By contrast, acquired resistance refers to patients who initially achieve an objective response to therapy but eventually progress over time. The mechanistic basis for primary versus acquired resistance to immune checkpoint inhibitors is still poorly defined. To date, studies into the biological mechanisms of resistance to immunotherapies have centered around preclinical studies and analyses of repeat biopsies obtained from patients at the time of disease progression.[2] These efforts have been complemented by similar studies in other immuno-oncology settings (e.g., melanoma),[3,4] since there is potential for shared biology underlying immunotherapy resistance across malignancies. Both tumor cell-intrinsic and tumor cell-extrinsic factors have been implicated in mediating resistance to immunotherapies.2 In the setting of primary resistance, disease progression is commonly driven by a lack of neoantigens sufficient to illicit an initial immune response, commonly due to a low tumor mutation burden.5 Alternatively, tumors may actually harbor antigens capable of generating an immune response, but defects in antigen processing may ultimately limit the presentation of these antigens on the cell surface via MHC. Defective antigen presentation may be due to loss of beta-2 microglobulin (B2M), elimination of transporters associated with antigen processing (TAP) proteins, or downregulation of HLA.2,3 In addition, intrinsic resistance to immune checkpoint inhibitors may be due to altered oncogenic cell signaling (e.g., WNT/B-catenin pathway) and/or tumor de-differentiation with impaired antigen expression. Molecular mechanisms of acquired resistance to checkpoint blockade likely include many of the same processes as those implicated in intrinsice resistance. Indeed, homozygous loss of B2M, which is required for stabilization of HLA on the cell surface, has been described in NSCLC at the time of acquired resistance to PD-1 pathway blockade.6 Additionally, neoantigen loss through elimination of specific tumor subclones (i.e., immunoediting), genetic alterations in interferon gamma (IFN) signaling, and upregulation of alternative checkpoints (e.g., TIM3) have also been purported to confer acquired resistance to checkpoint inhibitors.4,7,8 At present, the relative frequencies of these processes and the interplay among them within NSCLC and other malignancies remains to be defined. Moving forward, it will be critical to pursue more in-depth preclinical and clinical studies of resistance to PD-1 pathway blockade in NSCLC. Just as insights into the molecular mechanisms of resistance to targeted therapy have transformed the therapeutic landscape for oncogene-driven tumors, it will be imperative for immuno-oncology to develop a framework for understanding resistance to checkpoint inhibitors and apply this framework to clinical development of next-generation immuno-onclogy agents. This is especially critical due to the sheer number of immuno-oncology combinations currently in clinical testing. Ultimately, knowledge of the mechanisms of resistance to immune checkpoint inhibitors may help better inform the rationale design of trials evaluating PD-1 inhibitor combinations. 1. Garon EB, et al. MS01.02 TREATMENT DETERMINING MARKERS - WHAT HAVE WE ACHIEVED SO FAR?

N. Rizvi

Columbia University Medical Center, New York/United States of America

Progress has been made selecting patients for immune checkpoint blockade employing expression of PD-L1 however limitations exist with this approach. Increasing use of genetic markers has been incorporated into clinical trials and clinical practice. Beyond MSI testing, tumor mutation burden has gained increasing traction and prospective trials employing TMB are under way and will be reviewed. Additional unique sensitivity and resistance mutations are emerging and may be incorporated into our genetic analysis paradigm. Additionally genetic studies are now being performed with success on plasma ctDNA and emerging ctDNA analyses will be discussed.

MS01.03 OVERCOMING RESISTANCE - CLINICAL RESULTS?

R. Soo

Department of Haematology-Oncolgy, National University Hospital, Singapore/Singapore

The management of oncogene negative advancednon-small cell lunghas been transformed with the use of immune checkpoint inhibitors targeting programmed death receptor-1 (PD-1) and programmed death receptor ligand-1 (PD-L1). However, in a significant number of patients, either primary or acquired resistance has been observed. Primary resistance, usually defined as disease progression upon the first radiologic evaluation, represents an important clinical problem and has been reported in up to 20% of patients. Acquired resistance, defined as tumors with initial response following treatment but eventually develop disease progression, has been reported in approximately 20-40% of patients. The mechanisms of primary and acquired resistance to immunotherapy are complex and are interdependent, involving alterations in immune cells, cytokines, metabolic and oncogene signaling pathways in the tumor cell and the tumor microenvironment. The usual treatment following progression on first line immune checkpoint inhibitor with or without a platinum doublet is single agent docetaxel or a platinum doublet +/- bevacizumab. With an improvement in the understanding of the mechanisms of resistance to immune checkpoint inhibitors, to improve patients' outcomes following resistance, strategies have been devised to tailor subsequent therapy according to the mechanism of resistance, including the use of therapies to increase antigenicity, enhance immune cell function, and modulate the tumor microenvironment.

MS01.04 SMOKING AND IMMUNOTHERAPY

N. Yamaguchi

Instituto Nise Yamaguchi de Oncologia, Brazil/Brazil

Smoking disrupts the homeostasis of the innate and the adaptive immune system. Carcinogenic and pro-inflammation compounds of tobacco leaves and other chemicals present in cigarette interfere with the regulation of immunity in two opposing ways. Some compounds trigger chronic inflammation inducing cell damage and transformation; others inhibit apoptosis, a protective strategy against transformed cell proliferation. Smoking attenuates response by dendritic cells (DC), natural killer cells (NK), macrophages against transformed cells[1]. Smoking affects as well the adaptive immune cells, B lymphocytes, T helper cells, CD4+ / CD25+ regulatory T cells, and CD8+ T cells.[1] Patients with NSCLC had low levels of serum bilirubin

correlated with tumor progression and poor response to platinum-based chemotherapy[2]. Studies found that high normal levels of serum bilirubin indicated favorable prognosis in NSCLC and colorectal tumor.[3],[4] Bilirubin has anti-inflammatory, anti-oxidative, and anti-proliferative effects[5] and smoking decreased bilirubin in a cohort study using metabolomics profiling.[6] Zhang et al. reported that pretreatment with bilirubin correlated with overall survival (OS) in NSCLC patients with EGFR mutations.[7] Epithelial to mesenchymal transition (EMT) is an important process of cell-transformation that facilitates metastases and smoking induced hypoxia, inflammation, and oxidative stress, culminating in malignancy and EMT.[8],[9] The effect of smoking on EMT also occurs in other cancer histologies. A study showed that the HDAC inhibitor MS-275 restores E-cadherin expression, reversing EMT, metastases, and invasion induced by smoking.[10], [11],[8] Smoking impairs lung cancer chemotherapy, requiring increased doses for patients who smoke. The polycyclic aromatic hydrocarbons (PAH) of smoke increases the synthesis of enzymes that metabolize many antineoplastic drugs. PAH increase clearance, requiring dose adjustments to reach toxicity levels of efficacy.[12] Smokers receiving irinotecan had increased clearance and lower exposure to therapeutic metabolites; and treatments with paclitaxel, docetaxel, irinotecan, and gemcitabine showed lesser neutropenia in smokers than in nonsmokers.[12] Nicotine-derived nitrosamine ketones antagonizes cisplatin and carboplatin regimens by blocking apoptosis.[13],[14],[15] Erlotinib blocks the receptor for tyrosine-inhibiting epidermal growth activation (EGFR) and is metabolized by CYP3A4 and, by CYP1A2 and CYP1A1.[16] Smoking accelerates drug catabolism, decreasing erlotinib plasma concentrations and survival rates in NSCLC. Retrospective analysis of 88 patients NSCLC receiving erlotinib or pemetrexed showed better progression-free survival (PFS) with erlotinib in never smokers than in former smokers (3.5 versus 2.7 months, p = 0.005) [17] and smokers with squamous histology receiving erlotinib lived longer than former smokers.[18] A study on the efficacy of second-line docetaxel and erlotinib in NSCLC patients with smoking history versus never smokers shoed decreased overall survival (hazard ration [HR] 3.61 [1.77–7.4], p = 0.0005) in the erlotinib arm.[19] Nicotine affected *EGFR/AKT/ERK* pathways, preventing/decreasing erlotinib action in NSCLC, promoting tumor growth in the PC9 xenograft model. SUNDAY, SEPTEMBER 8 10:30–12:00

MS02.01 PLATFORM SELECTION IN AN ERA OF INCREASING NUMBERS AND TYPES OF RELEVANT BIOMARKERS

D. Carbone

The Ohio State University, Columbus/United States of America

30 years ago, the selection of therapy for lung cancer patients was simple, with only a few choices available, and very little personalization beyond that which can be defined by standard light microscopy and physical exam. The treatment of lung cancer patients today has greatly improved with the discovery of features of tumors and patients that enable the selection of specific targeted and immunotherapy approaches resulting in substantially improved quality and quantity of life. Selection of the appropriate therapeutic based on these features makes huge differences in the lives of these patients, and many studies are now showing that starting with the matched therapy improves survival over switching to it after trying "one size fits all" therapy. Scientific advances are introducing more and more of these markers every year, and while this is undoubtedly a good thing for our patients, each of them has sensitivity, specificity, and platform issues that need to be defined, and adds a level of complexity to lung cancer management that is unprecedented. Individually, many of these features are rare so that the vast majority of individual assays performed are negative, further adding to clinical frustration. Technology has advanced to allow the testing of hundreds or thousands of gene sequences in a single analysis, but other markers are not simple gene sequence alterations, but rather gene rearrangements, protein expression alterations, and some RNA expression profiles that require testing on different platforms. As a result, optimal tumor profiling can involve several different analyses, can cost a significant amount of money, and take a significant amount of time to return a result in a disease where both time and resources available are scarce. Biopsy adequacy also becomes an issue with multi-platform testing, and the availability of blood-based testing lessens this issue for certain types of testing, but introduces issues of limited sensitivity and scope of analyses. Layered upon this are the different health care systems and availability of testing platforms found worldwide, each of which has to make hard decisions about doing the best thing for their patients within these local constraints. However, the impact on patient outcomes and the health care system of missing a key tumor feature and the selection of inappropriate and potentially toxic therapy, in a world where a single dose of a drug costs several times the cost of the testing makes cost of testing less of an issue than sample adequacy, speed of results availability, accuracy of results interpretation, and availability of matching drugs. In this section, the clinical and technical features of the currently available platforms in use and their advantages and disadvantages will be reviewed and compared.

MS02 WHAT MOLECULAR SCREENING FOR WHICH PATIENTS?
SUNDAY, SEPTEMBER 8 10:30–12:00

MS02.02 LIQUID BIOPSY: WHO, WHEN, WHAT AND HOW

C. Rolfo

University of Maryland Greenebaum Comprehensive Cancer Center, Baltimore/United States of America

Liquid biopsy (LB) refers to a multitude of biomarkers that can be isolated with minimally invasive methods from human body fluids (blood, saliva, urine, ascites, pleural effusion, etc.) that include cell free DNA (cfDNA), circulating tumor cells (CTCs), microRNAs (miRNAs), long non coding RNAs (lncRNAs), and exosomes ( ). Plasma genotyping of cfDNA entered clinical practice in non-small cell lung cancer (NSCLC) for detection of *EGFR*mutations in both treatment-naïve and EGFR-mutated NSCLC after progression to EGFR tyrosine kinase inhibitors (TKIs) as an alternative source to tissue when histological samples are insufficient or when a biopsy is not feasible. Indeed according to the LB IASLC statement[1], plasma cfDNA analysis should be offered to the same population candidate for molecular testing using DNA isolated from tissue (all non-squamous NSCLC subjects, or adenosquamous or in patients with clinical features suggestive of the presence of a molecular driver) in cases with insufficient tumor tissue specimens or where tissue specimens are not obtainable. Moreover, LB is indicated for the identification of acquired resistance mutations in EGFR-mutated NSCLCs progressing during treatment with first- or second-generation EGFR TKIs, reserving tissue re-biopsy in case of negative or inconclusive results. The PCR-based cobas EGFR Mutation Test v2 was the first FDA approved LB test for NSCLC, although several limitations on sensitivity of this technique. Fortunately, LB is a rapidly evolving field and several commercial and *"in house"*NGS platforms have been developed, allowing a more comprehensive plasma genotyping that include genetic rearrangements (such as ALK, ROS1, RET, and NTRK) as well as other relevant oncogene drivers, including mutations of BRAF, HER2, MET, and KRAS. Some of the vendors have a Medicare reimbursement in United States. Recently, the multicenter prospective Noninvasive versus Invasive Lung Evaluation (NILE) study demonstrated that a validated and highly sensitive plasma 73-gene NGS test (Guardant360) used at the time of diagnosis of NSCLC was non-inferior to standard-of-care tissue genotyping in identifying guideline-recommended genomic biomarkers, allowing a guideline-complete genotyping in a higher proportion of patients with a shorter median turnaround time[2]. These results support the rationale for a *"blood-first"* approach, reserving tissue for PD-L1 immunohistochemistry or in case of negative liquid biopsy testing. In addition to cfDNA, cfRNA is a novel approach to enhance the comprehensive analysis of circulating biormakers. Furthermore, the increasing use of more sensitive detection methods, such as NGS, poses novel technical and biological challenges in our clinical practice, including the identification of non tumor-related mutations due to clonal hematopoiesis (CH), increased risk of false positive in presence of low variation allelic fraction (VAF), need for standardization and validation of the analytical methods, definition of requirements for appropriate report and interpretation of the results. Novel technologies such as CH-filtering ultradeep NGS have been tested with promising results[3]. Moreover, the adoption of molecular tumor board is essential for helping oncologists in interpreting NGS testing results[4], using evidence-based scales, such as OncoKB and ESCAT tiers[5,6]. Recently, LB use has been advocated in immunotherapy-treated patients as a minimally invasive method that can allow a real time monitoring of treatment response and interpretation of challenging radiographic situations, overcoming the limits of conventional radiological assessment methods[7,8]. Further prospective studies are needed to better clarify the role of cfDNA as a predictive biomarker for immune checkpoint blockage in NSCLC. LB can also allow the estimation of tumor mutational burden (TMB) in plasma, proving a valuable alternative to tissue. Exploratory analyses of two large randomized phase III studies explored the potential utility of blood TMB (bTMB) as predictive biomarker for immunotherapy, using two different platforms (Foundation Medicine and GuardantOMNI)[9,10]. The results of these studies support bTMB as potential biomarker for immunotherapy in NSCLC. Further prospective studies will clarify the role of bTMB in treatment selection of patient candidate for immunotherapy, as well as the optimal cut-off value, the minimum number of genes necessary for TMB estimation, and the specific mutations useful. MS02.03 ACHIEVING EFFECTIVE LUNG CANCER GENOTYPING WHILE BALANCING CONSTRAINED RESOURCES

L. Sholl

Brigham and Women's Hospital, Boston/United States of America

Modern oncologic practice for patients with non-small cell lung carcinoma (NSCLC) demands real time data for an increasing numbers of tumor biomarkers. As a result, laboratories are embracing panel-based approaches to tumor molecular profiling, a trend that is facilitated by the adoption of next generation sequencing (NGS) assays. NGS assays may be designed for highly sensitive and focused detection of hotspot mutations (typically by amplicon sequencing) or broader, more comprehensive profiling for detection of a wide variety of alterations in oncogenes and tumor suppressor genes (typically by hybrid capture technology). There are benefits and drawbacks to both approaches. In general, amplicon sequencing offers speed and sensitivity but limited scope and a propensity for PCR-related artifacts that may adversely affect detection of certain mutation types. In contrast, hybrid capture techniques offer tremendous breadth, enabling capture of 100s of genes to whole genomes, but are limited by sensitivity and longer turnaround time.[1] Preanalytic steps including sample acquisition, pathologist review to confirm sample adequacy, and nucleic acid extraction often comprise the majority of the turnaround time required to complete focused tumor tissue molecular profiling. Some assays have been optimized for turnaround times of just a few hours- these assays bypass the separate nucleic acid extraction step, [2] but are limited by the few number of mutational targets detected, ultimately requiring the use of multiple simultaneous or sequential focused panels.[3] This practice, while perhaps the optimal current model from the standpoint of patient care, may be financially prohibitive for many laboratories. This approach additionally requires careful stewardship of patient tissues, as the use of multiple competing assays and may lead to exhaustion of tumor tissue and incomplete tumor molecular profiling. For patients with limited tissue, a considered plan incorporating input from the treating physician, surgical pathologist, and molecular laboratorian should developed early in order to guide assay priority and ensure adequate tissue is available to confirm any unexpected or contradictory results. When the turnaround time for comprehensive large panel testing is clinically acceptable, this approach may be theoretically more cost effective and in most cases will deliver information for essential and emerging biomarkers.[4] It is important to keep in mind, however, that even comprehensive DNA-based assays may lack optimal sensitivity for certain structural variants (fusions, large insertion-deletion events), and it may be necessary to couple these tests with focused RNA-based panels optimized for transcript fusion detection.[5] 1. MS02.04 THE ROLE OF MOLECULAR BOARD

L. Pijuan

Hospital del Mar, Barcelona/Spain

The Role of Molecular Board Lung Tumor Board is a multidisciplinary group of specialists who are responsible for diagnosing and deciding the best treatment for a patient with lung cancer. In cancers with little to no metastatic evidence, the case is handed over to surgeons or sometimes to radiotherapists for local and curative treatment. But in cases of locally advanced or metastatic stages, the patient visits the oncologist alone or in conjunction with the radiotherapists for a more systemic approach. A few years ago, the patient was presented to tumor board immediately, but now because we are in the age of precision medicine, the oncologist can gather more information about the tumour itself to initiate the best personalized treatment for each patient's cancer. In fact, the oncologist requires 3 types of information: accurate histological diagnosis, molecular characteristics of the tumor, and PD-L1 expression. Prior to the creation of this molecular tumor board, this information could be given by mail, mobile phone messaging, phone call or in person, since all the information usually arrives a few days after the patient is presented at Lung Tumor Board. If all this information is presented in a room with all the specialists involved in obtaining it, the data can be better analysed and the therapeutic decision making will be much more precise. Hence the idea of creating a MTB with oncologists, pathologists, biologists, bioinformatics, technicians, palliative care, and residents to review the different results for a lung cancer patient. The type of patients to present in this type of Molecular Tumour Board is widely variable, but usually fall into one of these 6 categories: 1) Newly diagnosed patients with metastatic disease. The MTB would reaffirm that there is sufficient material and that all the molecular or immunohistochemical techniques are underway (EGFR, BRAF, ALK, ROS1, and PD-L1). Oncologists re-assign the patient for the next MTB to review final results. The pathologist also comments on the percentage of tumour cellularity, so that technicians and biologists can make optimized calculations of the cuts and the type of sample that the biologist has to work with (biopsy and/or cell block and/or cytological smears). 2) Patients with progressive disease with a known molecular marker. They can be patients where the oncologist repeats sampling. Usually the patient is more familiar to the biologist because he receives liquid biopsies to monitor the disease and the pathologist only knows the patient if he has a re-biopsy. 3) Patients with possible disease progression, pseudoprogression or hyperprogression after immunotherapy. 4) Patients with molecular results received from outside (FM, FOne, clinical trials) The patient is more familiar to the oncologist who treats him and who has decided to send a sample for a clinical trial or external platform. They are presented in the MTB in order to reaffirm the mutation or translocation found with technology available in the center or maybe it can be consulted outside. 5) Surgical patients with multiple adenocarcinomas that require definitive staging. The patient is most familiar to the pathologist who diagnosed the surgical tumor. They are presented in order to know molecular details of multiple synchronous tumours. 6) Patients that wish to utilize stored material for new diagnostic studies/techniques For reasons of disease progression, the patient may enter a clinical trial or has the option of systemic treatment, so some studies that were not previously performed in are required.

MS03 WORKUP AND MANAGEMENT OF SMALL ANTERIOR MEDIASTINAL MASSES/LESIONS
SUNDAY, SEPTEMBER 8 13:30–15:00

MS03.01 DIFFERENTIATION OF SMALL ANTERIOR MEDIASTINAL LESIONS USING IMAGING

E. Marom

The Chaim Sheba Medical Center, Ramat Gan/Israel

Mediastinal masses are relatively uncommon in the general population and no specific algorithm exists for the evaluation and diagnosis of these lesions. Most mediastinal masses occur in the anterior, or prevascular compartment and these lesions demonstrate tremendous heterogeneity in clinical and pathologic features. The selection of laboratory tests, whether to perform a biopsy, immediate surgery, follow-up imaging or order further imaging investigation varies between medical disciplines, and patients' clinical features. The use of CT has grown exponentially over the last decade. This has led to an increasing amount of incidental prevasscular mediastinal lesions encountered, often smaller than those encountered in symptomatic patients. There is no agreement as to what defines a mediastinal lesion as 'small'. For the radiologist, this usually constitutes a lesion, which is too small to characterize, perhaps smaller than 1cm. For the surgeon, this may be a lesion, which could be approached with minimally invasive surgery, or perhaps a lesion which one may suspect is benign. When dealing with the incidental prevascular lesion, the most important role for the radiologist is to correctly identify a "no touch lesion": a benign lesion or normal variant that should not be treated. The second task the radiologist must face is diagnose correctly a lesion or at least narrow the differential to tailor the diagnostic approach causing minimal harm in the process. The imaging modality of choice for identifying, localizing, and characterizing most mediastinal masses is CT. Most clinicians and radiologists are most familiar with this imaging modality and it has the ability to accurately locate, identify densities such as fat, bone, calcification and fluid. There are some prevascular mediastinal lesions that have a pathognomonic appearance on CT, which may obviate the need for a biopsy, such as goiter, mature teratoma or thymolipoma. However, CT has two major drawbacks: it does expose individuals to a relatively large amount of ionizing radiation, and it is not as good as MRI in tissue characterization. Thus, when a prevascular lesion measures as fluid, it is sometimes difficult to identify nodular thickening within the fluid to distinguish a benign cyst for example, from a cystic thymoma. Similarly, cysts may seem solid on CT. Proteinaceous cyst, when measured by CT, have Hounsefield Units, which measure as soft tissue rather than fluid. MRI overcomes these issues, with its better contrast resolution. MR imaging is not routinely performed to evaluate all mediastinal masses; however, it is the best modality for distinguishing cystic from solid masses (e.g., thymic cysts from solid tumors), identifying cystic and/or necrotic components within solid lesions, demonstrating septations and/or soft tissue within cystic lesions, and distinguishing thymic hyperplasia and normal thymus from soft tissue tumors. Tissue characterization, whether using CT or MRI, relies on visible assessment or measuring the density/intensity of the lesion. When a tissue is measured, a region of interest (ROI) is placed in the lesion. For the measurement to be accurate, the ROI should include more pixels, should be about 1cm in diameter and not include soft tissue around the lesion. It is because of this, that in small lesions, smaller than 1cm, the density/intensity cannot be accurately measured. Another example is the use of MRI to distinguish thymic hyperplasia from a soft tissue malignancy. The MRI chemical shift sequence shows a signal drop when fat and soft tissue abut each other. This causes the fat-soft tissue interface to appear as a dark linear outline on this sequence. Since thymic hyperplasia contains a combination of fat and soft tissue, there is a signal drop in thymic hyperplasia using this sequence, not seen with other masses in the prevascular mediastinum. However, when a soft tissue lesion in the prevascular mediastinum is too small, chemical shift imaging is not useful. The periphery will drop out due to the soft tissue interface with the surrounding mediastinal fat, leaving insufficient amount of tissue centrally for investigation. Positorn emission tomography (PET) integrated with CT using fluorodeoxyglucose as the isotope, is commonly used in staging different malignancies. Its role however in differentiating benign from malignant masses is limited. That is because some benign entities, such as thymic hyperplasia may be FDG avid, whereas some malignancies, such as some types of thymoma, are sometimes not FDG avid. Also, the FDG uptake of commonly encountered malignancies in the prevascular mediastinum is high, so that it is impossible to distinguish between them. For example thymic carcinoma, paraganglioma and non-seminomatous germ cell tumor show similar FDG uptake. In addition, the spatial resolution of PET is

low, much lower than CT or MRI so that small lesions, those smaller than 1cm, are not accurately assessed by this modality. We will review the imaging approach to the incidentally discovered, usually small, prevascular mass. How to identify the 'no touch lesion', when to order additional imaging and which imaging modality to select in order to prevent futile surgery.

MS03.02 RESECTION, BIOPSY OR OBSERVATION OF SMALL ANTERIOR MEDIASTINAL LESIONS

F. Detterbeck

Yale University School of Medicine, United States of America/United States of America

With greater prevalence of CT scanning for many reasons, the incidental detection of a prevascular lesions has increased markedly. 3 sources of data show the incidence to be around 0.5-1% in asymptomatic adults. There is no accepted standard for how to manage these patients, and until recently there was little data to base an approach on. Recently, examination of scans done for lung cancer screening provide some answers. The majority of these lesions have CT characteristics that are consistent with a thymic epithelial tumor (TET). However, the vast majority are stable over a median follow-up of approximately 5 years. While a minority exhibit growth, on further observation most of these do not continue to grow or decrease in size. It is well documented that thymic cysts and other benign lesions sometimes grow slightly. The overall incidence of a malignancy is around 2%. Even after a prolonged period of observation, when resection is undertaken for a TET, the vast majority are stage I (8th edition of TNM) and there have been no recurrences over a median follow up of approximately 5 years. This has been the case even with thymic carcinoma. In summary, simple observation of incidentally discovered prevascular lesions appears to be safe, without losing a window for intervention in the small percentage of patients that need this.

MS03.03 MINIMALLY INVASIVE SURGICAL STRATEGIES AND CONSIDERATIONS FOR SMALL ANTERIOR MEDIASTINAL LESIONS

B. Weksler

Allegheny Health Network, Pittsburgh/United States of America

Minimally Invasive Surgical Strategies and Considerations for Small Anterior Mediastinal Lesions Thymomas are the most common anterior mediastinal masses. These are slow growing relatively indolent tumors that are often curable with surgical resection. Thymomas are often detected in asymptomatic patients who had a computed tomography of the chest for other reasons. Until recently, the surgical standard of care for curative surgery was resection of the thymus en-bloc with the mass through an open sternotomy. Advances in video surgery have allowed resection of the thymus and the anterior mediastinal masses through small incisions. Currently, there are multiple minimally invasive approaches to the anterior mediastinum, including thoracoscopy though the chest wall, thoracoscopy through a subxiphoid incision, and robotic assisted thoracoscopy. Although data comparing the techniques is sparse, there is no reason to believe that one has oncologic or survival advantages over the other. Data comparing minimally invasive approaches with open approaches have shown better short-term outcomes such as postoperative complications and blood loss, and similar long-term survival. Several authors have questioned the need for a complete thymectomy in patients with small anterior mediastinal lesions, hence the term thymomectomy. Thymomectomy involves the removal of the thymoma only, with margins around it, but without a formal complete thymectomy. Data comparing complete thymectomy with thymomectomy is sketchy and likely unreliable. Another area of intense investigation is the role of nodal dissection or sampling in the surgical management of thymomas. Data from multiinstitutional database suggests that the incidence of nodal metastases is higher than previously thought. Although data is lacking, removal of enlarged nodes, or sampling of nodes in the anterior mediastinum is likely indicated. In summary, small anterior mediastinal masses can be removed using minimally invasive techniques. The need for complete thymectomy, and nodal sampling are areas of investigation. Until more data is available, complete thymectomy with nodal sampling appears prudent.

MS03.04 FOLLOWUP/SURVEILLANCE OF SMALL ANTERIOR MEDIASTINAL LESIONS

W. Fang

Shanghai Chest Hospital, Shanghai/China

With increasing popularity of CT screening for early stage lung cancers, there is a tendency toward increased detection of small anterior mediastinal nodules. However, work-up and management strategy for such incidentally found small mediastinal lesions remains to be established. During 2013-2018, 415 patients with incidentally found small anterior mediastinal mass less than 3 cm in diameter were retrieved from a prospectively kept database at the Division of Mediastinal Surgery, Shanghai Chest Hospital. A marked increase was seen in the annual number of such cases detected (Figure 1). MRI was used in addition to CT scan for differential diagnosis in 413 cases. The other 2 patients could not receive MRI because of metal implantation at previous surgery. Eight-nine patients received surgery, 82 (92.1%) of them turned out to have thymic epithelial tumors (Table). Among thymic tumor patients, 36 had a follow-up history for a median of 18 months, and 27 (75%) of the lesions increased in size. Thymic carcinomas and neuroendocrine tumors enlarged more rapidly than type B2/B3 thymomas, and the latter more rapidly than type A/AB/B1 tumors (Figure 2). Two of the seven thymic carcinomas were upstaged to UICC T3 lesions, and nodal involvement was found in two thymic carcinoma and one atypical carcinoid patients. The other 33 tumors were all in UICC stage Ia. Seven patients turned out to have bronchogenic cysts (3) or thymic cysts (4). None of them had follow-up history and 5 of them received surgery because of MR suspected thymomas. Thus the accuracy of MRI for diagnosing thymic tumors was 94.1% (80/85). Three-hundred-twenty-six patients are still under follow-up, 311 of them were diagnosed of having benign lesions (cysts, hyperplasia, lymph nodes) by MRI. With a median follow-up of 33 months, none but one MRI diagnosed cyst increased by 0.3 cm after 3 years. Two MRI diagnosed cystic and two hyperplasic lesions decreased in size during follow-up. Thirteen patients with MRI diagnosed clinical stage I thymomas refused surgery. Only two of the lesions increased in size by 0.2-0.3 cm after 2 years (Table). In conclusion, MRI is highly useful in differential diagnosis of small anterior mediastinal lesions. Follow-up could be safely recommended for those MRI diagnosed benign lesions. Table. Change in size during follow-up for small anterior mediastinal lesions.

Diagnosis	Patient (Number)	Size (Mean, cm)	Follow-up (Median, month)	Size (+) (Number)	Size (-) (Number)
Surgery (TET)	36	2.4	18	27	0
AB	11	2.4	36	2	0

MS03.05 RELEVANCE OF NODAL INVOLVEMENT AND THE THYMIC LYMPH NODE MAP

J. Kim

Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul/Korea, Republic of

Thymic epithelial tumors (TET) including thymoma, thymic carcinoma, and thymic neuroendocrine tumors are rare cancers, accounting for less than 1% of all tumors. No official staging system was defined by the Union Internationale Contre le Cancer and the American Joint Commission on Cancer (AJCC) until 2017. This led to several proposals being published over the years, but few received clinical validation. Unlike lung cancer, where regional spread through the lymphatics has been proved, most common patterns of recurrence in TET are local failure, or dissemination into the pleural or pericardial spaces. Therefore, the role of additional intraoperative nodal assessment is uncertain in TET, for which total thymectomy is the standard procedure. Lymph node metastasis in TET is more common with thymic carcinoma. Kondo et al. reported in their retrospective study (n=1320) that lymphogenous spread with or without distant metastasis was found in 3.2% of thymomas, and more commonly in 33% of thymic carcinomas.[1] In particular, anterior mediastinal lymph nodes were thought to be the primary drainage location for TET. Anterior mediastinal lymph nodes were involved in approximately 90% of thymomas, 70% of thymic carcinomas, and 90% of thymic neuroendocrine tumors with lymph node metastasis. Furthermore, a cadaveric study found that the anterior mediastinal nodes are the primary drainage basin and the intrathoracic lymph node group are secondary.[2] In 2017, the first TNM classification of TET was announced in the 8thedition of the AJCC Cancer Staging Manual, based on proposals made through a collaboration between IASLC and ITMIG.[3] A new N category was presented based on the lymph node drainage pattern found in anatomic studies and international databases. Prominent nodes defined by anatomic studies are included as regional nodes in the lymph node map (Table 1).[2] In addition, the IASLC lymph node map of lung cancer and AAO-HNS/ASHNS node map were referenced to define boundaries. This new N category classifies the node involvement into three groups according to a region-based system: N0, N1 (anterior region: anterior mediastinal and anterior cervical nodes), and N2 (deep region: middle mediastinal and deep cervical nodes) (Fig. 1). However, this classification is limited by the fact that the amount of data included was too limited to determine statistical significance.[2,4,5] Although the first official N category has been published, controversy still remains over the lymph node involvement in TET. The prognosis with nodal metastasis is clearly poor, but the clinical significance of the criterion dividing the current N1, and N2 groups is uncertain. Moreover, the treatment strategy according to each stage is not yet fully defined. ITMIG recommends removal of anterior mediastinal nodes at the time of resection for thymoma.[6] This fits into the generally accepted definition of an extended thymectomy which includes anterior mediastinal nodes. For locally advanced thymomas (Masaoka stage III or IVA) and thymic carcinoma, a systematic removal of intrathoracic nodes is encouraged (i.e., those corresponding to the deep region). However, for minimally invasive surgery, which is currently in widespread use, the extent and level of lymph node removal should be discussed further. It also remains to be determined whether different treatment strategies should be adopted according to the histological classification of thymomas, as well as whether it is appropriate to apply the same staging for the different TET pathological entities (i.e. thymoma, thymic carcinoma, and thymic neuroendocrine tumor). Therefore, the current official staging system will play a major role in settling these debates through collection from appropriate databases under uniform definitions. Further research is needed to establish the relevance of the node map, the prognostic role of nodal involvement, and the clinical implications of node dissection. Reference 1. Kondo K, Monden Y. MS04 NEW SYSTEMIC ADJUVANT/NEO-ADJUVANT STRATEGIES IN EARLY STAGE LUNG CANCER: TARGETED THERAPY AND I/O
SUNDAY, SEPTEMBER 8 15:15–16:45

MS04.01 EGFR TKIS FOR RESECTED EGFRMUT NSCLC

Y.-L. Wu

Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangzhou/China

Adjuvant chemotherapy became the standard treatment for resected stage 2-3 non-small cell lung cancer (NSCLC). It increased overall survival (OS) by 5% at 5 years, and resected NSCLC was considered "curable disease." Stage II to IIIA resected NSCLC is heterogeneous. The 5-year survival was only 40% -50%. There is a huge medical need to improve the long-term survival for these patients whose cancers are destined to recur after surgery. BR.19, the first trial to evaluate an EGFR TKI (gefinitib) in the adjuvant setting, and the subsequent RADIANT trial, which compared erlotinib to placebo, were not designed specifically for patients with *EGFR* mutations. Thus, these two adjuvant TKIs failed to show meaningful benefits.[1,2] The ADJUVANT trial, first randomized phase 3 trial compared gefitinib with doublet chemotherapy for stage 2 and 3 (N1N2) resected EGFR mutant NSCLC. The results showed that adjuvant gefitinib significant improved disease-free survival (DFS). HR for recurrence was 0.60 with 28.7 months in gefitinib vs 18.0 months in chemotherapy[3]. Subsequently the EVAN -- another Chinese phase 2 trial confirmed that adjuvant erlotinib was superior to chemotherapy in DFS[4]. SELLECT trial from American once again confirmed that adjuvant EGFR TKI improved DFS[5]. The both Chinese adjuvant trials targeted the patients with the highest risk of recurrence and are more likely to respond to EGFR TKIs in patients harboring an *EGFR* mutation. Unlike BR.31 and RADIAN EGFR TKIs were used following adjuvant chemotherapy. the ADJUVANT trial was a direct comparison of adjuvant TKIs with Vinorelbine plus cisplatin instead of comparing TKIs with placebo after chemotherapy, as evaluated in the BR.19 and RADIANT trials. Compliance with adjuvant TKIs (95.5%) was better than that with chemotherapy (78.4%) in ADJUVANT trial. This means that patients receiving adjuvant TKIs were more likely to complete treatment than patients receiving standard chemotherapy. The design of ADJUVANT is different from RADIANT, and the hypothesis of the two trials designs is different. The ADJUVANT study was created to test whether an EGFR TKI might be a viable treatment alternative to chemotherapy in the adjuvant setting, specifically in EGFR mutant (+) NSCLC. In this situation, using DFS as the primary endpoint was rational. The U.S. Food and Drug Administration has stated that a prolonged delay in the development of metastatic disease is an objective and a clinically relevant outcome and that agents can be approved based on metastasis-free survival (MFS) if substantial effects on this endpoint are demonstrated and the safety profile is acceptable.[6] In addition, after adjuvant gefitinib or erlotinib, patients with disease recurrence still have the opportunity to be re-challenged with TKIs. And the median duration of treatment approximates the DFS in a de novo advanced *EGFR*-mutant population.[7] Recently Zhong et al reported a phase 2 trial on neo-adjuvant setting for EGFR mutant stage 3A resectable NSCLC. Of 386 patients screened, 72 were randomized to treatment. The ORR for neoadjuvant erlotinib versus GC chemotherapy was 54·1% versus 34·3% (p=0·092). pCR was 10·7% vs 0. Median DFS was significantly longer with erlotinib (21·5 months) versus GC chemotherapy (11·9 months; HR 0·42; 95% CI, 0·23–0·76; p=0·003)[8]. The results of neo-adjuvant EGFR TKI treatment in CTONG 1103 was similar to adjuvant EGFR TKI in CTONG 1104. The difference of DFS comparing with chemotherapy in both trials are 10 months. Definitely EGFR TKIs could be safely and effectively used in early resected NSCLC. The treatment paradigm for early resectable NSCLC is evolving. Similar to advanced NSCLC early stage NSCLC should be divided to driver mutation or wild type NSCLC. For wild NSCLC check point blockade should be tested in peri-operation. For driver mutation NSCLC TKIs including EGFRi or ALKi even other rare mutation should be tested. Some issues should be evaluated. One issue is how to select populations more precisely for adjuvant or neo-adjuvant treatment. Whether circulating tumor DNA (ctDNA) could serve as biomarker of minimal residual disease (MRD) and how to monitor it[9]? Second issue is what is the primary endpoint for neo-adjuvant or adjuvant treatment in NSCLC? Apparent OS is rational but the trial will last a long time even beyond 10 years. The third issue is how to choose neo-adjuvant or adjuvant treatment for recectable NSCLC either clinical trial or clinical practice. For personalized adjuvant treatment in the future, we need to identify patients precisely and match the appropriate treatment with appropriate patient. 1. Goss GD, O'Callaghan C, Lorimer I, et al. MS04 NEW SYSTEMIC ADJUVANT/NEO-ADJUVANT STRATEGIES IN EARLY STAGE LUNG CANCER: TARGETED THERAPY AND I/O
SUNDAY, SEPTEMBER 8 15:15–16:45

MS04.02 NEO-ADJUVANT PD-(L)1 CHECKPOINT INHIBITORS

L. Raez

Memorial Cancer Institute/Florida International University, Pembroke Pines/ United States of America

Neoadjuvant chemotherapy never made to become standard of care for non-small cell lung cancer (NSCLC) and until today it is being used in special circumstances. However neoadjuvant immunotherapy as single agent or in combination with chemotherapy has become a very promissory intervention. In 2018 we had the publication from Forde et al in the NEJM showing that using nivolumab as neoadjuvant approach did not delay surgery in any of the treated patients (pts) and there were no unexpected safety signals were seen. Very interesting 45% of resected tumors demonstrated a major pathologic response (MPR) that correlated with mutational burden. MPR was defined as less than 10% viable tumor in the resected specimen [1]. Following these results there were also several presentations at ASCO 2018: The LCMC study Rusch et al [2] (treats pts with atezolizumab for 2 cycles follow by surgery then standard of care chemotherapy follow by immunotherapy for 1 year) showed 4/19 (21%) pts had MPR after 2 doses of atezolizumab. Shu et al (Abstract 8532) showed that 4 cycles carboplatin/nab-paclitaxel/atezolizumab had 7/14 (50%) pts with MPR and 3/14 (21%) had pCR. [3] Later at the 2018 World lung Cancer Conference in Toronto in September, we have had the Spanish Lung Cancer Group presenting the study NADIM by Provencio-Pulla that was briefly presented before at ASCO 2018 [4,5]. They had a phase II open label study for patients with stage IIIA NSCLC that received carboplatin/paclitaxel/nivolumab for 3 cycles follow by surgery and adjuvant immunotherapy for 1 year. The CR was 10%, PR 60% and SD 30% for a DCR of 100%. MPR was 80% and complete response 75%. The toxicity profile was tolerable and not unexpected. During the same meeting Rusch [6] did an updated of the LCMC study this time with 45 pts: the ORR was 10% and the DCR 100%. 22% of the pts had MPR. There was no observable correlation between pathologic and radiographic responses. Neoadjuvant atezolizumab did not cause major delays to surgery or interfere with surgical resection, and there were no unexpected safety findings. There was also a poster presentation of the CheckMate 816 [7]: Phase 3 Neoadjuvant Trial of Chemotherapy with and without nivolumab for stage I-IIIA NSCLC presented by Enriqueta Felip with 21 pts in the nivolumab arm that have 10% CR and 45% MPR. Following this success from 2018 at this year in ASCO 2019 there will be 2 important presentations

Neoadjuvant nivolumab (N) or nivolumab plus ipilimumab (NI) for resectable non-small cell lung cancer (NSCLC): the NEOSTAR study for pts with stage I-IIIA [8] and another updated of the LCMC study that is expected to showed data with larger number of pts [9]. There are also several studies with targeted agents for NSCLC that will be presented at 2019 World Lung Cancer Conference where we will have the opportunity to review the updates of some of the studies mentioned before and new ones. MS04.03 ADJUVANT PD-(L)1 CHECKPOINT INHIBITORS

J. Hellyer, H. Wakelee

Stanford University, Stanford/United States of America

Advances in adjuvant therapy for early stage, resectable, non-small cell lung cancer (NSCLC) have been slow for many years. Four cycles of post-operative platinum-based chemotherapy remains the standard of care in most of the world, yet this confers a survival benefit of only ~5% at 5 years.[1] Early efforts to stimulate adaptive immunity to prevent tumor recurrence via several immunologic interventions including antigen specific cancer vaccines, Bacillus Calmette-Guerin (BCG), adoptive cell transfer and tumor-infiltrating lymphocytes failed to show a benefit in overall survival in a meta analysis of the early trials[2,3] In 2018 though positive results from the PACIFIC trial ushered in a new era of immunotherapy with PD-L1 checkpoint blockade in non-operable, stage III non-small cell lung cancer (NSCLC) and established consolidation durvalumab following chemoradiation as the new standard of care.[4] These data provided further enthusiasm for ongoing trials of checkpoint inhibitors in early stage, surgically resectable disease. Promising preliminary data has been presented from ongoing neoadjuvant PD-(L)1 checkpoint inhibitor trials, many of which contain an adjuvant component. The most exciting results to date have come from the NADIM trial of neoadjuvant carboplatin/paclitaxel/nivolumab followed by adjuvant nivolumab for one year after surgical resection. Analysis of the first 41 patients following surgical resection showed 35 (86%) of patients with a major pathologic response (MPR) (defined as <10% viable tumor cells present) and of those, 25 (71%) had a complete pathologic response (CR).[5] The NEOSTAR study of induction nivolumab or nivolumab/ipilumumab and the LCMC trial with neoadjuvant followed by adjuvant atezolizumab in resectable NSCLC patients were both updated at ASCO 2019 with reported MPR in 17%, 33%, and 19% (with 5% CR) of the nivolumab and nivolumab/ipilumumab and atezolizumab intent to treat populations, respectively.[6,7] However, immune toxicity was reported in all of these trials and there were some patients who were not able to complete definitive surgery. We also do not know how MPR with immune therapy correlates with disease free survival (DFS) and overall survival (OS). Thus there is still a lot of enthusiasm for the post-operative (adjuvant) use of checkpoint inhibitors. There are multiple adjuvant immunotherapy trials currently underway although there are no results reported to date. A branch of the US coopertive network (NCTN) ALCHEMIST trial, ANVIL, is currently enrolling patients with stage IB (>4cm)-IIIA NSCLC who test negative for EGFR and ALK mutations. After completion of surgical resection and standard of care adjuvant therapy (chemotherapy or radiation therapy if indicated), patients are randomized to up to a year of adjuvant nivolumab or observation. These patients are further stratified by stage, histology, adjuvant treatment received and PD-L1 status (≥1% or <1%). Co-primary endpoints are disease free and overall survival.[8] IMpower 010 is a randomized, phase III trial of adjuvant atezolizumab vs supportive care in stage IB (>4cm) - IIIA NSCLC patients following surgical resection and cisplatin-based adjuvant chemotherapy with enrollment of 1280 patients. This study does not allow for radiation therapy and mandates that the adjuvant chemotherapy contain cisplatin plus vinorelbine, gemcitabine, docetaxel or pemetrexed. Following completion of 4 cycles of adjuvant chemotherapy, patients are randomized 1:1 to a year of atezolizumab or observation. Primary outcome is disease free survival.[9] In KEYNOTE-091 patients with IB/II-IIIA surgically resected NSCLC who have completed standard of care adjuvant therapy will be randomized to one year of pembrolizumab vs supportive care. The target enrollment is 1080 patients. Primary endpoint is disease free survival. Finally, adjuvant durvalumab is being examined in a randomized, phase III prospective, triple-blind, placebo controlled trial of patients with stage IB (>4cm)-IIIA resected NSCLC being lead by the Canadian Cancer Trials Group. Standard adjuvant chemotherapy is permitted, but post-operative radiation is only allowed for N2 disease. Primary endpoint is disease free survival in PD-L1 positive patients and in all randomized patients. The study stratifies across PD-L1 subgroups (≤1%, 1-49% and ≥50%). Target enrollment is 1360 patients.[10] Checkpoint inhibitor therapy has been established as the new standard of care in unresectable and metastatic NSCLC. Many trials are underway with adjuvant and neoadjuvant immunotherapy for early stage lung cancer and preliminary data from the neoadjuvant trials are promising. In a setting where patients have only modestly benefited from chemotherapy, we eagerly await the results of the ongoing adjuvant immunotherapy studies with the hopes of improving outcomes for surgically resectable NSCLC. MS04.04 OPTIMAL CLINICAL TRIAL DESIGN FOR ADJUVANT SYSTEMIC THERAPY

J. Edwards

University of Calgary, Calgary/Canada

Surgery is the gold standard local therapy for medically operable patients with stage I or II NSCLC. Adjuvant chemotherapy is indicated for high risk patients with stage IB disease as well as those with stage II disease. While cytotoxic chemotherapy remains the standard of care in the adjuvant setting, the modest benefits offered leave much room to advance therapy and improve survival in patients with early stage NSCLC (1). One particular area of enthusiasm surrounds the potential role of novel agents such as immunotherapies in the treatment of early NSCLC, given the benefits seen in the advanced NSCLC setting (2). Select ongoing studies addressing novel adjuvant therapeutic regimens in NSCLC are summarized in Table 1. This presentation examines issues surrounding advancement of knowledge in systemic therapy in the adjuvant setting. First, clinical trials must identify and address questions of relevance to both care providers and patients. These include optimal biomarker testing, the use of biomarkers as predictive and prognostic factors, the role of targeted and immunotherapies, novel and combination regimens, optimal duration of therapy and the role of maintenance therapy. Second, outcomes with clinical relevance which are also of interest to cancer patients should be prioritized such as prolongation of survival and improvement in quality of life. Third, studies should be designed in a robust manner focusing on improved efficiency and generalizability. Novel trial designs such as platform studies employing umbrella and basket protocols, driven by biomarkers with flexible objectives should be considered to accelerate clinical development and generate enthusiasm in the community of practitioners treating NSCLC. In platform studies, a single master protocol is employed in which multiple treatments are evaluated simultaneously. Platform designs can be implemented in an adaptive fashion, allowing treatments to be added as they become available, dropped for futility, or declared superior during the course of a trial (3). Inclusion and exclusion criteria, which are often quite restrictive in explanatory trial designs such as conventional randomized controlled trials, limit generalizability and are often not reflective of the real world setting. Consideration of a more pragmatic approach with broadened inclusion criteria may increase both enrollment and applicability in the broader clinical context. Other novel study designs focused on precision medicine such as co-clinical trials provide an attractive alternative to traditional early phase clinical trials. The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trials (ALCHEMIST) trial is reviewed as an example of a biomarker driven platform study with the potential to provide actionable molecular targets, guide personalized approaches to the care of patients with early NSCLC, and establish standard of practice in those without defined genetic targets (4). Finally, in this post surgical setting, involvement of surgeons in the design and implementation of trials should be encouraged. This could serve to maximize identification and enrollment of patients. Also the integration of surgical questions with those of medical therapy will allow further advancement in the personalized care of patients. In conclusion, the ongoing challenge will be to efficiently and robustly answer questions that matter to researchers, clinicians and patients in a rapidly changing treatment landscape, keeping in mind the ultimate goals of improved survival and quality of life. MINI SYMPOSIA

MS05.01 EPIGENETIC THERAPEUTICS IN LUNG CANCER

K.-K. Wong

NYU Langone Perlmutter Cancer Center, New York/United States of America

Epigenetic Targets and Drugs to enhance immune response in Lung Cancer Kwok-Kin Wong Effective therapies for non–small cell lung cancer (NSCLC) remain challenging despite an increasingly comprehensive understanding of somatically altered oncogenic pathways. It is now clear that therapeutic agents with ability to impact the tumor immune microenvironment potentiate immune-orchestrated therapeutic benefit. We have previously demonstrated the immunoregulatory properties of histone deacetylase (HDAC) and bromodomain inhibitors, two classes of drugs that modulate the epigenome, with a focus on key cell subsets that are engaged in an immune response. By evaluating human peripheral blood and NSCLC tumors, we have shown that the selective HDAC6 inhibitor ricolinostat promotes phenotypic changes that support enhanced T-cell activation and improved function of antigen-presenting cells. The pan-bromodomain inhibitor JQ1 attenuated $CD4^{+}FOXP3^{+}$ T regulatory cell suppressive function and synergized with ricolinostat to facilitate immune-mediated tumor growth arrest, leading to prolonged survival of mice with lung adenocarcinomas. Finally, we have recently performed in vivo CRISPR screens to identify additional novel epigenetic targets that would synergize with PD1 blockade in KRAS driven NSCLC.

MS05.02 GENETICS ABNORMALITIES IN CHROMATIN MODIFIERS: CONNECTION WITH MYC PATHWAY AND EXPLORATION FOR THERAPEUTICS

M. Sanchez-Cespedes[1,2]

[1]*Cancer Epigenetics and Biology Program-PEBC (IDIBELL), L'Hospitalet de Llobregat/Spain,* [2]*Institute Josep Carreras, Badalona/Spain*

The understanding about the complexity of the molecular networks that regulate the epigenetic control of gene expression is boosting. Moreover, it is accepted that an abnormal function of these networks, due to genetic alterations of its components, play an essential role during tumorigenesis. Among the networks involved in this epigenetic control, there is the SWI/SNF-chromatin remodeling complex, a regulator of the accessibility of the chromatin to DNA-binding proteins (1-2). Inactivating mutations at different members of the complex have been found to be inherent to most human cancers. Our team had pioneered these investigations, being the first to report inactivating mutations at BRG1 (also SMARCA4) which codes for the ATPase of the SWI/SNF complex (3-4). In lung cancer (LC), alterations at any member of this complex affect about half of the tumors and occur in a background of wild type MYC (either C, L or N) (3). In the lasts years, inactivating mutations at other members of the complex (e.g. SNF5, PRBM, ARID1A, ARID2) have been shown to evolve in most human cancers (2,5). More recently, our laboratory also pioneered the identification of tumor-specific inactivation of the MYC-associated factor X gene, MAX, in small cell lung cancers, where it is present in tumors that are wild type for MYC and BRG1 (6). Altogether, the genetic observations indicate the existence of an important network, involving SWI/SNF and MAX/MYC, which is critical to LC development. Using LC as a model, we have scrutinized genomic data, whole exome sequencing (WES) and RNA-sequencing, collected from patient-derived xenografts (PDXs), from patient-derived cells (PDCs) and from public databases (Sanger-COSMIC and CCLE), to delineate the gene alteration profile at epigenetic controllers (including already known drivers and novel candidates) in LC. Combined, all the alterations at epigenetic controllers include different members of the SWI/SNF complex (SMARCA4/BRG1, ARID1A, PBRM1) as well as interesting candidates such as the MAX-binding protein, MGA, or the histone-modifying enzymes (KMT2D/MLL2, KMT2G/SETD1B), among others. Some of these alterations appeared in a mutually exclusive pattern, suggesting a functional connection We have also integrated this information to search for cancer vulnerabilities.Components of the SWI/SNF complex are known to bind to various nuclear receptors, such as those of estrogens, progesterone, androgens, glucocorticoids (GCs) and retinoic acid (RA), thereby adapting the gene expression programs to the demands of the cell environmental requirements (7-9). We found that the restitution of BRG1 in LC cells restores the gene expression signature of normal lung and that cells lacking BRG1 did not respond to RA or GCs, while restoration of BRG1 restored sensitivity (10). The co-administration of the epigenetic compounds azacitidine (demethylating agent) and SAHA (inhibitor of histone deacetylases) enhanced all these effects, both in cell cultures and *in vivo,* accompanied by sustained reductions in genome-wide DNA methylation. Together, these data support the notion that an inactive BRG1 confers resistance to RA and GCs, which prevents cancer cell differentiation. In contrast, the observations also indicate that RA/GC-based treatments could be designed to treat LC patients with MYC-amplified tumours. On the other hand, recent investigations have searched for vulnerabilities of BRG1-mutant cells that may be therapeutically approachable and have found that the inhibition of cyclin-dependent kinase 4/6 (CDK4/6) appear to be synthetic lethal in BRG1-deficient tumours (10). In my presentation I will be showing our last and novel observations of epigenetic-related compounds that promote cell growth inhibition specifically in BRG1-mutant lung cancers. In parallel, gene alterations at other epigenetic-related components have also been reported in cancer. Some of these include the methyltransferase EZH2, a transcriptional repressor, the transcriptional co-activator protein p300, a histone acetyltransferase that regulates transcription via chromatin remodelling or the histone acetyltransferase CREBBP, which also acts as a scaffold to stabilize additional protein interactions with the transcription complex. In LC these alterations are more common in small cell lung cancer (SCLC). In SCLC, there is also recurrent inactivation of MAX and of MGA, proteins directly linked to the MYC trans-activation activities. Here, we found that the gene expression profile of MAX-mutant SCLC cells cluster to that of the ASCL1-transcription factor dependent group of SCLCs, which also includes NMYC- and LMYC-activated but not with MYC or BRG1-mutant SCLC cells. MGA, is an extraordinary large protein that is also recurrently inactivated in NSCLC. The MYC-MAX and MADs/MGA-MAX complexes have opposed functions in transcription, being MAX a central player in this network. MAX and MGA have shown to also act as part of the Polycomb Repression Complex 1 (PRC1), specifically the non-canonical PRC1 complex designated as ncPRC1. I will also present our data on the functional characterization of the role of MYC and of MGA in the MAX-deficient SCLC cells. References: 1.Peterson CL et al. MS05.03 NOTCH SIGNALLING

S. Gadgeel

Rogel Cancer Center/University of Michigan, Ann Arbor/United States of America

The Notch signaling pathway is a highly conserved pathway that has a vital role in embryonic development and post-embryonic functions such as hematopoiesis, neural cell development and angiogenesis (1). The signaling pathway is activated by the interaction of 4 Notch receptors and their interactions with 5 different ligands. Signaling is characterized by juxtacrine interaction between ligands and receptors on neighboring cells or within the same cell. Alterations in this pathway have been detected in several tumors both as tumor promoter and tumor suppressor. Notch signaling does appear to have relevance in non-small cell lung cancers (NSCLC) (2). In approximately 30% of NSCLCs loss of Numb, a negative regulator of Notch1, leads to increased Notch activity and about 10% of NSCLCs have gain of function mutations in Notch1. A meta-analysis demonstrated that higher expression of Notch1 was correlated with more advanced tumors (3). In addition, higher expressions of both Notch1 and Notch3 were associated with poor prognosis (4,5). In pre-clinical studies inhibition of Notch3 signaling has reduced growth of lung cancers. In addition, it has been demonstrated that there is cross talk between Notch3 and EGFR pathways and inhibition of both pathways can induce expression of anti-apoptotic protein BIM. Finally, Notch signaling may have a role in induction of the epithelial to mesenchymal phenotype (EMT) in cancers (6). EMT is known to be associated with resistance to both cytotoxic agents and targeted agents and inhibition of Notch signaling can not only reverse EMT but also can enhance the anti-tumor activity of cytotoxic agents such as cisplatin and targeted agents such as erlotinib. The EMT phenotype is frequently observed in a sub-population of cancer cells with self-renewal capacity or cancer stem cells. Notch signaling may be crucial to survival of cancer stem cells and persistence of this population may contribute to resistance to therapeutic agents. In squamous cell lung cancers Notch signaling may have tumor suppressive properties (7). Loss of function mutations in Notch family of genes, predominantly in Notch receptors, are frequently identified in several squamous cell cancers including squamous cell cancer of the lung. Similarly, loss of function mutations in Notch genes, particularly Notch1 have been identified in small cell lung cancer (SCLC). Expression of Notch receptor in a mouse model of SCLC reduced tumor burden, suggesting its tumor suppressive properties. The expression of DLL3, one of the Notch ligands is induced in SCLC by a key transcription factor ASCL1.DLL3 is shown to downregulate Notch signaling in SCLCs and enhance the carcinogenic phenotype. All the above data suggest that Notch signaling is highly contextual. In some tumors this pathway may have tumor suppressive properties but in others tumor promoting properties. Defining the role of this pathway in tumor types may guide development of therapeutic strategies targeting the Notch signaling pathway. References Bigas A, Espinosa L. MS05.04 INNATE IMMUNE MEDIATORS IN LUNG CANCER

G. Mollaoglu, B. Guo, T. Reyes, T. Oliver

University of Utah, Salt Lake City/United States of America

Non-small-cell lung cancer (NSCLC) accounts for about 85% of total lung cancer cases. The major types of NSCLC—squamous cell carcinoma and adenocarcinoma—harbor distinct histopathologies, biomarker expression, genomic alterations, and response to therapy [1,2]. Recent studies have shown that there are also differences in their tumor immune microenvironments [3–6]. Specifically, adenocarcinomas have increased infiltration of tumor-associated macrophages, while squamous lung tumors exhibit an enrichment in tumor-associated neutrophils (TANs) in both mouse and human lung tumors. The two major subtypes of NSCLC are also associated with distinct lineage-specific master regulators: SOX2 is commonly amplified and up-regulated in the vast majority of squamous tumors anddrives the squamous fate, whereas NKX2-1 is highly expressed in adenocarcinoma and governs adenocarcinoma fate [2]. We developed novel genetically engineered mouse models (GEMMs) of squamous lung cancer on the basis of overexpression of the transcription factor Sox2 and loss of the tumor suppressor Lkb1 (SL mice) (Mukhopadhyay et al, *Cell Rep*, 2014 [7]). SL tumors recapitulated gene expression and immune infiltrate features of human squamous NSCLC, including an enrichment of TANs and a decrease in expression of NKX2-1. Deletion of *Nkx2-1*in SL mice (SNL) revealed that NKX2-1 suppresses SOX2-driven squamous tumorigenesis by repressing adeno-to-squamous transdifferentiation. We further employed multiple GEMMs to elucidate the role of SOX2 and NKX2-1 in tumor cell fate and TAN recruitment. In Kras-driven adenocarcinomas,mis-expression of Sox2 or loss of Nkx2-1 led to TANrecruitment. SOX2 recruits, whereas NKX2-1 suppresses, TANs at least partly through inverse regulation of the chemokine*Cxcl5*. Tumor-derived CXCL5 is sufficient to recruit TANs. Single cell RNA sequencing (scRNA-seq) revealed that TANs exhibit tumor-promoting features, including production of reactive oxygen species (ROS), and distinct gene expression profiles compared to blood neutrophils (Mollaoglu et al, *Immunity*, 2018 [8]). Depletion of TANs through LY6G blocking antibodies or CXCR2 inhibitors in SNL mice reduced squamous tumors, suggesting that TANs foster squamous cell fate. Furthermore, TAN depletion coupled with scRNA-seq suggests that TANs regulate distinct aspects of tumor cell fate. Together, these data suggest that lineage-defining transcription factors determine the tumor immune microenvironment, which in turn can impact the nature of the tumor. MS05 NOVEL BIOLOGICAL PATHWAYS AND DRUGGABLE TARGETS
MONDAY, SEPTEMBER 9 11:00–12:30

MS05.05 HARNESSING ONCOGENE DEPENDENCIES IN LUNG CANCER

M. Sos

Molecular Pathology, Köln/Germany

The introduction of precision medicine had a dramatic impact on the overall survival of genomically selected lung cancer patients. This is primarily true for lung adenocarcinomas in which druggable targets like mutant EGFR or rearranged ALK are frequently oncogenically activated. The major challenge in these patients is the inevitable emergence of drug resistant clones that abrogate the effects of selected tyrosine kinase inhibitors. Through a detailed characterization of patients that relapse under osimertinib treatment we identified novel routes to overcome individual resistance mutations in EGFR. At the same time, the majority of lung lacks directly druggbale targets and thus remains largely unaffected by this therapeutic revolution. The induction of programmed cell death by perturbing the pro- and anti-apoptotic members of the BCL-2 family may represent an attractive strategy to circumvent this medical need. We sought to explore dependencies on individual BCL-2 family members with different therapeutic strategies to identify therapeutically relevant pathways in lung cancer models.

MS06.01 RADIOLOGIC STAGING

J.M. Goo

Departments of Radiology, Seoul National University College of Medicine, Seoul/Korea, Republic of

Current definitions of borders for lymph node stations based on a few anatomic landmarks have limitations to explain the three-dimensional location of lymph nodes. Variability in the classification of lymph node stations (especially N1 vs N2 and N2 vs N3 categories) inevitably results in different management and also has an impact on database for the future revision of staging. Several articles have dealt with the ambiguity of the IASLC map and proposed recommendations. The Japan Lung Cancer Society and the Japanese Society for Radiation Oncology map provided more detailed description about the borders of lymph node stations (1). 1. Station 1 and 2 - Proposal: Changing the lower border of #1 station (upper border of #2 station) to the thoracic inlet: upper border of the 1st ribs (anterior border of the 1st ribs on axial CT) (2) and manubrium 2. Station 3a - Potential problem: Absence of sideness - Proposal: Split 3a to 3aR and 3aL with a left lateral border of the SVC (3) OR No change (like subcarinal lymph node) 3. Station 3p Current border - Potential problem: Absence of sideness - Proposal: Right-sided lymph node OR No change (like subcarinal lymph node) 4. Precarianl area (below the lower border of the azygos vein in the right side and upper rim of the left main pulmonary artery in the left side) - Current border: Lymph nodes located in the precarinal area is currently #10, hilar lymph nodes, but there is no description for the border between the right and left. - Proposal: Midline of the trachea In the current IASLC lymph node map, the pleural reflection no longer serves as the border between nodal stations. However, still many physicians regard N2 lymph nodes as mediastinal lymph nodes, and a survey also support this trend (3). Therefore, if the IASLC abandons the notion that N2 lymph nodes are mediastinal lymph nodes, the current map needs only a minor modification. Instead, a clear announcement should be provided to avoid confusion from other researchers (2). If the IASLC regards N2 lymph nodes as mediastinal lymph nodes, major modifications are required. 5. Station 4 and 10 - Problematic area: Anterior aspect of the lower trachea and carina below the lower border of #4 lymph nodes are located in the mediastinum. 6. Station 5 and 10 - Problem: Pulmonary arteries are curved structures craniocaudally, and different interpretation of this border results in differeces among altases. The intersection of the left superior pumonary vein branch and left main pulmonary artery may serve as a clear border. If # 10 lymph nodes are classified as non-mediastinal lymph nodes, the border definition should also be modified. 1. Itazawa T, Tamaki Y, Komiyama T, et al. MS06.02 ENDOSCOPIC NODAL STAGING

J. Sanz Santos

Hospital Universitari Mutua Terrassa, Terrassa/Spain

Endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) were first described in the early 1980's and 1990's respectively. However, their incorporation into clinical practice began some years later, after the development of echoendoscopes and echobronchoscopes. EBUS-TBNA allows the sampling of retrotracheal (3P), upper paratracheal (2L,2R), lower paratracheal (4L/4R) and subcarinal (7) nodal stations. Moreover, EBUS-TBNA can access hilar (10L/10R) and interlobar nodal stations (11L/11R). EUS-FNA can access stations 2 and 4, subaortic (5), 7, paraesophageal (8L/8R) and pulmonary ligament (9L/9R). EBUS-TBNA/EUS-FNA is usually performed under conscious sedation or general anaesthesia in an outpatient setting. The reported complications rate for EBUS and EUS is < 1%. The current international guidelines for preoperative mediastinal staging of lung cancer[1] recommends, for an endoscopy-based mediastinal staging procedure, as a minimum requirement, sampling the largest LN in 4R, 4L and 7 stations, as well as positron emission tomography (PET) positive LNs within each of these stations. Thus, 3 nodes is the minimum sampling requirement for an endoscopy-based staging procedure. Overall, the reported pooled sensitivity, specificity, negative predictive value (NPV) and positive predictive value (PPV) of EUS-FNA for lung cancer staging is 0.83, 0.97, 0.78 and 0.98 respectively[2]. Two meta-analysis focussed on EBUS-TBNA in lung cancer staging were published ten years ago[3,4]. Most of the studies included patients with abnormal mediastinum on CT and/or PET/CT and thereby a high prevalence of disease. The reported pooled sensitivity was 0.9 and 0.93, respectively, ranging from 0.69 to 0.99. More recently, two meta-analysis[5,6] have analysed the usefulness of EBUS-TBNA in lung cancer staging in patients with radiologically normal mediastinum. Both have shown similar pooled results for sensitivity (0.49, 0.495) and NPV (0.99, 0.93) with a similar median prevalence of N2/N3 disease (15.2%, 12.8%). EBUS and EUS are complementary techniques that can access to different nodal stations. Thus, combination of both techniques may result in an increase of the sensitivity. A meta-analysis that included 2395 patients[7] reported a mean sensitivity of the combined approach of 0.86 with a mean NPV of 0.92. Depending on the order of both techniques, the addition of EUS(B) to EBUS increased sensitivity by 0.12, and addition of EBUS to EUS(B) increased sensitivity by 0.22. However, no differences in sensitivity and NPV were shown between studies that performed EBUS first and studies that performed EUS first. Combining EBUS with EUS has several limitations: usually needs to be performed by two different operators (pulmonologist/thoracic surgeon or gastroenterologist), in different settings, increasing the cost and waiting time of the procedure. These problems can be solved using a single scope (EBUS), in the same setting, by the same operator, by introducing the EBUS scope into the esophagus (EUS(B)). Several studies have demonstrated that EUS(B) combined with EBUS-TBNA results in an increase of the sensitivity compared with EBUS-TBNA alone[8]. On the last years, several lung-sparing treatments for lung cancer have been developed. To select candidates for these techniques, accurate staging not only of the mediastinal nodes but also of the hilar nodes is crucial. One of the advantages of EBUS-TBNA is the ability to access N1 nodes. A study conducted by Yasufuku et al.[9] that included patients with clinically N0/N1 disease eligible for surgical resection demonstrated that EBUS-TBNA can accurately access the hilar and interlobar LNs with a reported sensitivity, specificity, diagnostic accuracy and NPV of 0.76, 1, 0.96,

and 0.96 respectively. Currently there are two questions that have to be answered: As mentioned before[7], EUS (B) needs to be added to EBUS in 25 patients and EBUS to EUS (B) in 14 patients to detect one additional patient with mediastinal nodal disease that would not have been detected if only one test had been performed. One recent meta-analysis[10] studied the rate of unforeseen N2 disease in patients with lung cancer with or without mediastinoscopy after negative endosonography. In patients with EBUS and or EUS alone, the rate of unforeseen N2 was 9.3% for EBUS, and 13.4% for EUS. In patients with confirmatory mediastinoscopy the rate of unforeseen N2 disease after negative findings of EBUS (plus mediastinoscopy) was 11.2%, and after negative EUS (plus mediastinoscopy) was 14.9%. 1.De Leyn, et al. MS06.03 PATHOLOGIC STAGING: OPERATIVE EVENTS

T. D'Amico

Duke Cancer Institute, Durham/United States of America

Accurate pathologic nodal staging, a powerful prognostic factor after resection of lung cancer, requires thorough examination of the mediastinal lymph nodes. Accurate pathologic staging of lung cancer requires effective collaboration between the surgery and pathology teams. There is a quality gap in pathologic nodal staging from three sources: poor surgical lymph node examination practice (failure to collect nodes), problems in the pathologic transfer of specimens (loss in transit or improper communication of the source of specimens), and poor pathology examination practice (incomplete examination or inaccurate and inconsistent reporting). Adequacy of mediastinal lymph node dissection (MLND) during resection for lung is an important quality measure that is not universally met in the US. For most patients with lung cancer, mediastinal lymph node dissection or systematic sampling is recommended at the time of resection, but it is only infrequently performed. For example, 62% of pathologic N0 and N1 non-small cell lung cancer resections in the US SEER database have no mediastinal lymph nodes examined. There is also significant discordance between surgeon claims of the extent of mediastinal lymphadenectomy and verifiable lymph node examination from pathology reports. Review of pathology reports in one study suggested that only 8% of all resections meet systematic sampling criteria, 50% have random sampling, and 42% have no mediastinal lymph nodes examined. However, a blinded independent audit of the surgeons' operation notes suggested that 29% of cases had described a mediastinal lymph node dissection procedure. Some surgeons utilize a strategy of using several pathologic variables to determine the need for MLND during resection for non-small cell lung cancer. The premise is that it is an important goal to "minimize surgical trauma". However, most surgeons would agree that there is not significant trauma related to the dissection of clinically negative lymph nodes, and that the incremental trauma related to MLND is itself minimal. Other strategies to obviate MLND have been suggested. Sentinel lymph node identification has been proved unsuccessful for lung cancer; sentinel technologies do not reliably identify a single lymph node, and N2 disease may still be present even when the sentinel node is negative. In any case, that strategy was tested in an era when only N2 patients could receive adjuvant chemothererapy, and the strategy was based on finding micromestastic disease, not limiting surgical trauma. In an era where N1 disease and tumor size both direct adjuvant therapy, the effort to limit lymphadenectomy is even less useful and this practice should be scrutinized. Even in major cancer centers, the targets of ten lymph nodes and three N2 stations is not universally met. In summary, patients with cT2 or > N0 lung cancer should undergo pre-resectional staging with either endobronchial ultrasound or mediastinoscopy. At the time of anatomic resection, adequate management of mediastinal lymph nodes should also be performed, either complete mediastinal lymph node dissection (favored) or rigorous systematic mediastinal lymph node sampling, with the goal of at least 3 N2 stations, and at least 10 lymph nodes.

MS06.04 APPROACHES TO OVERCOMING THE NODAL STAGING QUALITY GAP

R. Osarogiagbon

Baptist Cancer Center, Memphis/United States of America

The importance of pathologic nodal staging. Surgical resection remains the most important curative-intent treatment modality for non-small cell lung cancer (NSCLC), with 75-85% of 5 year survivors having undergone resection. For such patients, the status of nodal involvement is the most important prognostic factor, which also has implications for subsequent management, since patients with any nodal involvement (pN1-3) benefit from adjuvant chemotherapy and those with mediastinal nodal involvement (pN2-3) may benefit from adjuvant radiation therapy. Nodal staging also influences risk-stratification for clinical trials eligibility. *Defining nodal staging quality.* There are no universally accepted criteria for defining nodal staging quality, but various professional organizations, including the American College of Surgeons Oncology Group (ACOSOG), the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC), the American College of Surgeons Commission on Cancer (CoC), the European Society for Thoracic Surgery (ESTS), the International Association for the Study of Lung Cancer (IASLC) and the National Comprehensive Cancer Network (NCCN) have all proposed slightly different measures of the quality of pathologic staging, including nodal staging parameters.[1] *The nodal staging quality gap.* Despite the importance of pathologic nodal stage, the quality of application of nodal staging is highly variable. Three examples are: non-examination of lymph nodes in resection specimens (pNX) which exists in 12-18% of resections; non-examination of mediastinal lymph nodes, which is reported in up to 50% of resections; failure to achieve aggregate nodal staging quality requirements, such as the NCCN definition of quality, which is achieved in as few as 4% of surgical resections in population-based cohorts in the United States.[2] *Survival implications.* pNX resections have significantly inferior survival to pN0 resections, and are more similar to resections for pN1 NSCLC; pN0 and pN1 resections without examination of mediastinal nodes have 14% lower adjusted 5-year survival than those with at least one examined mediastinal lymph node; and achievement of all 4 elements of the NCCN definition of resection quality (anatomic resection, negative margins, examination of at least 1 hilar/intrapulmonary lymph node and at least 3 mediastinal nodal stations) is associated with 30% lower hazard of death within 5 years.[3] *Causes of the gap, corrective interventions.* The nodal staging quality gap can be localized to events during the surgical operation, the transfer of resection specimens and the pathology examination. Effective interventions must correct the problem at all its potential sites of origin. In the

'chain of responsibility' conceptual model, any breakdown in the surgical retrieval of lymph nodes, labeling of specimens, transfer of specimens, gross retrieval of lymph nodes from submitted material and pathologic examination of the retrieved material can break down the quality and accuracy of the final pathology report which is used for all subsequent oncologic care decision-making. Devices such as pre-labeled specimen collection kits are able to prevent breakdown at all links of this chain: they significantly increase the thoroughness of lymph node evaluation; rates of attainment of nodal staging quality measures; and survival. However, their impact on retrieval of intrapulmonary lymph nodes is limited. Specific interventions are also required to improve pathologic retrieval of intrapulmonary lymph nodes, given evidence that up to 90% of pulmonary resection specimens have lymph nodes discarded without examination, approximately 30% of which have metastasis, including in 12% of patients reported as having pN0. Patients with discarded intrapulmonary lymph node metastasis have worse survival than those without, irrespective of their pathologic nodal stage. Even in the mediastinal nodal dissection arm of the ACOSOG Z0030 trial, in which there was extensive evaluation of hilar and mediastinal lymph nodes, poor examination of intrapulmonary lymph nodes was common and had significant negative survival impact.[4] Novel, anatomically sound gross dissection methods designed to focus on retrieval of lymph nodes in the peri-bronchial tree with particular emphasis on sites of bronchial bifurcation, significantly improve the yield of lymph nodes and decrease the incidence of discarded lymph nodes. Therefore, combining surgery with lymph node specimen collection kits and improved gross dissection methods is necessary to comprehensively overcome the nodal staging quality gap. *What are the putative pathways for survival impact?* Correct prognostication by more accurate risk-stratification, although beneficial in itself, would only impact on stage-stratified survival, without changing survival in aggregate populations. The finding of aggregate survival differences suggests benefit beyond mere stage re-categorization. One likely mechanism is improvement in identification of candidates for adjuvant therapy, which then provides an indirect means of risk-mitigation. However, given the larger reduction in hazard for death when surgical specimen collection kits are used, than would be expected from adjuvant therapy benefits alone, another plausible hypothesis is an inherent benefit of resecting oligo-metastatic lymph node disease. This hypothesis requires further testing. Interestingly, it fits the emerging understanding of suboptimal nodal staging as a type of incomplete resection (R-uncertain) and the IASLC's proposal for creating a new category of 'R-uncertain' resections, the overwhelming majority of which are caused by poor nodal staging.[5] The emerging ability to conduct tests for minimal residual disease such as with cell-free DNA will provide a means of directly testing this hypothesis. If proven, it would open a pathway to future clinical trials of novel adjuvant treatments, such as checkpoint inhibitor therapy and other immunomodulatory treatments for these residually high-risk patients. MS06.05 TRANSCERVICAL LYMPHADENECTOMIES

M. Zielinski

Pulmonary Hospital, Zakopane/Poland

Introduction: The aim of his study is to analyze the issue of transcervical lympadenectomies for Non-Small-Cell Lung Cancer performed by the techniques of Video-Assisted Mediastinoscopic Lymphadenectomy (VAMLA) and Transcervical Extended Mediastinal Lymphadenectomy (TEMLA). Methods The Pubmed search was performed and there were 27 articles found on VAMLA and 33 articles on TEMLA. After further analysis there were 13 original article on VAMLA and 18 original articles on TEMLA. In the current paper all proven and possible advantages of transcervical lymphadenectomies representd by VAMLA and TEMLA are described. Results The proven advantages of VAMLA and TEMLA: 1. Superior diagnostic value in discovery of the metastatic mediastinal nodes for staging and restaging of NSCLC. 2. bilateral mediastinal lymphadenectomy, more extensive than the techniques of lymphadenectomy used during standard thoracotomy or Video-Assisted Thoracic Surgery (VATS) approaches. Possible advantages include: 1. Improved selection of patients for pulmonary resection for NSCLC 2. Combination of VAMLA/TEMLA with VATS pulmonary resection, 3. Combination of VAMLA/TEMLA with esophegeal resection, 4. Combination of TEMLA and Stereotactic Radiotherapy (SBRT) for advanced NSCLC 5. The use of TEMLA for preoperative staging of mesothelioma, 6. Combination of TEMLA and pulmonary lobectomy through a sole transcevical approach 7. Resection of various metastatic tumors, including thyroid cancer and metastatic mediastinal nodes. 8. Possible impact of VAMLA/TEMLA on improvement of survival for NSCLC patients, which is the most important issue. In case of VAMLA superior survival of patients operated on with the use pulmonary resection with VAMLA in comparison to the pulmonary resection with addition of standard mediastinoscopy. In case of TEMLA no reports on survival has been published, yet Disadvantages of VAMLA/TEMLA include 1. Possible complications, especially the left recurrent nerve palsy 2. Possible delay or elimination of some patients from pulmonary resection due to postoperative complication in case of negative result of VAMLA/TEMLA 3. Scar in the neck (cosmetic) 4. Demanding surgical technique Conclusions 1. Bilateral transcervical lymphadenectomies representd by VAMLA and TEMLA are more extensive than the techniques of lymphadenectomy used during standard thoracotomy or Video-Assisted Thoracic Surgery (VATS) approaches and superior to the other techniques of staging and restaging of NSCLC in regard to the diagnostic value. 2. There are several other possible advantages of TEMLA/VAMLA for the treatment of NSCLC, esophageal cancer, mediastinal tumors and malignant mesothelioma. 3. Possible impact of VAMLA/TEMLA on survival of NSCLC has not been proven, yet. MS06 AN INTERDISCIPLINARY APPROACH TO OPTIMAL NODAL STAGING
MONDAY, SEPTEMBER 9 11:00–12:30

MS06.06 THE CONCEPT OF COMPLETE RESECTION

J. Edwards

Northern General Hospital, Sheffield/United Kingdom

The basis of the definition of complete resection is the Union for International Cancer Control (UICC) residual tumor classification (R classification), which considers the presence or absence of tumor in the primary site, lymph nodes and distant site following treatment. It has established clinical relevance, reflects the effectiveness of treatment, may be used to determine whether further therapy is indicated and has established prognostic relevance in lung cancer [1-3]. However, there are deficiencies in that locoregional recurrence may occur after an apparent R0 resection. The Complete Resection Subcommittee was tasked by the IASLC Staging Committee in 2001 to prepare a proposal of the definition of complete resection, based on expert opinion. The proposal that was derived [4] proposed the term uncertain resection, R(un), according to the following criteria: *An uncertain resection is defined when resection margins are proved to be free of disease microscopically, but one of the following applies: (a) The intraoperative lymph node evaluation has been less rigorous than systematic nodal dissection or lobe-specific systematic nodal dissection. (b) The highest mediastinal node removed is positive. (c) The bronchial margin shows carcinoma in situ. (d) Pleural lavage cytology is positive (R1 cy+).* In addition, this proposal considered cases with positive pleural lavage cytology (PLC) as R(un), rather than R1, and cases with extracapsular extension of tumor in nodes removed separately, or those at the margin of the main lung specimen, were considered R1, rather than R0. The analysis of the proposed R Classification using the database informing the 8thEdition of the TNM was presented at the 18thWorld Conference on Lung Cancer. The predominant reason for re-classification as R(un), performed in 56% of cases, was less than systematic nodal dissection (96% of cases). Survival in the R(un) category was significantly worse than R0 in node positive cases (median survival 50 and 70 months respectively, Hazard Ratio 1.27, Figure). The status of the highest lymph node station also had prognostic significance in pN2 cases (HR 1.32). Further work, that will require the submission of high quality data to the IASLC Lung Cancer Staging Project, will investigate again the impact of the individual R factors, particularly those for which the prevalence (or data completeness) in the previous dataset was low. Participation by institutions worldwide is essential to ensure success [5]. However, there are several aspects about R Factor assessment that require clarification. These are being considered by the R Factor Subcommittee of the Staging and Prognostic Factors Committee. A survey of the current application and interpretation of the R Classification for NSCLC has been designed. The R Factor Sub-Committee will be determining and disseminating best methodological practice for intra-operative and histopathological aspects of R factor assessment

MS07.01 PREOPERATIVE OPTIMAZITION: REDUCING SURGERY COMPLICATIONS THROUGH TOBACCO CESSATION

D. Harpole

Duke University, Durham/United States of America

Optimizing Outcomes after Pulmonary Resections with Smoking Cessation Data on increased risk of complications after major thoracic surgery for current smokers has been documented for several decades, suggesting that smoking cessation for even a few weeks may significantly reduce this risk based on early return of muco-ciliary clearance of respiratory secretions and decreased risk of atelectasis and pneumonia. Moreover, the awareness of potential lung cancer mortality on patients is a potent "teachable moment" for a smoking intervention. However, the literature is anything but definitive on: 1. Method of smoking cessation / counseling (including pharmacological and non-pharmacological adjuncts) 2. Length of time required for maximal risk reduction 3. Durability of cessation after surgery This presentation will review the strongest trials in the literature, as well as recent data on a concerted risk reduction programs of Enhanced Recovery from surgery (ERAS) that include smoking cessation. MS07.02 POST SBRT MANAGEMENT: SURGERY

M. Antonoff

UT MD Anderson Cancer Center, Houston/United States of America

Background: For early stage NSCLC, lobectomy and mediastinal lymph node dissection has been a long-standing, established standard of care. For patients unable to tolerate surgical resection, several single-institution studies have demonstrated SBRT to be an efficacious and well-tolerated treatment strategy.[1-3] The RTOG-0236 trial, subsequently published in 2010, prospectively evaluated SBRT among patients at multiple North American centers, revealing high rates of local tumor control with acceptable treatment-related morbidity, which has been corroborated by other investigators with reproducibly acceptable rates of intermediate-term local control and minimal toxicities.[4-6] Given the success of using SBRT for Stage I NSCLC in medically inoperable patients, increasing interest has arisen regarding the potential application of this modality for healthier, potentially operable patients. In order to expand indications for use of this modality, important issues warranting investigation will include determination of the ideal means of following patients radiographically following SBRT as well as establishing protocols for intervention upon local failure. The outcomes for salvage lung resection following SBRT have been minimally reported. In this study, we aimed to evaluate our experience with operative lung resection in patients where SBRT has failed. Further, we review the combined outcomes in patients from our center along with those previously reported in the published literature. Methods:We utilized our Departmental surgical database to identify all patients who underwent salvage pulmonary resection after prior radiation between January 2009 and September 2015. Among 716 patients who underwent pulmonary resection after previous radiotherapy, 21 met inclusion criteria, and these patients comprised the study cohort (MDACC group). Detailed patient data were retrospectively collected from our departmentally maintained, prospectively entered database and supplemented with additional chart review. In addition, a MEDLINE search was performed to identify all previous reports of surgical resection following local failure after initial treatment with SBRT. This resulted in 56 articles, which were reviewed to specifically identify publications regarding lung resection following local recurrence after SBRT. Four studies were identified, totaling 18 patients; however, as one report[7] included resection of specimens lacking any residual disease, we used only the other 3 reports for cumulative analyses.[8-10] From these previous publications, data were extracted for each patient and were combined with those of the MDACC cohort, thus constituting the final aggregate cumulative group. Student's paired t-tests were used to compare pre-SBRT and pre-salvage surgery pulmonary function test results. Kaplan Meier analyses were performed in order to evaluate survival from the time of surgery as well as survival from completion of SBRT. Results:At our institution, 21 individuals met inclusion criteria and comprised the MDACC group, and the cumulative group included 37 patients at 4 institutions. Baseline details regarding histology, sex, age, and medical operability are included in Figure 1. Elements of the radiation treatment received are also shown in Figure 1. Salvage surgery was performed at a median of 16 months following completion of SBRT, with a range of 6.4 to 104 months. Extent of resection is shown in Figure 1. Three (8.1%) operations were performed via minimally invasive approaches (2 thoracoscopic and 1 robotic-assisted). Adhesions were noted intraoperatively for nearly all (36/37, 97.3%) patients. Final pathology resulted in upstaging for 9/15 (60%) of patients in the MDACC group. Early postoperative outcomes were available for the 21 patients in the MDACC group (Figure 2). Two (9.5%) required post-operative admission to the intensive care unit (ICU), and stayed for a median of 5.5 days. Pulmonary complications were most common, occurring in 7 (33.3%) patients. Two (9.5%) patients had a prolonged air leak and 2 (9.5%) patients were discharged home on oxygen. During follow-up of the 21 MDACC patients, 5 developed recurrence. The three-year cumulative incidence of distant recurrence was 23.8%, with all recurrences distant and median time to recurrence 36.2 months. The median disease-free survival among MDACC patients was 19.2 months. Median survival from surgery for the MDACC group was 46.9 months, with 3-year survival of 53.2%. Thirty- and 90-day mortality were both 1 (4.8%). In the cumulative group, median survival was also 46.9 months and 3-year survival was 71.8%. Conclusions: Our findings demonstrate that resection following local failure of SBRT in highly select individuals is feasible, safe, and has an overall acceptable morbidity and mortality, albeit higher than what is typically observed in non-irradiated patients. In considering salvage resection, we recommend careful consideration of the patient's performance status and the likely extent of required resection, to be discussed thoughtfully both with the patient and in a multi-disciplinary tumor board setting. Further studies are clearly warranted to establish treatment algorithms for those patients who demonstrate locally persistent or recurrent disease following SBRT and to clinically characterize the most appropriate operative candidates.

Figure 1: Baseline and Treatment Details of MDACC & Cumulative Groups

	MDACC group	Cumulative group
Total patients	21	37
NSCLC	15 (71.4%)	26 (70.3%)
Squamous cell	*10 (66.7%)*	*17 (65.4%)*
Adenocarcinoma	*4 (26.7%)*	*7 (26.9%)*

MS07.03 POST SBRT MANAGEMENT: VS RADIATION

M. Trovo

ASUIUD, Udine/Italy

Stereotactic Body Radiation Therapy (SBRT) represents the standard of care for medically inoperable patients affected by early-stage Non-small cell lung cancer. Numerous phase I/II and retrospective studies have reported very high rates of local-progression free survival, ranging from 85% to 100% at two years. Interestingly, these data are reproducible among the published series, despite their heterogeneity. Severe lung toxicity (Grade ≥3 lung toxicity) is low, excluding centrally located tumor, ranging from 0% to <10%. Because of the following factors: 1) Very high local control rate, 2) very low clinical toxicity rate, 3) fragility of the treated population, the assessment of the response after SBRT has not be considered crucial in the patient management. Recently the perspective changed. Due to the excellent results in terms of local control, the publications of several paper that documented a superior outcome of SBRT vs. limited lung resection, and comparable data vs. lobectomy, more medically operable patients and less fragile populations have been treated in recent years. Moreover prospective trials on operable patients have been conducted. It is implicit that for operable patients the evaluation of a possible failure after SBRT is mandatory to guide further local (or systemic) therapies. Most patients with recurrent disease after SBRT will succumb to progressive cancer if left untreated. Although this is a frail patient population with competing risk of death, lung cancer specific mortality remains crucial. Even though chemotherapy might improve survival, the majority of patients are unfit to receive cytotoxic chemotherapy. However this scenario is going to be completely changed by the arrival of "immune-therapy" due to the overall favorable toxicity profile. The ESTRO-ACROP consensus guideline on implementation and practice of SBRT for early-stage NSCLC were recently published (1). Patient follow-up according to published guidelines is a mandatory component of any SBRT protocol. A frequency of 3-6 months in CT of the thorax is suggested, at least for the first year, thereafter the frequency might be tailored to whether the patient is medically operable or not. Three major items are considered of crucial importance when conducting the follow-up of the patient for the correct interpretation of follow-up images: 1) knowledge of the patterns of lung injury after SBRT; 2) detailed knowledge of the SBRT dose distribution, 3) knowledge of the pattern of failure. The discrimination between malignant lesion and post-radiation pneumonitis or fibrosis is often challenging. Both the radiation oncologist and the radiologist must be aware of the radiological patterns of SBRT-induced lung injury and of their relative frequency. This will become of crucial importance as SBRT is employed for treatment of operable patients, who can eventually benefit from salvage surgery for local relapse. The pattern of changes in lung parenchyma on CT post-SBRT can generally be categorized as acute (within 6 months) or late (after 6 months). Several patterns were described both for early and late radiographic changes (2). The differential diagnosis between local recurrence and fibrosis appear to be challenging in those patients who develop pattern characterized by dense consolidation and diffuse fibrosis. Such patterns can be classified as mass-like and modified conventional pattern, as we showed. Those patterns occur in about 74–76% of the cases. Patients who relapse have lesions that enlarged during the follow-up. Thus, a PET/CT in cases of enlargement of the lung fibrosis may be reliable in the differential diagnosis between recurrence and lung injury. FDG-PET imaging is considerate mandatory in case of suspected local recurrence on CT images, but it should be considered only optional during regular follow-up. Biopsy confirmation of suspected local failure is recommended only in patients who are likely to undergo salvage therapy if recurrence is detected. We share the idea of Huang and colleagues, who proposed an algorithm for follow-up of patients who are candidates for salvage therapies (3). 1. Guckemberger M, Andratschke N, Dieckmann K, et al. MS07.04 STAGE I (RESECTABLE) NSCLC: SURGERY

R. Tanaka

Kyorin University School of Medicine, Tokyo/Japan

Lobectomy and lymph node dissection have been the standard therapeutic procedure for localized lung cancer since Cahan's "Radical lobectomy" was published in 1960 [1]. In 1995, the Lung Cancer Study Group (LCSG) published findings from a randomized controlled study of clinical stage T1N0 non-small cell lung cancer (NSCLC), [2] that showed inferior overall survival and ~3× local recurrence rate in the limited (sublobar; segmentectomy or wedge) resection arm compared with the lobectomy arm. Although the LCSG study had some flaws (30% of patients had tumors >2 cm; wedge resections without lymph node dissection were performed as limited resections; inclusion of non-peripheral NSCLC in the limited resection arm, which could cause higher local recurrence rates), its results suggested that lobectomy is the superior option. Lobectomy has since been adopted worldwide as the surgical standard of care, whereas the indication for segmentectomy to treat lung carcinomas with solid appearances on computed tomography (CT) is controversial, although several non-randomized studies have suggested that survival and recurrence may be equivalent between lobectomy and sublobar resection (SLR) in patients with smaller lesions (≤ 2 cm) [3,4]. Improvements in imaging technology, such as thin-section CT (TSCT), have led to more patients who present with localized, early-stage lung cancers; and increased detection of small, peripheral NSCLC has renewed interest in SLR as an alternative to lobectomy. In addition, tumors with ground-glass opacity (GGO) have been correlated with less-invasive pathological findings of lepidic adenocarcinoma (AD) growth. Therefore, these patients may be feasible candidates for SLR. The Japan Clinical Oncology Group (JCOG) conducted a cohort study of early peripheral lung cancer (JCOG0201) and investigated the use of TSCT criteria to diagnose non-invasive lung AD, to preoperatively predict pathological non-invasive cancers [5]. Following this observational study, three ongoing trials (JCOG0804/WJOG4507L, JCOG1211 and JCOG0802/WJOG4607L) were initiated to confirm the validity of limited resection for stage I lung cancers, stratified according to preoperative TSCT findings. A non-randomized phase III trial (JCOG0804/WJOG4507L) was conducted to evaluate the efficacy and safety of SLR for peripheral GGO-dominant small lung cancers (tumor diameter ≤ 2.0 cm) and with consolidation tumor ratio ≤ 0.25, based on TSCT [6]. Five-year relapse-free survival (RFS) was 99.7% (95% CI: 97.7–100.0%), with no local recurrences. This study showed SLR (mainly wedge resection) to provide sufficient local control and RFS for peripheral GGO-dominant lung cancer (as seen on TSCT). A randomized phase III trial (JCOG0802/WJOG4607L) was conducted to compare overall survival after segmentectomy with that of lobectomy in patients with peripheral small (≤ 2 cm) NSCLC lesions [7]. The ongoing Cancer and Leukemia Group B (CALGB) 140503 trial is another large, multicenter randomized trial to compare disease-free survival between SLR and lobectomy among patients with peripheral small (≤ 2 cm) NSCLC lesions [8]; and is similar to the JCOG0802/WJOG4607L trial. However, as CALGB 140503 allows wedge resection as a surgical intervention, the JCOG0802/WJOG4607L trial offers a more definitive comparison of segmentectomy vs lobectomy for small invasive AD. The JCOG0802/WJOG4607L trial completed enrolling 1106 patients in 2014 and will clarify whether limited resection for primary lung cancer is not only function-preserving but also curative. The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines recommend segmentectomy or wedge resection for patients with insufficient pulmonary reserve or with other major comorbidities, and for patients with tumors ≤2 cm that are either (a) pure AD *in situ* (AIS) confirmed by histopathological analysis, (b) nodules with ≥50% GGO on CT, or (c) confirmed by radiologic surveillance to have long doubling times (≥400 days) [9]. However, we need the results from all prospective randomized trials to form new treatment strategies for early-stage lung cancers. [1] Cahan WG. Radical lobectomy. MS07 CONTROVERSIES WITH STEREOTACTIC RADIATION IN EARLY STAGE LUNG CANCER
MONDAY, SEPTEMBER 9 14:00–15:30

MS07.05 STAGE I (RESECTABLE) NSCLC: RADIATION

S. Senan

Amsterdam University Medical Center, Netherlands/Netherlands

For patients with a peripheral stage I NSCLC, the non-surgical treatment of choice is stereotactic ablative radiotherapy (SABR). Patients who are fit to undergo surgery, but instead undergo SABR, have a 3-year overall survival ranging from 76-86% [Siva S, Oncologist 2016], which is superior overall survivals in medically unfit patients treated using SABR. In 2013, the ESMO Clinical Practice Guidelines recommeded that surgery 'should be offered to patients with stage I or II NSCLC who are willing to accept procedure-related risks' [Vansteenkiste J, Ann Oncol 2013]. In the absence of completed randomized clinical trials of surgery versus SABR, a number of recent propensity score matched analyses have been performed. A pooled meta-analysis of propensity score matched data showed no significant differences in cancer specific survival between the two local treatments [Chen H, IJROBP 2018]. Changes in the treatment patterns for patients with early-stage NSCLC have be reported in a number of countries, all showing an increase in the utilization of SABR in mainly elderly patients [Damhuis R, Ann Oncol 2019; Holmes JA, JNCI Ca Spectrum 2017]. These findings are in part due to the increase in the frail elderly presenting with lung cancer, and to the growing awareness of treatment-related mortality in this population. For example, data from the US National Cancer Database revealed that differences in 30- and 90-day post-treatment mortality between surgery and SABR increased as a function of age, with the largest differences in favor of SABR observed among patients older than 70 years [Stokes WA, JCO 2018[. Ongoing and future randomized studies comparing both modalities will also have to take account of the view of patient preferences. This is illustrated by recent randomized trial of surgery versus SABR (SABRTOOTH, ISRCTN13029788), in which 84 high-risk patients were approached by pulmonologists and oncology nurses for study participation, and 24 (29%) were randomized [Franks K, WCLC 2018]. The main reason for declining study participation was patient preference with 29% preferring surgery and 42% SABR. Overall 9 patients (38%) did not receive their randomized treatment. Of 7 patients who had been randomized to surgery but not undergoing surgery, 6 received SABR, 1 radical radiotherapy. Similarly, of 2 patients randomized to SABR, but who did not undergo SABR, 1 patient received radical radiotherapy, and another was lost to follow-up. Other research which may influence the ongoing debate are the effects of both local therapies on the immune system. The systemic inflammatory response induced after surgery can promote the emergence of tumors whose growth was otherwise restricted by a tumor-specific T cell response [Krall 2018]. SABR, on the other hand, is actively being investigated as an immunomodulator to enhance systemic anticancer effects [Marciscano AE, IJROBP 2019], with a randomized placebo-controlled trial of immune-checkpoint blockade underway in this population (NCT03833154). MS07.06 HOT TOPICS IN SBRT - BIOPSY, CENTRAL LESIONS, RADIOLOGIC EVALUATION

C. Le Pechoux, A. Botticella, A. Levy, O. Henry, I. Chabert, C. Caramella

Gustave Roussy Cancer Campus, Villejuif/France

Stereotactic body radiotherapy (SBRT) has taken a growing place among treatment strategies in lung cancer in the past ten years because of its reported good results and favourable risk-benefit ratio especially in high-risk patients. This treatment modality allows delivering precisely a very high dose of radiation therapy to a targetable lesion, using a small number of fractions (3 to 5 more frequently). It has become the standard of care in medically inoperable peripheral early stage non-small cell lung cancer (NSCLC) patients. It is also frequently used in metastatic patients to treat cranial as well as extra-cranial metastases. Recently small randomised studies evaluating SBRT in oligometastatic NSCLC have shown promising results. Its role is now well accepted however there are situations where SBRT is still a subject of controversy and may be regarded as a hot topic because of the lack of pre-treatment biopsy because of less favourable outcome in central lesions and higher risk of complications because of the difficulty of radiologic evaluation When a peripheral lung nodule is discovered, suspect of being lung cancer, attempt should be made to obtain a pathological diagnosis before any treatment is proposed. Percutaneous CT–guided transthoracic biopsy is the established investigation in the work-up of pulmonary nodules, but there is a risk of complications such as pneumothorax (20-40%). However in patients with poor lung function (severe COPD, emphysema.), tissue sampling can be particularly challenging especially when the nodule is beyond the reach of conventional bronchoscopy. These are typically the patients that may be considered for SBRT, possibly presenting a contra-indication to transthoracic biopsy. Criteria for definition of a nodule as lung cancer without biopsy confirmation have been proposed such as progressive growth on CT imaging or presence of a hypermetabolic lesion on PET scan, and multidisciplinary tumor board consensus on the clinical diagnosis of lung cancer; there should be at least a 85% risk of malignancy, based upon accepted criteria [Postmus; Louie, Reid]. If stereotactic radiotherapy in peripheral early NSCLC is presently a standard of care in inoperable patients due to co-morbidities and age, its role is more controversial for centrally located tumors because of less favorable outcome and higher risk of complications. In the past years, there has been a need to better classify these patients differentiating ultra-central from central lesions. The RTOG 0813 phase I/II trial, evaluated dose escalation in 120 patients with centrally-located non-small lung cancer with a five-fraction schedule that ranged from 10 to 12 Gy per

fraction [Bezjak 2019]. The maximum tolerated dose was 60 Gy (5 fractions of 12 Gy), which was associated to a 2 year local control rate of 87.9%. They reported a fatal hemoptysis rate of 4%, potentially attributable to stereotactic radiotherapy [Bejzak 2015]. Even if the authors of this prospective study reported that outcome was comparable with that of patients with peripheral early-stage tumors, the risk of severe toxicity seems to be higher than in peripheral tumors. In another prospective phase II study, the Nordic hilus trial, which included 74 patients with central tumors within 1 cm from the proximal bronchial tree (PBT), the administered dose was 8 fractions of 7 Gy [Lindberg]. The authors reported a grade 4-5 toxicity of 19% among patients with tumor close to the main bronchus (ultra-central location) versus 3% in patients with tumor close to a lobar bronchus (central location). In a retrospective study of 88 patients with ultra-central lesions defined as tumors abutting PBT or trachea, or close to esophagus, a grade 3 toxicity or higher was reported in about 20% patients [Wang]. In another smaller retrospective study, where patients received 12 fractions of 5 Gy, outcome was quite good but toxicity ≥ grade 3 was reported in 38% of patients [Tekatli]. Thereby stereotactic radiotherapy for ultra-central tumors cannot be considered a standard treatment and more studies are needed for all central tumours to find the optimal dose regimen. Radiological evaluation after SBRT is performed mostly with chest CT scan, and changes occurring early and/or late are very common but can be tricky for radiologists as well as clinicians [Ronden, Febbo]. If FDG PET-CT is well established as staging tool prior to treatment, it is generally not used for surveillance. It may be useful though to differentiate local recurrence from radiation-induced lung opacity. Ideally, a treatment failure suspicion should be confirmed with a biopsy. These hot topics regarding SBRT show the difficulty to include patients into prospective trials; efforts have been made and should be pursued. References Postmus PE, Kerr KM, Oudkerk M, et al. MS08 MANAGEMENT OF THYMIC CARCINOMA
MONDAY, SEPTEMBER 9 14:00–15:30

MS08.01 ADJUVANT RADIOTHERAPY FOR RESECTED THYMIC CARCINOMA

A. Brade

Trillium Health Partners, Mississauga/Canada

Thymic carcinoma is a rare malignancy with peak incidence in the 4th-6th decade. In contrast to thymoma, it is commonly associated with higher rates of both lymph node and distant metastatic spread and also with shorter disease free survival. For localized or locally advanced disease, surgical resection, with the intention of complete disease extirpation, remains the standard of care. Due to its rarity however, definitive clinical trial data regarding optimal and appropriate addition of adjuvant therapy is lacking. Thus decision making for post-operative patients is guided by data from large institutional, national or international retrospective series or databases (evidence level IV or V). Recommendations for adjuvant therapy for thymic carcinoma are influenced principally by stage and adequacy of resection (R0 vs R1 vs R2). Thymic carcinoma is classically staged us the Masaoka-Koga (MK) system but, based on recommendation to the AJCC by the IASLC Staging Prognostic Factors Committee and the International Thymic Malignancy Interest Group (ITMIG), using a database of more than 10 000 patients (Detterbeck et al 2014), a TNM-based system has now been incorporated into the 8th Edition of the AJCC/UICC TNM Classification of Malignant Tumours. However, since much of the published data regarding thymic malignancies is based on the Masaoka-Koga system, at present this remains commonly used for clinical decision-making but, as data continues to accumulate, will likely be superseded by the TNM system over time. Post-operative radiotherapy is routinely recommended for patients with MK stage III (TNM Stage I – T1bN0, Stage II, IIIA/B) thymic carcinoma following R0 resection. Similarly, adjuvant radiation is recommended following R1 resection, regardless of stage, with adjuvant chemoradiation recommended following R2 resection. Adjuvant radiotherapy is not recommended for MK I or IIA (TNM Stage 1 T1aN0 with no extension to mediastinal fat) disease. Controversy exists regarding the utility of adjuvant radiotherapy in the management of MK IIB (TNM Stage I – T1aN0 with extension to mediastinal fat) disease but can be considered for this group of patients. The optimal adjuvant radiotherapy dose remains undefined for thymic carcinoma patients but typical doses reported in the literature for patients in the above recommended groups range from 45-50 Gy in 1.8-2 Gy per fraction daily. Following R1 resection, 50-54 Gy in 1.8-2 Gy per fraction is typically recommended. Following R2 resection, 60-70 Gy (with or without concurrent chemotherapy) is considered standard. Nodal involvement is much more frequent in patients with thymic carcinoma compared with thymoma. Resected, unexpectedly N+ patients are typically recommended to receive adjuvant RT to 45-60 Gy if complete resection was obtained or 60-70 Gy (with or without concurrent chemotherapy) if residual nodal disease is suspected/documented. Under the TNM staging system, N1 nodes are defined as those in the anterior mediastinal compartment (IASLC levels 1, 3a, 6 and/or supradiaphragmatic/inferior phrenics/pericardial) and N2 nodes are defined as deep intrathoracic or cervical nodes (IASLC levels 2, 4, 5, 7, 10 and/or internal mammary nodes). Whether inclusion of N1 or N2 nodal compartments in adjuvant RT target volumes is of benefit for N0 or completely resected N1 or N2 patients remains unknown but may be prudent to consider during radiotherapy planning based on clinical factors. Radiotherapy should conform to modern standards with CT-based simulation with photon-based 3D conformal or beam-modulated treatment delivery, motion management and image guidance to reduce margins and dose to organs at risk. The utility of adjuvant proton-based RT for patients with resected thymic malignancy remains the focus of ongoing study but may offer some dosimetric advantages with respect to OAR dose (e.g. lung or heart). MS08.02 INDUCTION THERAPY FOR LOCALLY ADVANCED THYMIC CARCINOMA

R. Korst

Mount Sinai Health System, New York/United States of America

Thymic carcinoma (TC) is a rare mediastinal malignancy that occurs in approximately 10% of all patients with thymic epithelial tumors. There are several different histologic subtypes of TC with squamous cell carcinoma predominating. TC is an aggressive lesion, and frequently presents in more advanced stages and metastasizes to other organs compared to thymoma. This biologic behavior is reflected in the survival rates associated with TC, which are significantly shorter than that of thymoma. Clinical trials conducted exclusively in TC patients have been scarce with only a handful of studies reported in the literature, all focused on advanced, nonsurgical patients. Locally advanced, nonmetastatic disease is a common presentation of TC. In the largest retrospective series reported to date, locally advanced disease was the most common stage at presentation, accounting for 45% of patients in whom pathologic stage was recorded[1]. The importance of complete resection for patients with locally advanced TC cannot be overemphasized. Virtually all reported series of exclusively TC patients that undergo surgical resection have determined that the ability to perform a complete resection is an independent favorable prognostic factor. Despite this, the rate of complete resection in the large, aforementioned series for locally advanced TC was only 64%. Given that thymic epithelial tumors (thymoma and TC) are sensitive to both chemotherapy and radiotherapy, an approach that has been favored for patients with locally advanced disease is to administer one or both of these agents preoperatively (neoadjuvant therapy). This strategy is thought to increase the chances of performing a complete resection for marginally resectable or unresectable tumors. Although no clinical trials have been reported exclusively for TC patients using the neoadjuvant strategy, two retrospective reports in TC patients utilizing neoadjuvant chemotherapy or chemoradiation demonstrated complete resection rates of 86% and 69% in marginally resectable or unresectable locally advanced disease[2,3]. In a phase II clinical trial of neoadjuvant chemoradiotherapy for locally advanced thymic tumors, the complete resection rate for the seven patients that had thymic carcinoma was 71%[4]. Despite these data, the ability of neoadjuvant therapy to definitively enhance the resectability of locally advanced TC has not been demonstrated due to the absence of randomization and a control group in these studies. Some published data have also suggested that TC may respond better to neoadjuvant therapies when compared to the thymoma histotypes. In the previously described phase II trial of neoadjuvant chemoradiotherapy, the patients with TC not only had a better radiographic response to treatment, they were more likely to have a near complete pathologic response (<10% viable tumor) than the patients with thymoma (57% versus 8%)[4]. Similarly, in a retrospective pathologic analysis of 49 patients with unresectable thymic tumors that underwent neoadjuvant therapy followed by surgical resection at a single institution, the median percent viable tumor in the surgical specimen was significantly less in the TC specimens compared to thymoma (20% versus 91%)[5]. These two studies also suggest that TC may respond better to chemoradiotherapy than chemotherapy alone. Whether targeted or immune therapies can be used successfully in the neoadjuvant setting for TC remains to be determined. Active targeted agents against this disease have remained elusive and immunotherapy may be associated with autoimmune toxicities that may preclude their use in this approach[6]. In summary, the use of induction therapy for locally advanced TC is based on the premise that this approach may enhance resectability of these aggressive tumors, which is an overwhelmingly positive prognostic indicator. However, no published data has conclusively determined that this strategy is effective in enhancing resectability due to a lack of controlled studies. TC may respond better to induction therapy when compared to thymoma, and chemoradiotherapy may induce more radiographic and pathologic responses than chemotherapy alone, but these data are preliminary. MS08.03 OPTIMAL MANAGEMENT OF METASTATIC THYMIC CARCINOMA

G. Giaccone

Georgetown University, Washington/United States of America

Thymic carcinoma represents approximately 10-15% of all thymic epithelial tumors, it is more aggressive than thymomas and also somewhat less sensitive to chemotherapy. More often than thymomas, thymic carcinomas are not resectable and therefore the use of systemic therapies and radiation are more often required than in thymomas. In general the sensitivity of thymic carcinomas to chemotherapy is lower than with thymomas, with response rates usually less than 50% in metastatic disease, and somewhat higher in locally advanced disease. In presence of borderline operable cases, neoadjuvant chemotherapy is indicated, in order to make the tumor more easily operable. Because thymic carcinomas often infiltrate surrounding tissues, radical resection are sometimes not achievable. The use of postoperative radiation is indicated even if margins are clear. Several chemotherapy regimens have been used, and the more commonly employed remain platinum combinations, with or without an anthracycline (mainly doxorubicin). More recently data the combination carboplatin-paclitaxel has been added to the potential chemotherapy regimens and it is often preferred becasue of its milder toxicity profile. When radiation is planned, the use of doxorubicin is contraindicated, becasue of the enhanced toxicity. The role of debulking surgery, reoperation and metastasectomy is much more controversial in thymic carcinomas than in thymomas, given the more aggressive behaviour. However, the histological diagnosis sometimes is not paralleled by an aggressive phenotype and individual treatment decisions should always be considered. Unfortunately thymic carcinoma have the tendency to metastatize wildly to virtually all organs, and brain metastases are all but rare. Complete staging procedures, including brain MRI are therefore indicated in patients with thymic carcinoma. In patients with metastatic disease, chemotherapy is indicated as first line therapy, and the CAP regimen (cisplatin, doxorubicin, cyclophosphamide) or carboplatin-paclitaxel, are the preferred regimens, with response rates in the range of 30-50%. Unfortunately, chemotherapy at this stage is not curative and most patients will require further systemic therapies after failure of chemotherapy. There have been a number of studies in recent years, which have established activity of a few agents, such as sunitinib and pembrolizumab in thymic carcinomas. Both of them are now listed in the NCCN guidelines and have a response rate of about 25%. Pembrolizumab however has a much longer duration of response, albeit the frequency of severe autoimmune disorders is higher than in other diseases in which immune checkpoint inhibitors are used. Further chemotherapy also has some activity, such and the combination gemcitabine-capecitabine and other single agents, with responses in the 20-30% range. The biology of thymic carcinoma does not appear to provide clues to specific treatments, although mutations in epigenetic genes have been found in a significant number of patients. No easily targetable mutations or genetic abnormalities have so far been found. The most common mutation is in the p53 gene, in about 30% of cases, which is not targetable and is associated with a poorer survival.

MS08.04 NOVEL BIOMARKERS FOR THYMIC CARCINOMA

B. Casini[1], E. Gallo[1], E. Melis[1], F. Cecere[1], V. Laquintana[1], V. Cerasoli[1], F. Facciolo[1], E. Pescarmona[1], F. Fazi[2], M. Marino[1]

[1]*IRCCS Regina Elena National Cancer Institute, Rome/Italy,* [2]*Sapienza University, Rome/Italy*

Thymic carcinoma (TC), the rarer among Thymic Epithelial Tumors (TET), occur with an incidence rate of 0.2-0.5/million/yr. Difficulties in the evaluation of molecular aspects derive from the extreme rarity of these tumors. The Squamous cell carcinoma (SQCC) is the most frequently analyzed, however the other rarer histotypes could differ both in molecular pathogenesis and in clinical behaviour. The Cancer Genome Atlas Thymoma study (TCGA-THYM) in a series of ten TC cases including four SQCC, four undifferentiated carcinoma and both one large cell neuroendocrine carcinoma as well as one TC, NOS, identified a few genes rarely mutated, including KIT, HRAS, NRAS and TP53, reflecting the low mutational burden of these tumors (1). In the last years, only a limited number of TC has been investigated by other groups and only a limited number of relevant alterations has been identified. In addition to genomic events, however, epigenetic factors could contribute to TET carcinogenesis. Wang et al. in 2014 performed targeted sequencing of 197 cancer-associated genes in 78 advanced-stage TET patients, including 47 TC and 31 thymoma (THYM) cases. They reported that TC showed a higher incidence of somatic non-synonymous mutations than THYM. Moreover, they found that mutations of epigenetic regulatory genes involved in chromatin modification pathways are common in TC in comparison to THYM (2). In the last years we have been interested in the characterization of genomic and epigenetic findings related to TET development. In our earlier microRNA (miR) study, we reported, among other findings, preliminary data on mature microRNAs differentially expressed in TC vs THYM, as revealed by microarray-based unsupervised clustering analysis. Among the differentially expressed miRs, 3 were validated by RT-qPCR (miR128, miR142-5p and miR-181c-5p) (3). By a different approach, we analyzed by Next Generation Sequencing (NGS) thirteen TC cases and one Atypical Type A thymoma case. The tissues derived from Formalin-fixed, paraffin embedded (FFPE) material including biopsies/surgical specimens of tumors and a single case of matched peritumoral thymus. The percentage of neoplastic cells was not < 70-80% of total cells. The DNA was extracted using the QIAcube and QIAamp DNA FFPE Tissue Kit (Qiagen, Valencia, CA) from microdissected 5 μm FFPE tissue sections. The NGS platform Ion S5 (Thermofisher) and the Ion AmpliSeq™Cancer Hotspot Panel v2 were used. This panel is designed to amplify 207 amplicons covering over 2,800 COSMIC mutations from 50 oncogenes and tumor suppressor genes. Libraries from Ion AmpliSeq Cancer Hotspot Panel v2 were prepared and sequenced by Ion Chef and S5 system. Data analysis was conducted by using the dedicated Ion Reporter Software. Among other genomic variants (polymorphysms and mutations were found in four cases), in one out of these four TC cases a KIT mutation (c.1900C>T; p.R634W, exon 13), already reported in TC, was identified. Moreover, a further KIT mutation (c.1718C>T p.P573L, exon11) was found in a second case. In addition, a missense TP53 mutation (c.824G>T; p.C275F), occurring in exon 8, was observed in a single case of TC, NOS. The patient harbouring a TC with this TP53 mutation had a R0 robotic-assisted thymectomy of a pT2 Thymic carcinoma (according to the 8th TNM edition), and after adjuvant chemotherapy and radiotherapy is alive and in complete remission with a follow-up of 22 months. The recent case of Atypical Type A thymoma showed a NOTCH1 c.4732_4734delGTG p.V1578del in exon 26 of uncertain significance. Basing on the relatively few cases reported in the literature, analyzed by different techniques for their genomic alterations, it appears that the mutation status of TC is highly heterogeneous. In the cases examined so far by NGS we didn't find recurrent genetic aberrations, but a variety of alterations. Each case, with the panel available, revealed either polymorphisms or, in few cases, mutations in cancer-associated genes, both oncogenic and oncosuppressor. Among the genes involved, both the KIT reported variants could be considered relevant for targeted therapy. Moreover, the tumor suppressor gene TP53 is already known for its importance and frequency of mutations particularly in TC. Moreira et al reported recurrent TP53 mutations with unfavorable prognostic value (4). The TP53 mutation found in one of our cases (previously reported in cases of SQCC of upper respiratory tract, in lung, head & neck and esophageal carcinoma) affects, among others, the DNA damage repair, the cell cycle and the apoptosis pathways. In human thymus, the Notch pathway, activated in thymic EC, is crucial to T cell differentiation; moreover the Notch signaling is also involved in hematological and in solid tumors. The NOTCH1 c.4732_4734delGTG p.V1578del in exon 26 we reported in a Atypical case A thymoma was already described in lymphoid tissues. The clinical and prognostic value of the genomic alterations we observed needs to be definied. 1) Radovich M, et al., The integrated genomic landscape of thymic epithelial tumors - Cancer Cell, 2018 Feb 12;33(2):244-258 2) Wang Y, et al., Mutations of epigenetic regulatory genes are common in thymic carcinomas - Sci Rep. 2014 Dec 8;4:7336 3) Ganci F, et al., MicroRNAs Expression Profiling of Thymic Epithelial Tumors - Lung Cancer 2014, 85 (2) 197–204 4) Moreira AL, et al, Massively parallel sequencing identifies recurrent mutations in TP53 in thymic carcinoma associated with poor prognosis - J Thorac Oncol. 2015 Feb;10(2):373-80

MS08.05 BASIC PATHOLOGICAL FEATURES

C. Moran

MD Anderson Cancer Center, Houston/United States of America

Pathologic Features The basic pathological features of thymic carcinomas are essentially those seeing in other tumors elsewhere and require the presence of conventional features such mitotic activity, cellular and nuclear atypia, and necrosis among others. However, the diagnosis of thymic carcinoma contrary to the diagnosis of carcinomas in other anatomical areas requires a more strict radiological correlation, as thymic carcinoma can show similar histological features as other tumors such lung or head and neck area. Therefore, the clinical information of an anterior mediastinal mass in the absence of tumor elsewhere becomes an important diagnostic tool in the assessment of thymic carcinoma. The histopathological features of thymic carcinomas are vast and highly heterogeneous. It is possible that such heterogeneity may be due the different cell types that may be encountered in the normal thymus. However, in general terms, thymic carcinomas can be separated into neuroendocrine and non-neuroendocrine carcinomas, and further sub-divided into: 1) low grade and 2) high grade carcinomas (see table 1). Among the neuroendocrine carcinomas, similar spectrum as in other organ systems has been recognized, including: low grade, intermediate grade, and high grade neuroendocrine carcinoma. Some of these tumors may have special association with particular syndromes. Aside from the neuroendocrine carcinomas, the vast majority of thymic carcinomas are of the squamous type, which can show diversity in their growth pattern from well-differentiated keratinizing to the high-grade lymphoepithelioma-like carcinoma and anaplastic/pleomorphic carcinoma. In addition, the tumors may show different cell types and growth patterns that may include: papillary, micropapillary, clear cell, sarcomatoid carcinomas, and micronodular among others. In addition, it is important to highlight the occurrence of salivary gland type carcinomas in the thymus, examples of that include: mucoepidermoid carcinoma, adenoid cystic carcinoma and epithelial-myoepithelial carcinoma. More interesting is the fact that a small subset of thymic carcinomas will belong to the adenocarcinoma type, with similar features as those adenocarcinomas in other organ systems – mainly a malignant glandular proliferation. These tumors may also show variability in their growth pattern and may show a solid glandular proliferation or a predominantly mucinous component. Needless to say, these thymic adenocarcinomas can mimic metastatic disease from other organ systems such as lung or colon. Therefore, a close clinical correlation is also highly suggested before determining site of origin. It is due to this heterogeneity that the diagnosis of primary thymic carcinoma requires more strict clinical-radiological-pathological criteria, as there are no pathognomonic features that can define a thymic carcinoma, mainly in cases in which there is only a small mediastinoscopic biopsy for evaluation. From the immunohistochemical point of view, thymic carcinomas commonly express keratin, keratin 5/6, p63, p40, CD5. In addition, it is also well known that some neuroendocrine markers such as synaptophysin may be seen positive in otherwise conventional thymic carcinomas. On the other hand, thymic adenocarcinomas may express different immunohistochemical phenotype that may include: keratin 7, keratin 20, CDX-2, and CEA. In cases of neuroendocrine carcinomas the use

of neuroendocrine markers including chromogranin, synaptophysin, and CD56 may prove useful. However, the grade of differentiation still can be done on morphological grounds. More recently, it has been identified a poorly differentiated carcinoma the so-called NUT carcinoma that by histology most likely represents a poorly differentiated squamous carcinoma but that shows positive staining using the immunohistochemical stain for NUT and also may show more specific cytogenetic and chromosomal abnormalities. Such diagnosis should be suspected in poorly differentiated carcinomas. Regarding the prognosis of thymic carcinoma, it has been identified that the presence of lymph node metastasis, regardless of the location of the lymph node, plays an important role in the clinical outcome of these patients. Therefore, thymic carcinomas are best suited for a TNM staging, contrary to the use of the TNM for thymomas. MS09.01 IMMUNE CHECKPOINT BLOCKADE FOR SCLC: STATE OF THE ART

S. Antonia

Duke Cancer Institute, Durham/United States of America

It is clear that small cell lung cancer can be an immunotherapeuticly responsive disease. Single agent anti-PD1 and anti-PD-L1 can produce tumor regressions. Anti-PD-L1 given in combination with chemotherapy produces a survival benefit when given as first-line therapy for extensive stage disease. Anti-PD1 is also an option in third line. Although responses are produced in the second line setting neither anti-PD1 nor anti-PD-L1 has proven to produce a survival benefit in unselected patients. The proper application of relevant biomarkers such as TMB has the potential to identify patients who are likely to benefit. Given the fact that small cell lung cancer tumors have a paucity of tumor infiltrating lymphocytes, it is not surprising that immunotherapeutics solely directed at the immune suppressed tumor microenvironment have limited clinical activity. It is likely that combination immunotherapy, with a component of the combination influencing the lymphoid compartment to increase the number of tumor reactive T cells will be necessary to significantly increase the clinical activity of immune-based therapies. There are several potential ways that this could be accomplished. Anti-CTLA.4 can have an impact on regulatory T cells in the tumor microenvironment, however at least in melanoma it has been shown to be operational within the lymphoid compartment as well to increase circulating tumor reactive T cells. Anti-CTLA.4 has been combined with both anti-PD1 and anti-PD-L1. Response rates of the combination have been higher than what can be produced with anti-PD 1 monotherapy. The combination has not yet been shown to produce a survival advantage. Another approach to increasing tumor reactive T cells is to utilize radiation which can release tumor antigens and immunogenic fashion. Trials are ongoing combining radiation with anti-PD1 and anti-CTLA.4. Vaccines offer another potential means to accomplish expansion of tumor reactive T cells. An autologous dendritic cell based vaccine with p53 as the tumor antigen has been shown to produce clinical responses in small cell lung cancer as monotherapy, and is now being combined with anti-PD1 and anti-CTLA.4. An alternative approach is to redirect peripheral T cells through ex vivo transduction with tumor protein-specific antigen binding molecules. An example of this is a chimeric antigen receptor specific for DLL 3. These sorts of combinations have the potential to advance the efficacy of immunotherapy for small cell lung cancer.

MS09.02 CLINCAL AND MOLECULAR BIOMARKERS FOR SELECTION OF SCLC PATIENTS CANDIDATE TO IMMUNECHECKPOINT BLOCKADE

L. Byers

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Immunotherapy has dramatically altered the treatment options available to patients with lung cancer. In the past year, small cell lung cancer (SCLC) fully joined the immunotherapy era with approvals by the US Federal Drug Administration (FDA) for three separate immune checkpoint inhibitors – atezolizumab for frontline therapy in patients with extensive stage SCLC (ES-SCLC) (in combination with platinum-etoposide chemotherapy) and nivolumab and pembrolizumab (each as monotherapy) for relapsed SCLC. The combination of nivolumab plus ipilimumab also demonstrated durable activity in a subset of patients treated on the Phase 1/2 CheckMate032 trial, with an overall response rate of 22% and a 2 year overall survival rate of 26%.1 The addition of atezolizumab to carboplatin and etoposide as a new standard of care was based on results from the Phase 3 IMpower133 trial.2 In that randomized trial, the addition of atezolizumab to carboplatin-etoposide, followed by atezolizumab maintenance, led to improvements in both progression free survival (PFS) (4.3 months in the placebo control arm versus 5.2 months in patients receiving atezolizumab) and overall survival (OS) (10.3 months with placebo versus 12.3 months with atezolizumab). Additional randomized trials testing other immune checkpoint inhibitors in combination with standard platinum-etoposide chemotherapy are ongoing, with clinical findings expected in the next several months. This includes the phase 3 trial of durvalumab plus platinum-etoposide (CASPIAN), which has now been reported to show improved overall survival (OS) with the addition of durvalumab at a planned interim analysis (press release). Despite these landmark approvals for immune checkpoint inhibitors in ES-SCLC, a large number of patients with SCLC do not appear to receive clinic benefit with the currently available inhibitors of PD-1/ PD-L1 and/or CTLA-4. Furthermore, there are not yet established biomarkers for identifying those patients with SCLC who are likely to respond. As with non-small cell lung cancer, immunohistochemistry (IHC) for PD-L1 levels and tumor mutation burden (TMB) are both candidate biomarkers.3,4 However, neither of these have been prospectively validated to date in SCLC and there may be important differences in their performance depending on how testing is done (e.g., variation between antibodies, scoring methods/cutoffs, or technical differences between molecular platforms). Recently, new combinations of targeted therapies together with immune checkpoint inhibitors (such as inhibitors of DNA damage response (DDR) such as PARP1 or Chk1 to enhance STING pathway activation) have demonstrated promise in preclinical studies of SCLC and are being translated into the clinic for further investigation.5 In addition, other new immunotherapeutic approaches are being tested in ongoing trials. Examples of these include studies of chimeric antigen receptor T-cells (CAR-T) and bi-specific T-cell engagers (BiTE molecules) targeting the notch inhibitor ligand DLL3 for patients with relapsed SCLC. In this context, additional biomarkers related to specific combinations of targeted and immune-therapies and/or new classes of immunotherapy (e.g., SLFN11 levels for PARP inhibitors; cMyc status for Chk1 inhibitors; markers of STING pathway activation; or DLL3 expression levels) may emerge as additional biomarkers relevant to immune responses. Finally, a better understanding of tumor and immune environment heterogeneity between patients – as well as intra-tumoral heterogeneity – will lead to more effective

strategies for matching patients to specific immunotherapies and overcoming immunotherapy resistance. REFERENCES 1. Della Corte CM, Gay CM, Byers LA. MS09.03 SMALL CELL LUNG CANCER: THE IMMUNE MICROENVIRONMENT

S. Liu

Georgetown University, Washington/United States of America

Based in part on the relatively high tumor mutational burden (TMB) and the strong link to tobacco use, there was a relative optimism regarding the prospects of success with immunotherapy in small cell lung cancer (SCLC). Over the past few years, while we have seen promising activity with checkpoint inhibitors in SCLC, the gains have been somewhat modest. As in other immune-responsive tumors, durable responses and long-term survival are possible. Nivolumab and pembrolizumab monotherapy have both demonstrated impressive durations of response, circling 18 months in the third line setting (Ready, JTO 2018; Chung, AACR 2019). Landmark survival rates far exceed historic controls in this setting. Meaningful benefit, though, is limited to a subset of patients, with response rates of only 12-19%. Both agents received accelerated approval by the FDA as third-line therapy for SCLC, but given the high attrition rate in SCLC, the impact of these approvals will be limited. Second-line and maintenance trials have failed to improve upon historic standards (Reck, ESMO 2018; Owonikoko, ELCC 2019). Fortunately, the addition of the PD-L1 inhibitor atezolizumab to first line carboplatin and etoposide improved both progression-free survival and overall survival (Horn, NEJM 2018). While the long-overdue improvement in survival was important and led to the FDA approval of atezolizumab in March 2019, there is significant room for improvement. The current use of checkpoint inhibitors in SCLC is empiric, though it is glaringly obvious that the true, durable benefit is limited to a subset of patients. Biomarkers are needed to identify those patients – to ensure they receive the appropriate therapy but also to help direct other patients to novel strategies. Predictive biomarkers can also provide valuable insight into the underlying biology of immune responses. Biomarker studies are challenging in SCLC; tissue samples are often scant, and the aggressive nature of the disease often precludes in depth study. Early data, though, speak to particular importance of the immune microenvironment in SCLC. Expression of PD-L1 by immunohistochemistry holds predictive value in non-small cell lung cancer (NSCLC). Its role in SCLC is evolving. In the CheckMate-032 study, nivolumab alone or in combination with the anti-CTLA-4 antibody ipilimumab, was explored in patients with previously treated SCLC (Hellmann, ASCO 2017). Using the 28-8 PD-L1 clone and a cutoff of 1%, only 18% of evaluable samples expressed PD-L1. Surprisingly, responses were more frequent in the PD-L1 negative tumors. With nivolumab alone, the response rate was 9% in PD-L1 positive tumors compared to 14% in PD-L1 negative tumors. With the combination of nivolumab and ipilimumab, the difference was even greater with a 10% response rate in PD-L1 positive tumors compared to 32% in PD-L1 negative. Some parallels are seen with pembrolizumab, but our understanding of PD-L1 as a biomarker is evolving. In a single arm study of maintenance pembrolizumab for SCLC (Gadgeel, JTO 2018), only 3 out of 30 patients had tumors with PD-L1 expression using the 22C3 clone (tumor proportion score, TPS). While the median PFS for the entire population was only 1.4 months, the 3 patients with TPS PD-L1 positive tumors all had a PFS over 10 months. Expression of PD-L1 at the stromal interface was also explored (combined proportion score, CPS). More patients had PD-L1 positive tumors using the CPS approach (8/20, 40%) and outcomes were superior in the CPS PD-L1 positive population: response rate was 37.5% vs. 8.3%, median PFS was 6.5 months vs. 1.3 months, and median overall survival was 12.8 months compared to 7.6 months. Similar results were seen in the salvage setting. In KEYNOTE-158, patients with previously treated SCLC received pembrolizumab monotherapy (Chung, ASCO 2018). Using the CPS approach, 39% of patients were PD-L1 positive, 47% were negative and 14% were non-evaluable. Again, outcomes favored the CPS PD-L1 positive subset including response rate (35.7% vs. 6%) and overall survival (14.9 months vs. 5.9 months). A separate retrospective analysis of a 95-sample cohort noted tumor expression of PD-L1 in 18% of samples but PD-L1 expression on tumor infiltrating lymphocytes (TILs) was seen in 67% of samples (Rivalland, ASCO 2017). There was no difference in survival based on tumoral expression of PD-L1, but median survival was longer in patients with PD-L1 positive TILs compared to PD-L1 negative TILs (17.2 months vs. 7.9 months, HR 0.36; 95% CI 0.22-0.60). The importance of the immune microenvironment in facilitating an immune response is becoming increasingly clear but it extends beyond expression of PD-L1. The presence and the specific location of tumor-infiltrating T-cells also holds value. Specific immunophenotypes are present and have been described as immune-desert (with few or no CD8+ T cells), immune-excluded (with CD8+ T cells present but limited to the adjacent stroma), and immune-inflamed (with CD8+ T cells in contact with tumor cells). A study of olaparib and durvalumab examined these phenotypes in patients with advanced SCLC (Thomas, JTO 2019) and found 14% with an immune-desert phenotype, 64% of samples with an immune-excluded phenotype and 21% with an immune-inflamed phenotype. PD-L1 expression was noted in all patients who achieved a response but was also noted in non-responders. In contrast, all of the patients with an immune-inflamed phenotype achieved a response. Much more work is needed to fully understand how the immune microenvironment facilitates (or precludes) immune responses. It is not yet clear whether these characteristics can be used as a predictive marker for use of checkpoint inhibitors. It is also not clear whether strategies to alter the microenvironment (with radiation therapy or other immune modulators) will induce effective immune responses. What is clear is that empiric therapy can only take us so far in the management of this exceptionally lethal disease. The path forward will require insight into the complexities orchestrating immune responses and a personalization of therapy for specific subsets of SCLC, subsets that certainly exist but, to date, evade proper detection. We have made tremendous strides in recent years to improve outcomes in SCLC but there remains much work to do.

MS10.01 COPD/EMPHYSEMA

J. Zulueta

Clinica Universidad de Navarra, Pamplona/Spain

Lung cancer and COPD are now the second and third most frequent causes of death in the US. Mortality from COPD has increased by 86% in the last 25 years (1), but remains a greatly underdiagnosed disease. Furthermore, COPD, and in particular emphysema, has been shown to signficantly increase the risk of having, and dying from, lung cancer (2-4). In spite of these facts, the USPSTF continues to recommend against screening for COPD mainly because there is no evidence showing that any treatment or intervention can have an impact on the outcome of COPD. In this presentation we will review the latest data showing that lung cancer screeing may be an opportunity to uncover a large proportion of patients with underdiagnosed COPD, and that screening for lung cancer may have an impact on long term outcome of COPD. In addtition, the presence of COPD and/or specific subtypes of emphysema may be key in improving the selection of optimal candidates for lung cancer screening. Questions regarding the potential harms involved in screening for lung cancer in individuals with COPD/emphysema will be addressed. 1. Mulshine. AJPH 2018; 108:1294-5 2. de Torres et al.

MS10.02 CORONARY ARTERY DISEASES

J. Shemesh

Sheba Medical Center Affiliated to Tel Aviv University, Ramat-Gan/Israel

CT-based Coronary artery calcification (CAC) Agatston score on Lung cancer screening has an unequivocal prognostic contribution to future cardiovascular (CV) events and mortality. : To provide the radiologists with helpful information regarding on how to diagnose, quantify and routinely report on CAC while reading low dose chest CT (LDCT) performed for lung cancer screening. : CAC can be easily detected and its extent can be quantify or semi-quantify while reading the chest CT without extra radiation, efforts or cost. Most of the target subjects for lung screening are at the same time at high risk to develop cardiovascular (CV) events and mortality (1). Reporting on CAC enhances the lung screening benefit by providing the clinicians with an additive powerful risk stratification tool that can improve the management of primary prevention of CV events particularly the need for statin. Recently the Society of Cardiovascular Computed Tomography (SCCT) and the Society of Thoracic Radiology (STR) have jointly published guidelines for coronary artery calcium scoring derived from non contrast noncardiac chest CT scans (2). The experts of this guideline, recommend reporting on CAC as indication. It has been shown that the absence, presence and severity of CAC identify those who are most likely to benefit from statin therapy for primary prevention (3) Comparing those with and without statin exposure, statin therapy was associated with reduced risk of MACE in patients with CAC but not in patients without CAC. They further found that the effect of statin use on MACE was significantly related to the severity of CAC, with the number needed to treat to prevent 1 initial MACE outcome over 10 years ranging from 100 (CAC 1 to 100) to 12 (CAC >100). The most recent guidelines recognize the CAC score as disease score that can individualize the CVD risk and recommended its use to refine the risk estimation in order to better allocate asymptomatic subjects to statin treatment,intensification or avoidance, for primary prevention of CVD (4). The Multi-Ethnic Study of Atherosclerosis (MESA) score is a new score that incorporates the Agatston CAC score in addition to traditional risk factors to estimate the 10 years cardiac risk (5) CAC is the most prevalent incidental finding on LDCT. It can be easily detected measured and reported on lung screening CT without extra radiation, efforts or cost. CAC score helps to avoid or recommend life time statin or aspirin treatment. 10 Take home messages Most of the target subjects for lung screening are at the same time at high risk to develop cardiovascular (CV) events and mortality. CAC is the most prevalent incidental finding on LDCT CAC is the best biologic prognostic marker for the prediction of CV events and mortality. The measure of CAC is now accepted as common practice for primary prevention of CV events. CAC can and should be measured and reported on chest CT done for lung cancer screening. CAC is associated strongly and in a graded fashion with 10-year risk of incident ASCVD as it is for CHD, independent of standard risk factors, and similarly by age, gender, and ethnicity. While those with zero CAC are almost exclusively below 5% 10 years risk (statin is not indicated), those with CAC≥100 were consistently above 7.5% (statin is indicated). In a large-scale cohort without baseline ASCVD, the presence and severity of CAC identified patients most likely to benefit from statins for the primary prevention of CVDs: There was no benefit of statins in those with no CAC and low or intermediate baseline risk. Patients with a CAC >100 had a 64-71% reduction in MACE even with low (<5%) or intermediate risk (5-20%). Reporting on CAC enhances the lung screening benefit by providing the clinicians with an additive powerful risk stratification tool that can improve the management of primary prevention of CV events particularly for the initiation / withhold / intensification / avoidance of statin treatment. CAC can be estimated as none, mild, moderate or severe but it is recommended to perform the Agatston CAC score. CAC score can recategorize up to half of those who underwent chest CT into a higher or lower CV risk category. REFERENCES Hecht HS, Henschke CI, Yankelevitz D et al. MS10.03 AORTIC VALVE CALCIFICATIONS

Y. Zhu[1], Y. Wang[2], W. Gioia[1], R. Yip[1], A. Jirapatnakul[1], M. Chung[1], D. Yankelevitz[1], C. Henschke[1]

[1]*Icahn School of Medicine at Mount Sinai Hospital, New York/United States of America,* [2]*Zhongshan Hospital, Xiamen University, Fujian/China*

Smoking is a major risk factor for both cardiovascular disease and lung cancer. Low-dose computed tomography (LDCT) screening for lung cancer provides an opportunity to identify both diseases in asymptomatic smokers (1). The extent of aortic valve calcification (AVC) is the predominant driver of degenerative aortic valve stenosis (AS) (2), which is an underdiagnosed and undertreated disease. Cardiovascular morbidity and mortality is higher for people with moderate/severe AVC as compared to those with none or mild AVC as demonstrated on echocardiography (3). Our study aimed to assess sensitivity and reliability of visual AVC scoring on LDCT for predicting AS in older smokers. In addition, we aimed to determine the frequency of any AVC and its significant predictors in a program of LDCT screening for lung cancer, separately on baseline and annual repeat screenings. We reviewed 1225 consecutive participants in annual LDCT screening for lung cancer at the Mount Sinai Hospital before July 2018, who had at least two LDCTs without aortic valve replacement (AVR) before enrolled. The baseline LDCT was the first scan obtained at the time of enrollment and the most recent LDCT was the last LDCT obtained before July 2018, unless the participant had either AVR or had died before July 2018; for these cases, the last LDCT scan before surgery or death was used. Sensitivity and specificity of moderate/severe visual AVC score on LDCT to identify AS on echocardiogram was calculated for 126 participants who had both tests within 12 months. Using regression analyses, risk factors for AVC at baseline, for progression, and for new AVC on annual rounds of screening were identified. Reliability of AVC assessment on LDCT was assessed by comparing AVC visual scores with 1) standard-dose, electrocardiography (ECG)-gated CT for 31 participants who had both tests within 12 months, 2) with Agatston scores of 1225 participants on the most recent follow-up LDCT, and 3) by determining the intra-reader agreement on baseline LDCTs and separately for the most recent LDCTs of all participants. Results:Among these 126 participants who had LDCT and echocardiography within 12 months, 7 (5.6%) were diagnosed with moderate/severe AS, 3 (2.4%) were diagnosed with mild AS, 37 (29.4%) with aortic sclerosis, and 79 (62.7%) with no sclerosis or AS (Table 1). Of the 3 diagnosed as severe AS on echocardiography, all 3 had severe (grade 3) AVC on LDCT and of the 4 diagnosed as moderate AS on echocardiography, all 4 had moderate (grade 2) AVC on LDCT. Visual AVC scores on LDCT had substantial agreement with the severity of AS on echocardiography (weighted kappa=0.68, 95% CI: 0.56, 0.80). In addition, correlation was significant between the AVC visual scores on LDCT and both the echocardiographically determined mean pressure gradient (p = 0.02) and aortic valve area (p = 0.02) in these 10 participants with AS. Sensitivity and specificity of moderate/severe visual AVC scores for moderate/severe AS on echocardiogram was 100% and 94%, respectively. There is substantial inter- (total weighted kappa of 0.73) and excellent intra-observer agreement (Baseline LDCT: weighted Kappa=0.91, 95%

CI: 0.88-0.95; The most recent LDCT: weighted Kappa=0.90, 95% CI: 0.88-0.92). Of the 1225 participants, no AVC was identified on the baseline LDCT in 1081 (88.2%), while 116 had mild AVC (grade 1), 26 moderate AVC (grade 2), and 2 severe AVC (grade 3). On the most recent LDCT, median follow-up time from baseline LDCT was 10.9 years (IQR: 4.2 to 15.1 yrs.), 865 (70.6%) had no AVC, 262 (21.4%) mild AVC, 80 (6.5%) moderate AVC, and 18 (1.5%) severe AVC. Multivariable logistic regression analysis showed significant predictors for baseline AVC were male sex (OR=3.39), age (OR=1.11) and CAC score (OR=1.28), for AVC progression after baseline, was pack-years of smoking (HR=1.01), and for new AVC on annual LDCT, were male sex (HR=1.65), age (HR=1.06), and BMI (HR=1.06). Conclusions: Our results suggest that moderate to severe AVC scores could be reliably obtained on LDCT, should also be reported on screening LDCTs and further workup by echocardiography should be recommended as finding moderate or severe AVC on LDCT was associated with a high probability of AS in asymptomatic smokers. 1. MS10.04 LIVER - PULMONARY DISEASE

A. Branch

Icahn School of Medicine at Mount Sinai, New York City/United States of America

Evidence of an Association between Pulmonary Dysfunction and Fatty Liver Disease Background:There is an epidemiological association between pulmonary dysfunction and fatty liver disease. To investigate the association between pulmonary dysfunction and liver steatosis in members of the World Trade Center General Responder Cohort and other populations. : FIB-4 scores were calculated from the most recent data in electronic health records; fibrosis was defined as a FIB-4 score ≥ 2.67, which is associated with a 43-fold increased risk of liver-related mortality. Fatty liver was determined by automated analysis of non-contrast chest CT scans; attenuation < 40 Hounsfeld Units (HU) indicated moderate-to-severe steatosis, which means that ≥ 30% of hepatocytes contain excessive lipid. Primary liver cancer was identified by filtering on international classification of diseases (ICD9/10) codes 155/C22, and verifying the diagnosis by chart review. Multivariable logistic (MVL) regression was used to identify factors independently associated with liver fibrosis and steatosis. All reported findings are significant at $p < 0.05$. : Among 18,231 responders, 414 (2.3%) had liver fibrosis, which was associated with lower body mass index (BMI), obstructive pulmonary disease, male sex, smoking history, alcohol history, and less education. Among 7227 responders who denied smoking and/or heavy alcohol consumption, 112 (1.5%) had liver fibrosis, which was again associated with lower BMI, reduced pulmonary function, male sex, and less education. Among 1248 responders with CT scans available for analysis of liver status, 184 (15%) had moderate-to-severe steatosis. Fatty liver was associated with arrival at the WTC site on 9/11 and higher values of ALT, AST, bilirubin, neutrophils, and BMI. Among the responders with fatty liver, 38 (21%) were not obese (BMI < 30 kg/m^2). The non-obese responders had higher values of ALT, AST, and bilirubin, and lower values of platelets, indicating that they had more advanced liver disease. Thirty-three responders had primary liver cancer. : Among WTC responders, liver fibrosis was associated with pulmonary dysfunction and lower BMI; excessive weight and metabolic disease were not the primary drivers. Among responders with liver fat, those with lower BMI had more extensive liver damage, as often occurs in toxicant-associated steatohepatitis (FAMRI, NIOSHU01OH011489).

MS10.06 INTERSTITIAL LUNG DISEASES

M. Salvatore

Columbia University Medical Center, New York/United States of America

Patients with a history of smoking are enriched population for studying pulmonary fibrosis and as patients are living longer with fibrosis, they are becoming an enriched population for studying lung cancer (1). Usual interstitial Pneumonitis is the most frequent pattern of pulmonary fibrosis in the United States. There are 48,000 new patients with IPF each year in the US and 40,000 die (2). Ozawa found that the cumulative incidence of lung cancer is 3.3%, 15.4%, and 54.7% at 1, 5, and 10 years of IPF (3). Adenocarcinoma is most common lung cancer in the general population. Kawasaki found that of 53 patients with IPF and lung cancer, there was no predominant histology. There are similarities between lung cancer and fibrosis, which include invasion of normal tissue, lack of monoclonality, mutation of tumor suppressor genes and epithelial mesenchymal transformation (4). The tumor microenvironment often causes cancers in fibrosis to have shorter doubling times. The survival of patients with lung fibrosis and cancer is poor with up to 93% 5-year mortality (5). Screening for lung cancer in patients with fibrosis is different from screening in non-fibrotic patients because of the potential rapid growth of some cancers. Lung cancer occurring in a patient with fibrosis are different from lung cancer occurring in a patient with emphysema. The patients are often not candidates for surgery. If they have surgery, it should be as limited as possible to decrease the risk of exacerbation (6). Chemotherapy increase risk of an exacerbation as does immunotherapy (7). Radiation has an increased risk of exacerbation as well; perhaps proton therapy may have better outcomes (8). In summary as patients are living longer with fibrosis the incidence of lung cancer is increasing however the treatments for early cancer in patients with lung cancer increase the risk of fibrosis exacerbation and further study is necessary in this area to make recommendations for best practices. MS10.07 BREAST EVALUATION

L. Margolies

Icahn School of Medicine at Mount Sinai, New York/United States of America

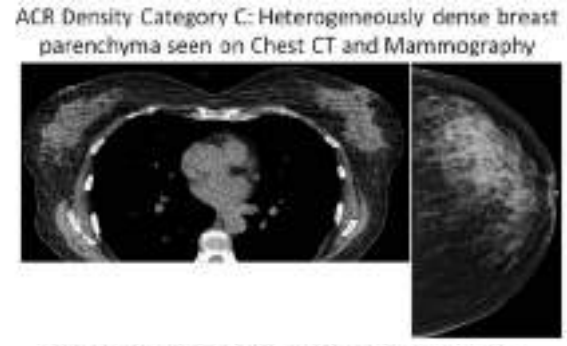

Figure 2: Medial Right Breast Mass is much easier to see on CT compared to mammogram

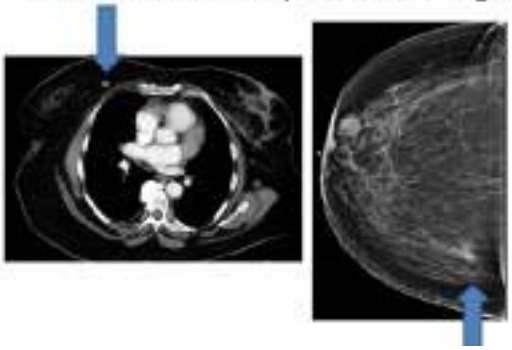

Opportunistic Evaluation of the Breast on Cross Sectional Imaging Breast tissue is visualized on Chest CT, Chest MRI and to a limited extent on cross sectional imaging of the abdomen; much information about the breasts can be obtained. While cross sectional imaging does not substitute for mammography, for those women who have not had recent mammograms it may be the only opportunity for the breasts to be evaluated. Additionally, there are portions of the medial and posterior breast which can sometimes be seen to better advantage on cross sectional imaging. Breast Density is a known risk factor for breast cancer development and can mask tumors on mammography. Traditionally, it has been taught that breast density can only be determined by mammography, but it can be reliably determined by evaluating the breasts on CT.[i] (figure shows a Chest CT of a woman with heterogenously dense breasts and corresponding cranio-caudal mammogram image) Reporting of breast density on Chest CT can better inform the patient of her risk and possible imaging strategies. Masses and some calcifications can be seen on CT. Some are known and require no further evaluation, others are classically benign and also require no further evaluation, but some appear new or changed and do require dedicated breast imaging. By using a breast assessment and recommendatin score (BARCS) system to evaluate and report breast CT findings one can communicate to referring physicians what the next steps if any might be. This is similar to the BI-RADS system used for reporting mammography A BARCS score of 1 or 2 is analogous to the commonly used BI-RADS 1 or 2 and indicates that the findings are negative or benign and no special evaluation is needed. A CT-BI-RADS 2 might be used, for example, in the setting of a classic fibroadenoma. A mass that does not exhibit classic benign features, however, might be given a BARCS 0 and the patient referred for dedicated breast imaging (or review and correlation with prior breast imaging) as the imaging evaluation is incomplete. [ii] Some of these findings will be breast cancer (figure 2 shows a mass in the medial right breast that is easier to see on Chest CT than on mammogram where there is only a developing asymmetry - arrows). The opportunity to fully include and evaluate the breasts on cross sectional imaging should not be missed.[iii] Breast masses can also be an incidental MRI finding.[iv] Dedicated breast imaging also has the opportunity to detect lung and other disease. Breast MRI, for example, typically includes portions of the lung and abdomen where osseous, lung, liver and renal lesions can be seen.[v] Mammography can detect lymphoma, metastatic melanoma and other systemic diseases such as congestive heart failure [vi] or even be the first indication of re-activation of Tuberculosis.[vii]Cardiovascular disease can manifest itself with breast arterial calcification evident on mammography; this often correlates with coronary artery calcification despite the differences in the pathogenesis of the calcifications. [viii] Patients[ix] and providers[x] want interpreting radiologists to report on all the imaging findings; chest imagers have the opportunity to detect breast disease and promote appropriate evaluation of findings as well as to assist in personalizing breast cancer screening algorithms. MS11.01 NEOADJUVANT CHEMOTHERAPY OR NEOADJUVANT CHEMORADIATION FOR POTENTIALLY RESECTABLE NSCLC - A SURGEON'S PERSPECTIVE

R. Terra

Sao Paulo State Cancer Institute (ICESP) University of São Paulo, Sao Paulo/ Brazil

Early studies of neoadjuvant therapy compared chemotherapy alone to surgery alone. Later, the Intergroup 0139 study utilized concurrent chemotherapy and radiation as its induction strategy, and this was the basis for adding radiation in the neoadjuvant strategy. Both strategies, neoadjuvant chemotherapy and neoadjuvant chemoradiation are considered alternatives for patients with stage IIIA non-small cell lung cancer deemed operable. However, the toxicity of combined chemotherapy and radiation is significant. Radiotherapy has an inflammatory effect that leads to a more difficult surgical procedure and increases the number of postoperative complications. Moreover, studies comparing both strategies failed to demonstrate superiority of any of the two strategies in terms of overall survival. On top of that, due to the limited number of radiotherapy clinics in emerging countries, radiotherapy schedules might delay the beginning of the patient's treatment. This is also an issue to be considered when offering neoadjuvant chemoradiation.

MS11.02 ROLE OF SURGERY IN OLIGOMETASTATIC NSCLC

C.S. Pramesh

Tata Memorial Centre, Mumbai/India

The management of oligometastatic non-small cell lung cancer (NSCLC) is controversial. Sixty percent of patients with NSCLC present with metastatic disease; 45% of those with initially localized disease eventually develop metastatic disease. With 15% of these being oligometastatic disease, this is a significant problem. Over the last two decades, several advances have occurred which frame this question better. First, advances in imaging techniques including improved PET-CT and MRI have helped identify what is likely to be truly oligometastatic disease. Second, there have been advances in local therapy including minimally invasive and robotic approaches and perioperative management, as well as advanced radiation techniques including stereotactic ablative radiotherapy (SABR) which have made it safer. Finally, systemic therapy has undergone major changes with targeted therapy and immunotherapy making considerable progress. Most patients with metastatic NSCLC would be treated with systemic therapy with local treatment being offered only for symptomatic palliation. However, recognition of a "oligometastatic" state (where metastases are limited in number and location) has led to series of patients being treated with potentially curative intent using local treatment options, predominantly surgical. Randomized trials to evaluate the role of surgery in oligometastatic NSCLC have not been performed, compelling a reliance on several published case series and meta analysis of these studies. These series have included highly selected patients with oligometastases, typically 1-3 metastases, most commonly located in the brain, and long term outcomes have been highly variable. Overall median five year survival of a meta analysis of studies was 23.3 percent. Five year survivals in patients treated with surgery both for the primary and the metastases range from as low as <10% to as high as 80% - this wide range is more likely a reflection of selection criteria for patients undergoing surgery rather than true variations in care. Moreover, with the lack of a true comparator arm, these results should be interpreted with caution. Important favourable prognostic factors include definitive treatment of the primary tumour, negative mediastinal nodal status and a longer disease-free interval. Lack of well conducted prospective studies make conclusive recommendations on surgery for treatment of oligometastatic disease difficult. This is especially true now when better radiation techniques like SABR and improved outcomes with systemic treatment in selected patients

with targeted and immunotherapy are available. Given the available evidence, it appears reasonable to consider surgical treatment in patients with oligometastatic disease fulfilling the following criteria: good performance status, accurately staged, with PET-CT and MRI brain showing no other sites of metastases, metachronous disease with relatively long disease free interval, negative mediastinal nodes on invasive staging, and controlled primary disease. With randomized trials being unlikely in this setting, further studies are required which prospectively collect real-world data systematically, enabling better selection criteria for patients for surgery in oligometastatic NSCLC.

MS11.03 MINIMIZING PERI-OPERATIVE MORBIDITY WITH PNEUMONECTOMY

S. Watanabe

National Cancer Center Hospital, Tokyo/Japan

1. Introduction The incidence of surgical morbidity after standard pneumonectomy is reportedly 30 to 60%. Many previous studies have addressed several risk factors for surgical morbidity after pneumonectomy, including age, cardiovascular disease, recent body weight loss, high smoking index, low FEV1.0 value, chronic obstructive pulmonary disease (COPD), right pneumonectomy, massive blood loss during surgery, long operation time, neoadjuvant therapy and so on. Although surgical morbidity after pneumonectomy easily lead to patients' mortality. When pneumonectomy seems to be inevitable to remove the tumor, surgeons sometimes intraoperatively weigh the oncological benefit of pneumonectomy against the postoperative poor QOL and high morbidity rate. In this paper, the cause and proper management of postpneumonectomy complications are discussed to minimize peri-operative morbidity with pneumonectomy as for especially following two life-threatening categories, cardiovascular and respiratory complications. 2. Type of Complications 2.1 Cardiovascular Complications 2.1.1 Supraventricular Arrhythmias Most of supraventricular arrhythmias present 1 to 4 days after standard pneumonectomy, but it sometimes present even a week after surgery. The incidence of supraventricular arrhythmia after pneumonectomy is reportedly 4 to 25%. Risk factors for supraventricular arrhythmias include old age, right pneumonectomy, intrapericardial pneumonectomy, major co-morbidities, and so on. For patients who are considered to be high risk for postoperative atrial fibrillation, following prevention strategies are indicated. According to the 2014 AATS guidelines, continuing β blockers in patients taking β-blockers before surgery, using intravenous magnesium supplementation if serum magnesium levels are low, using diltiazem in those patients with preserved cardiac function who were not taking β-blockers preoperatively, or using amiodarone in patients at an intermediate to high risk of developing postoperative atrial fibrillation. For hemodynamically stable patients with new onset atrial fibrillation, intravenous β-blockers or calcium channel blockers are used to reduce a heart rate down to 100 beats per minute. When patients are hemodynamically unstable, direct current cardioversion should be used. And for patients with refractory atrial fibrillation, systemic anticoagulation therapy should be used carefully weighing benefits against the risk of bleeding, especially after EPP. 2.1.2 Ischemic Heart Disease Ischemic heart disease is known to be an independent risk factor for severe complications after pneumonectomy. The risk of a myocardial infarction after pneumonectomy is reportedly approximately 0.2 to 2.1%. Patients who are candidates for pneumonectomy should undergo careful preoperative assessment to screen for untreated coronary ischemic disease. 2.1.3 Cardiac Herniation Cardiac herniation is a rare complication after intrapericardial pneumonectomy. Patients develop cardiac herniation when the intrathoracic pressure changes rapidly by severe cough or vomit with decubitus position. Rapid and severe hemodynamic collapse following a change in patient positioning should heighten the clinical suspicion. Chest X-ray and electric cardiogram clearly show the abnormal position of the heart (Figure 1 and 2). Correction of the cardiac herniation should be conducted immediately by re-thoracotomy after successful resuscitation. Sewing the patch to the weak tissues around the pericardium rather than the pericardium itself after intrapericardial pneumonectomy could increase the risk of cardiac herniation. 2.2 Respiratory Complications 2.2.1 Pneumonia The incidence of pneumonia after pneumonectomy is reportedly 2 to 10%. Since pneumonia after pneumonectomy could be a life-threatening complication, care must be taken to lessen the risk of pneumonectomy. Preoperative smoking cessation, chest physiotherapy by nurses or respiratory therapists, use of enough amount of post-thoracotomy painkillers, and bronchial toilet by bronchoscope are important practical factors for minimizing the risk of pneumonia. 2.2.2 Acute Respiratory Distress Syndrome (ARDS) According to the previous literatures, ARDS occurs in 2.7 to 3.1% of patients after standard pneumonectomy with very high mortality of 50 to 70%. Treatment of ARDS is supportive. Mechanical ventilation with small tidal volumes of less than 6 mg/kg body weight should be used to minimize the barotrauma, and the FiO2 level should be decreased to the lowest level to minimize the oxidative trauma. There has been no evidence that steroids improve the prognosis of patients developing ARDS. 2.2.3 Bronchopleural Fistula (BPF) The incidence of BPF, which is a life-threatening complication, is reportedly 2 to 11%. The mortality of BPF after pneumonectomy is very high rate of around 40%. Risk factors for BPF includes diabetes mellitus, malnutrition, long stump (especially for left side), right pneumonectomy, preoperative chemoradiation therapy, and so on. When a patient develop the BPF, open window technique should be applied to control thoracic cavity infection which can lead the patient to death. 3. Conclusion The mortality and morbidity rates after pneumonectomy are very high compared with those after lobectomy, simply because the patients have less cardio-pulmonary reservations. Therefore, when complications occur, surgeons must aggressively treat them not to lose the patient with taking abovementioned knowledge into consideration. Figure 1

MS11.04 SURGICAL RESECTION OF SCLC - NOT SO OBSOLETE ANY LONGER

G. Lyons

Buenos Aires British Hospital, Argentina/Argentina

More than 2 million new lung cancer cases were detected worldwide in 2018, and small cell lung cancer (SCLC) represents about 13-15 % of all lung cancers. Although surgery was initially regarded as the treatment of choice for all types of lung cancer, it was abandoned for SCLC almost 30 years ago after the results of the Medical Research Council (MRC) randomized trial conducted by Fox et al. in 1973, which showed poor mean survival for the surgical group when compared to the RT group (6.5 months vs. 10 months, P = 0.04). (1) These results led to the abandonment of surgery as a standard treatment in favor of chemotherapy. Two subsequent meta-analyses revealed that the addition of thoracic radiation to systemic chemotherapy improved survival, and that has become the standard of care. (2) After the introduction of TNM classification, investigators proposed that surgery was postulated to be indicated in limited-SCLC, particularly stage T1, N0, with 5-year survival rates of as high as 52.6% for stage 1 disease. (3) Further, surgical resection after induction chemoradiotherapy demonstrated a control of local relapse in almost 100% of the patients and 5- and 10-year survival rates for patients with stage IIB to IIA were 39% and 35%, respectively, for all patients (resected or not) and 44% and 41% for patients treated with a trimodality approach including adjuvant surgery. (4) Another argument for surgical resection is that the final histology of SCLC might reveal a component of NSCLC in 11-25% cases. (5) In a recent series of Wakeam et al. including 2,089 patients with SCLC undergoing surgery who were matched 1:1 to those undergoing NST, surgery was associated with longer survival for stage I (median overall survival [OS] 38.6 months vs. 22.9 months), for stage II (median OS 23.4 months vs. 20.7 months), and stage IIIA (median OS 21.7 vs. 16.0 months. In analyses by T and N stage, longer OS was observed in resected patients with stage T3/T4 N0 (median OS 33.0 vs. 16.8 months, p=0.008) and node positivity (N1+ 24.4 vs. 18.3 months p=0.03; N2+ 20.1 vs. 14.6 months p=0.007). (6) A recent meta-analysis that included a total of 41,483 patients concluded that surgical resection was associated with superior OS in stage I (HR = 0.56, 95% CI: 0.49–0.64, p< 0.001), stage II (HR = 0.75, 95% CI: 0.57–0.99, P = 0.04), and stage III diseases (HR = 0.70, 95% CI: 0.56–0.88, P = 0.002). (11) Unlike stage I disease, there is no consensus for surgery in stage II and stage IIIA SCLC. Surgical resection is concordant with NCCN and ASCO guidelines; however, evidence shows that in the vast majority of T1 and T2 N0M0 patients, surgery is not offered in the absence of any documented contraindication. Rostadt et al., in a series of 2,442 patients with SCLC, found out that 26% were stages IA and IB and thus candidates for surgical resection, while only 38 patients (1.5%) underwent surgical therapy. (8) CT screening identifies SCLC at an earlier stage – with better survival – than usual care and offers the hope that more SCLC patients may become long-term survivors. Austin et al. carried out a multinational study of baseline and annual repeat CT screenings of 48,037 volunteers at risk for lung cancer. (9) They found 48 SCLC cases, 92% of which were asymptomatic at diagnosis. Clinical stage was IA in 16 patients (33%), II in 5 (11%), III in 20 (42%), and IV in 7 (15%). Estimated cure rates were 36% overall and 54% for the clinical stage I cases. Surgical resection is indicated in SCLC in stages I and IIA after precise staging including mediastinoscopy. Patients should receive systemic therapy after resection and mediastinal radiation therapy in cases with nodal metastases. Surgical resection in stages I and IIA SCLC is concordant with NCCN and ASCO guidelines; however, surgery is offered only in one-third of the patients in the absence of any documented contraindication. CT screening identifies SCLC at an earlier stage and offers the hope that more SCLC patients may be candidates for surgical resection and become long-term survivors. Selected cases in stages IIB and IIIA may be candidates for surgery as part of the multidisciplinary treatment. 1) Fox W, Scadding JG. MS11.05 PATHOLOGICAL REPORTING OF RESECTED LUNG CANCER - THE IMPORTANCE OF USING ADDITIONAL TNM DESCRIPTORS

E. Nascimento

Hospital das Clinicas, Faculdade de Medicina, Universidade de Sao Paulo, Sao Paulo/Brazil

Context. The anatomopathological examination aims to establish a specific diagnosis of the tumor and to provide essential information related to cancer staging, patient management and prognosis. Such information, as histologic type, lymphovascular invasion, spread through air spaces, margins, treatment effect, and TNM descriptors should be disclosed concisely, following previously defined protocols, and correlate satisfactorily with radiological exams and clinical aspects in order to allow the best management for the patient. Histopathological (macroscopic and microscopic evaluation) combined with complementary immunohistochemical and molecular studies, provides prognostic and predictive information on tumor biology and clinical behavior. The TNM staging classifies the tumors according to the anatomic extent with an important prognostic impact. In addition, it allows the establishment of criteria for inclusion and exclusion of patients in protocol studies and subgroups of treatment, cancer registry, epidemiology and multidisciplinary management. The T component analysis is complex because it has many elements: presence or absence of invasion, tumor size, endobronchial location, atelectasis / pneumonitis and invasion of the various anatomical structures around the lung. The determination of the largest tumor diameter requires accurate measurements since in the eighth edition TNM stage classification for lung cancer each centimeter separates tumors with different prognoses from 1 to 5 centimeters (cm). Appropriate size measurement is especially important when it comes to subsolid tumors since the correlation with the computed tomographic imaging in this context is of great value. Tumors measuring larger than 5 cm up to 7 cm (T3 in the eighth edition) had a worse prognosis than found in the seventh edition of the TNM classification. Tumors larger than 7 cm (T4 in the eighth edition) have similar prognosis to other descriptors in the T4 category. Atelectasis or pneumonitis involving the whole lung (T3 in the seventh edition) has the same prognosis for partial atelectasis / pneumonitis (T2 descriptor in the seventh edition). Endobronchial tumor location less than 2 cm from carina (a T3 descriptor in the seventh edition), but without carina involvement, had the same prognosis as the endobronchial location further than 2 cm from carina (a T2 descriptor in the seventh edition). In the eighth edition, tumors involving the main bronchus and associated with atelectasis / pneumonitis are classified as T2. On the other hand, diaphragm invasion (a T3 descriptor in the seventh edition was upstaged to T4 in the eighth edition) since it has similar prognosis of T4 tumors. No changes to the N descriptors were proposed in the 8th TNM as the four N categories (N0, N1, N2, N3). The reassessment of the M

component validated the proposed M1a category descriptors in the seventh edition and separated the distant metastases into two categories with different prognoses, M1b (single metastatic tumor in one organ), and M1c (multiple metastases in either single organ or multiple organs). Objective. To review and discuss the 8th edition of the TNM classification of lung cancer with an emphasis on prognostic relevance and implications for the pathologist's report. Data Sources. The review is based on the available literature. Conclusion. The TNM (tumor-node-metastasis) classification system for lung cancer is the strongest prognostic indicator and fundamental for decisions on therapy. The eighth edition of the TNM classification of lung cancer enhances the prognostic discrimination of the different T categories and differentiates unique extrathoracic metastasis (better prognosis) from multiple metastases in one or several organs providing better definition of oligometastatic disease. Thus, the eighth edition of TNM improves the understanding of tumor anatomic extent and stratification of tumors for clinical trials. MS12.01 CIRCULATING BIOMARKERS

C. Dive

Cancer Research UK Manchester Institute, Manchester/United Kingdom

I will describe ongoing studies that seek to develop circulating biomarkers for the early detection of lung cancer. We are taking a multi-assay approach to develop a blood test with sufficient sensitivity and specificity. Our efforts are supported with targeted sample collection from a cohort that are typically described as the high risk, hard to reach. Individuals are asked to attend free lung health checks in supermarket car parks in socially deprived areas of North Manchester where many are offered a low dose CT scan. This approach has allowed a paradigm shift from detection of lung cancer at stage 4 to stage 1-2 where surgery can often be offered with curative intent. Individuals are also asked to provide a blood sample for exploratory research. This approach is generating an optimal blood sample set comprising samples from individuals with a CT positive scan (a proportional of which are false positives) or a negative CT scan with full clinical follow up. I will discuss the challenges of early detection with liquid biopsies (ctDNA, CTCs and plasma proteomes) and our strategies to mitigate them.

MS12.02 GENOMIC AND FUNCTIONAL APPROACHES TO UNDERSTANDING CANCER ANEUPLOIDY

A. Taylor[1], J. Shih[2], G. Ha[1], G. Gao[2], X. Zhang[1], A. Berger[2], A. Cherniack[1], R. Beroukhim[1], M. Meyerson[1]

[1]*Dana-Farber Cancer Institute and Broad Institute, Boston/United States of America,* [2]*Broad Institute, Cambridge/United States of America*

Aneuploidy, whole chromosome or chromosome arm copy number imbalance, is a near-universal characteristic of human cancers. We applied methods that define chromosome arm-level aneuploidy and a global cancer aneuploidy score to 10,522 tumors of 33 types in the Cancer Genome Atlas (TCGA). Aneuploidy level was correlated with *TP53* mutation, somatic mutation rate, and expression of proliferation genes. Aneuploidy was anti-correlated with expression of immune signaling genes, due to decreased leukocyte infiltrates in high-aneuploidy samples. Although yeast and mammalian models of whole chromosome aneuploidies have been extensively investigated, chromosome arm-level aneuploidies have rarely been modeled. Cancer subtypes are often characterized by tumor specific patterns of these arm-level copy number alterations; for example, squamous cell carcinomas (SCCs) from different tissues of origin (including lung, esophagus, and bladder) have a pattern of chromosome 3p loss and chromosome 3q gain. Our analysis of 495 lung SCCs found chromosome 3p deletion to be the most frequent genomic alteration, occurring in almost 80% of the tumors and covering the entire length of the chromosome arm. Over two-thirds of chromosome 3p genes showed significantly decreased expression in these samples. Without models of chromosome arm-level alterations, the phenotypic effects of specific aneuploidies in cancer, such as 3p deletion, remain unknown. However, recent advances in genome engineering and targeting of endonucleases allow new approaches to generate chromosomal alterations. Here, we used the CRISPR-Cas9 system to delete one copy of chromosome 3p *in vitro*. We successfully isolated almost 90 clones of immortalized lung epithelial cells with deletion of the 3p arm, with 8 validated by whole genome sequencing. Consistent with patient data, expression of 3p genes was also decreased upon deletion, as well as increased expression of interferon response genes. Phenotypic characterization revealed that cells with chromosome 3p deletion initially proliferated more slowly than their siblings. These chromosome 3p deleted cells had increased G1 arrest, but did not undergo increased apoptosis or cell death. Interestingly, after several passages in culture, the proliferation defect was rescued in chromosome 3p deleted cells; genome sequencing and karyotype analyses suggested that this was the result of chromosome 3 duplication. With our cellular model of chromosome arm-level aneuploidy, we uncovered a possible selection mechanism that allows aneuploidy tolerance *in vitro*. We used genome engineering to model chromosome arm-level deletions, providing a robust model that will address a gap in our understanding of aneuploidy in cancer.

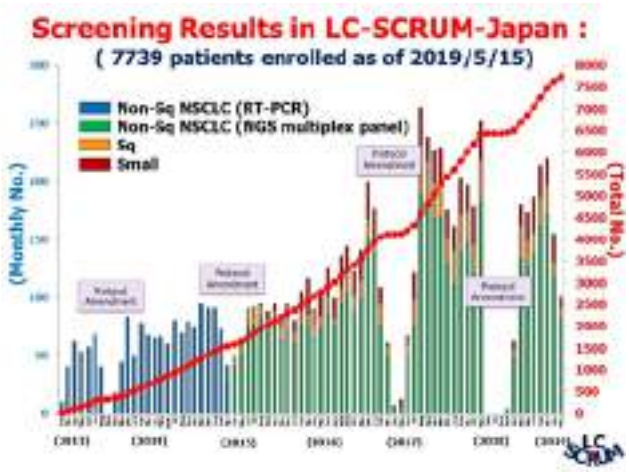
MS12.03 LC-SCRM-JAPAN, A PAN-JAPAN GENETIC SECREENING OF LUNG CANCER

K. Goto

National Cancer Center Hospital East, Kashiwa/Japan

Background: Recently many actionable driver oncogenes such as EGFR, ALK, RET, ROS1, BRAF and MET have been identified in non-small cell lung cancer (NSCLC). However, most of these driver oncogenes are rare and found in only about 1-2% of lung adenocarcinomas. To develop new molecular targeted agents for rare alterations, efficient genomic screening is needed to identify patients. A nationwide genomic screening platform (LC-SCRUM-Japan) was established to primarily screen for ALK, RET and ROS1 fusions using RT-PCR and FISH in advanced non-squamous NSCLC without EGFR mutations in February 2013. From March 2015, this project was expanded to an academic-industrial collaboration initiative with broader eligibility criteria and tumor samples were analyzed by next-generation sequencing (NGS multiplex analysis

with Oncomine™ Cancer Research Panel). In addition, non-squamous NSCLC regardless of EGFR mutation status and other histological type of lung cancer including squamous NSCLC and small cell lung cancer (SCLC) were enrolled. Clinical information of all patients have also been collected to generate a clinical-genomic database that enables detailed outcome analysis of the cohort. Since its inception, more than 200 Japanese hospitals participated in this project and 7739 patients were enrolled into LC-SCRUM-Japan. 776 squamous NSCLCs and 823 SCLCs were enrolled. Through this platform, many patients with rare driver oncogenes were identified for approved targeted therapies or successfully enrolled into various clinical trials that have helped develop new targeted agents. Based on our project, crizotinib and dabrafenib/trametinib were approved for ROS1 fusions and BRAF mutation positive lung cancers in Japan, respectively. From December 2017, liquid screening with Guardant 360 (LC-SCRUM-Liquid) was initiated and a large concordance study between tissue and liquid NGS analysis was performed in 2000 patients. Additionally, to identify novel biomarkers for immune checkpoint inhibitors, an immuno-oncology biomarker study (LC-SCRUM-IBIS) was conducted with 1017 patients enrolled from February 2017 to May 2018. PD-L1 assessment by IHC and whole exon sequencing was performed. The LC-SCRUM platform was recently expanded to hospitals in Taiwan and we will expand the collaboration to China and other Southeast Asia to establish an integrated Asia cancer clinical genomic database.



Genomic screening in LC-SCRUM has provided clinical value by identifying patients with actionable mutations and has helped accelerate clinical development of novel agents. To continue to elevate the standard of cancer care and treatment options for patients in Asia, we are establishing a high quality platform of genomic screening technologies and a mechanism of collecting clinical data that will help elevate precision medicine and drug development in Asia.

MS12.04 THE INTERNATIONAL LUNG CANCER CONSORTIUM (ILCCO), AN INTERNATIONAL STUDY TO IDENTIFY RISK FACTORS FOR LUNG CANCER DEVELOPMENT

R.J. Hung on Behalf of The International Lung Cancer Consortium

Lunenfeld-Tanenbaum Research Institute, Sinai Health System and University of Toronto, Toronto/Canada

Background: The International Lung Cancer Consortium (ILCCO) was established in 2004 to maximize research efficiency for lung cancer and to share comparable epidemiological and clinical data, and biological samples across studies. Since its establishment, over 70 studies have participated in the ILCCO and shared comparable clinico-epidemiological data and a subset with biological samples and genomic data. The data harmonization was conducted at the Sinai Health System in Toronto, and genomic data is managed at the Dartmouth College of Medicine/Baylor College of Medicine. In total, the ILCCO Data Repository now has epidemiological data for over 1.2 million study participants, including 100,000 lung cancer patients, and genomic data on approximately 50,000 study participants. The large-scale epidemiological and genomic data allow us to extensively study and characterize the etiological factors, including lifestyle risk factors, medical history and genomic architectures for lung cancer development. Data submitted from all studies are systematically checked for missing values, outliers, inadmissible values, aberrant distributions and internal inconsistencies before harmonization. Common variable definitions were developed. For lifestyle risk factors and medical history, we conducted meta-analysis based on study-specific estimates, when applicable. If heterogeneities were present, random effects models were employed to account for the heterogeneity across studies. For subgroup of interests or when sample size is limited, pooled-analyses based on individual-level data were applied. When applicable, the non-linearity relationship was assessed. For genetic susceptibility of lung cancer, we investigated the genetic loci associated with lung cancer risk using log-additive model adjusted for population ancestry and account for multiple comparisons. To assess the causality of specific exposures and lung cancer risk, we applied Mendelian Randomization and mediation analytical approaches. To estimate 5-year lung cancer absolute risk, we incorporated risk factors, medical history and genetic factors based on age-specific lung cancer incidence and the competing risk. Based on 17 ILCCO studies (24,000 cases and 81,000 controls), we observed a robust association between lung cancer risk and emphysema and pneumonia, even among never smokers, and after long latency period. Based on 24 ILCCO studies, we quantified the association between family history of lung cancer and its risk by their smoking status and affected relative types. Based on 6 studies in UK, Canada, UK and New Zealand, we assessed the association between cannabis smoking and lung cancer risk by intensity, duration and cumulative exposures and by histological subtypes. We have recently completed a largest lung cancer genetic analysis based over 29,000 lung cancer cases and 56,000 controls. We identified 10 novel lung cancer susceptibility loci, in addition to the known regions, such as *TERT/CLPTM1L, CHRNA5*, MHC region, *RAD52, CHEK2* and found specific associations mediated through mRNA expression. We helped to quantify the effect of specific genetic variant in nicotinic receptor gene on smoking cessation and age of onset. Using genetic instruments and Mendelian Randomization approach, we confirmed the association between lung cancer risk and long telomere length. Most recently, we investigated the association between impaired lung function and lung cancer risk based on UK Biobank and ILCCO OncoArray data, and we found that impaired lung function was associated with lung cancer risk in never smokers and particularly for adenocarcinoma, most likely through immune-mediated pathways. When combining all factors into an integrative risk model, we found that individuals with highly polygenic risk scores reached lung cancer screening threshold at younger age than those with average genetic risk background. ILCCO provides a powerful research platform for research on lung cancer. The collaborative projects based on ILCCO have contributed to the understanding of lung cancer etiology beyond tobacco smoking. As future perspectives, ILCCO has obtained clinical prognosis data for over 50,000 lung cancer patients and will also be able to investigate factors associated with lung cancer prognosis in depth. Finally, ILCCO has built close collaborations with several lung cancer low-dose computed tomography screening programs to jointly investigate the optimal strategy for risk stratification and early detection for lung cancer.

MS13 IMMUNOTHERAPY FOR MESOTHELIOMA
TUESDAY, SEPTEMBER 10 11:30–13:00

MS13.02 CON - RAPHAEL BUENO IS RIGHT (IT DOES NOT WORK)

R. Bueno

Brigham and Women's Hospital and Harvard Medical School, Boston/United States of America

Mesothelioma is a heterogeneous cancer and it is not always correctly staged in the absence of surgical extirpation. While some clinical trials utilizing a remarkably small number of patients showed some response to immunotherapy in mesothelioma, the response rate is relatively low (in the 10% rate) and it is unclear how durable. The heterogeneity of the tumor makes interpretation of such small number difficults leading to the conclusion that at this time immunotherapy remains experimental in mesothelioma

TUESDAY, SEPTEMBER 10 11:30–13:00

MS13.03 IMMUNOTHERAPY AND MESOTHELIOMA: UPDATE; REVIEW OF ALL PUBLISHED LITERATURE AND EPI/STATISTICAL EVIDENCE

J. Van Meerbeeck

Antwerp University Hospital, EDEGEM/Belgium

Unresectable malignant pleural mesothelioma (MPM) is a uniformly fatal rare cancer with increasing incidence worldwide. Combination chemotherapy with platinum/antifolate –either pemetrexed or raltitrexed- is the only standard of care 1st line treatment with proven improvement of survival, which varies according to series and patient selection between 12-16 months median overall survival (mOS), with corresponding 1 year survival rate of 50-60%. After a median progression-free survival of ~ 3 months, patients relapse and few if any drugs have any proven efficacy at this stage. Survival after progression varies from 3-18 months according to tumors' biological behavior and patient's prognostic factors. Therefore, innovative drugs are urgently needed. Although called 'immunologically cold tumours' and presenting with a low mutational burden, MPM express distinct targetable antigens (WT1, mesothelin), contain tumour-infiltrating lymphocytes (TILs) and PDL-1 expression is variably present, mostly on the sarcomatoid subtype. Experimental models have demonstrated chronic inflammation and local tumor suppression as crucial to MPM pathogenesis. This led to the investigation of immunotherapy in MPM. Monoclonal antibodies against immune check point inhibition (ICI-) molecules have been evaluated as salvage therapy after first-line chemotherapy in several phase 2 trials, either as single agent or in combination. The randomized DETERMINE trial evaluated in 564 patients the anti–CTLA-4 antibody tremelimumab versus placebo in second or third line and found no benefit in outcome (hazard ratio 0.92; p = 0.408). Results from the anti–PD-1 or anti–PD-L1 trials with nivolumab, pembrolizumab and durvalumab are fairly consistent with a response rate of 19-30%, a median PFS of 3.5 – 6.0 months and mOS of 12-18 m, all uncontrolled in selected patients with good prognostic features. Addition of CTLA-4 inhibitors to PD(L)-1 seem to increase efficacy and prolong the time-to-event endpoints. Preliminary results suggest that PD-L1 tumour proportional score (TPS) is both a predictive and prognostic biomarker. Several trials are underway investigating ICI alone or in combination with SOC-chemotherapy as frontline treatment. The DREAM trial, a single-arm, open-label phase II trial of durvalumab with cisplatin/pemetrexed, followed by durvalumab maintenance therapy for 1 year. The primary endpoint was PFS at 6months. Interim results in the first 54 patients show a mPFS of 6.2 months, with 48% achieved a partial response based on immune-modified RECIST. The -immature- 1-year OS estimate is 65% at a median follow-up of 14.4 months. Other randomized studies of triplet combinations are ongoing, including SOC-chemotherapy w/ wo pembrolizumab (NCT02784171) or durvalumab (NCT02899195). The phase III CheckMate743 (NCT02899299) trial randomly selected 600 patients with treatment-naïve MPM to nivolumab plus ipilimumab -until progression or unacceptable toxicity- versus up to six cycles of SOC-chemotherapy. Surgical management in resectable MPM represents an excellent opportunity for window-of-opportunity trials when treating patients with neo-adjuvant immunotherapies to improve resectability, fight residual disease and improve patient outcome. Several studies are ongoing with anti–PD(L)-1 with or without CTLA-4 inhibitors or chemotherapy in the neo-adjuvant setting, but results have not yet been published. Immunotherapy beyond ICI have been also tested in MPM but with discordant results. Several randomized phase II trials have targeted mesothelin, including amatuximab, an antimesothelin chimeric monoclonal antibody, anetumab-ravtansine, an antibody drug conjugate, and CRS-207, a vaccine targeting mesothelin: these have not yet shown any efficacy in MPM (unpublished data). Cell therapies in phase I trials are being investigated in MPM, including chimeric antigen receptor (CAR) T cells targeting surface antigens such as mesothelin, given both intravenously (NCT02159716) and intrapleuraly (NCT02414269). Vaccines targeting the Wilms tumor-1 (WT-1) antigen have also been tested in MPM with variable results. Dendritic cell vaccination was found to be efficacious in small trials of MPM, providing the rationale for ongoing trials, such as the large randomized phase II trial (DENIM) with dendritic cell therapy as maintenance after P/P frontline chemotherapy or a phase I/II trial testing autologous dendritic cells loaded with WT-1 tumor antigen following standard first-line chemotherapy. Autologous tumor infiltrating lymphocytes and interleukin-2 (IL-2) infusion after lympho-depletion are also currently under investigation in a phase I/II trial in MPM. Immune-gene therapy using intrapleural delivery of adenovirus-expressing interferon-α combined with celecoxib and chemotherapy was well tolerated and provided a remarkable mOS of 21.5 months as second-line treatment. Finally, oncoviral therapy is being assessed in a phase I trial with intrapleural injection of measles virus (NCT01503177), or with an oncolytic adenovirus coding for GM-CSF combined with chemotherapy and cyclophosphamide versus chemotherapy alone in a randomized phase II trial (NCT02879669). In conclusion, immunotherapies are being investigated in different settings of MPM. Regulatory approval is anticipated soon for ICI (anti–PD-1 with or without anti–CTLA-4) as salvage treatment in MPM. However, state of the art phase III trials comparing ICI with SOC-chemotherapy are needed to firmly establish immunotherapy, either alone or in combination with standard treatment, and to validate biomarkers for patient selection.

MS13.04 BIOMARKERS OF ANTI-PD1 THERAPY IN MESOTHELIOMA

P. Baas

Netherlands Cancer Institute, Amsterdam/Netherlands

Biomarkers of Anti-PD1 Therapy in Mesothelioma. Biomarkers have attracted attention for their usefulness in selecting the right treatment for the right patient. There are different types of biomakers; blood based, clinical markers and histological markers. Most of the biomarker studies have focused on the prognosis of patients while only a limited number examined the predictive value of a marker; to correctly predict the outcome of a certain treatment. After the reported successes of check-point inhibitors in melanoma and NSCLC (1-4), the use of these agents have found its way to mesothelioma(5-8). Since 2015 many studies have been initiated whit a comparable efficacy compared to NSCLC outcomes. Around 20-25% of cases do respond favorably to this approach. This is considered to be of great importance since there is a limited 2 years survival rate (8) and no standard second line therapy has yet been defined. There are a number of factors that have to be considered before embarking on Immuno-Oncology (IO) therapies as single agent or in combination. The choice of the drug or combination; the expected outcome in short time; the toxicity profile and the costs. Because of the lack of registration, there is a limited availability and patients can only join in studies or be part of a compassionate use program. When registration is a fact we merely have to deal with the questions; who will benefit, who will experience toxicity and is the treatment cost effective? In a series of studies we performed in patients with pleural mesothelioma we have collected samples to be used as biomarkers (6,7). Currently we are analyzing the predictive value of these biomarkers. 1. Histological biopsies: It is well known that the expression PD-L1 can be predictive in NSCLC of a success while in melanoma there is a better correlation with tumor mutational burden. For mesothelioma the expression of PD-L1 varies between the different subtypes of mesothelioma (with sarcomatoid type expressing higher PD-L1 levels) (9). In general the high expression correlates with a worse survival. In addition, the

expression of PD-L1 on tumor stroma also influences the outcome of IO treatment. In our study of 34 patients (7), we observed a clinical benefit of 18% in PD-L1 tumor negative patients compared with 15% in the (TIL+) stroma and 32% versus 35% in stroma for any PD-L1 expression. When analyzed for PD-L1 > 50% the stromal T+ cells showed a factor of 2 higher clinical benefit. This implies that a single analysis of the PD-L1 of the tumor cells might underestimate the effect of IO therapy. 2. eNose analyses. The use of exhaled air has attracted clinical interest since early data indicate that the Volatile Organic Compounds (VOCs) can predict an outcome of IO therapy (11). These VOCs probably represent a complex combination of tumor and immune cell interactions. Ongoing studies focus on the use of these electronic noses to select only patients for whom a treatment has a high chance of success. 3. Blood based biomarkers have been tested in many studies in mesothelioma. For well-known markers such as mesothelin, cyfra 21-1, osteopontin and fibulin-3 no positive outcomes have been reported in prediction studies. 4. MicroRNAs. These short, non-coding RNA sequences have attracted attention because of their prognostic capability in mesothelioma and other cancers. The huge number of miR's identified and the lack of comparative studies to date indicate that these markers can only be used for diagnostic and perhaps treatment purposes. (12) 5. BAP1 is a nuclear deubiquitinase which regulates the ubiquitination of selected histones and other translational factors. This mutation is occurring both in germline or, more frequently, as a somatic mutation in mesothelioma. It has different functions and can influence the inflammation status of the microenvironment. Although not tested in a proper study setting this marker may well have a predictive potential(13). 6. Other biomarkers. Finally there are a number of interesting biomarkers including chemokines like IL-6 which acts as a pro-inflammatory cytokine and is closely related to T cell function. Ongoing studies will try to elucidate the predictive effect of this and other markers. To date there is a lot of activity ongoing in mesothelioma and the introduction of the IO drugs have been welcomed full-heartedly. Although we have identified an abundant number of prognostic factors in cancer, the high costs of IO therapies presses us to find solid predictive markers. The combination therapies of IO drugs now proposed do increase the toxicity profile and we must not lose precious time of patients and doctors spend on ineffective and costly therapies. TUESDAY, SEPTEMBER 10 11:30–13:00

MS13.05 CAR T CELL IN MESOTHELIOMA

P. Adusumilli

Memorial Sloan Kettering Cancer Center, New York/United States of America

Chimeric antigen receptor (CAR) T-cell therapy has shown great promise in hematological malignancies and was approved by FDA for the treatment of leukemia and lymphoma patients. Adotpive cell therapy by use of CARs involves transducing patient's own T lymphocytes with antigen-specific CAR by retro or lenti virus, and infusing back to the patient following Cyclophosphamide preconditioning. This presentation will dicuss the challenges in developing CAR T-cell therapy, progress to date in translation of CAR T-cell therapy for thoracic cancers. Advances in understanding thoracic cancers tumor immune microenvironment and successes with checkpoint blockade agents has opened doors to devlop combiantion immunotherapy for thoracic cancer patients. Our laboratory has shown that in the presence of high tumor burden as in patients with metastases, a low-dose of CAR T cells adminsitered in phase I clinical trials can be exhausted. Addition of anti-PD-1 agents can rescue functionally exhausted CAR T cells and prolong their anti-tumor efficacy. Based on this strong rationale, our laboratory has translated mesothelin-targeted CAR T-cell therapy for patients with malignant pleural mesothelioma and demonstrated anti-tumor efficacy in addition to safety in combination with anti-PD-1 agents. The results of the ongoing trials will be discussed. While extrinsic anti-PD-1 agent administration requires multiple doses and potential off-tumor side effects, we have developed T-cell intrinsic anti-PD-1 strategies which are in translation. The preclinical and clinical data supporting this upcoming clinical trial will be presented.

MS13.06 ROLE OF SECOND LINE CHEMOTHERAPY AND NEW TARGET TREATMENT IN RECURRENT MESOTHELIOMA

S. Novello, P. Bironzo

Department of Oncology, University of Turin; San Luigi Gonzaga Hospital, Orbassano/Italy

Malignant pleural mesothelioma (MPM) is a highly lethal disease, with a median overall survival (OS) between 12 and 18 months. Following first-line treatment, neither chemotherapy nor target treatments have clearly shown to increase overall survival (OS), to date. Historically, second-line cytoxic drugs, such as gemcitabine and vinorelbine have been the backbone in pre-treated patients, with response rates ranging from 7% to 16% [*Zucali PA, Perrino M, Lorenzi E, et al. Vinorelbine in pemetrexed-pretreated patients with malignant pleural mesothelioma. Lung Cancer 2014; 84:265-270; Stebbing J, Powles T, McPherson K, et al. The efficacy and safety of weekly vinorelbine in relapsed malignant pleural mesothelioma. Lung Cancer 2009; 63:94-97; van Meerbeck JP, Baas P, Debruyne C, et al. A phase II study of gemcitabine in patients with malignant pleural mesothelioma. European Organisation for Research and Treatment of Cancer Lung Cancer Cooperative Group. Cancer 1999;85(12):2577-2582*]. Pemetrexed rechallenge was assessed in small retrospective studies, suggesting its role, especially when combined with platinum compounds, in selected patients with a pemetrexed-free interval of at least 3 to 6 months [*Zucali PA, Simonelli M, Michetti G, et al. Second-line chemotherapy in malignant pleural mesothelioma: results of a retrospective multicenter survey. Lung cancer 2012; 75: 360-367*]. "*Omics*" studies have enlarged our knowledge of MPM, describing high prevalence of TP53, *NF2*, *BAP1* and cyclin dependent kinase inhibitor 2A (*CDKN2A*) mutations, along with the lack of tyrosine receptor kinase (TRK) activating mutations [*Lo Iacono M, Monica V, Righi L, et al. Targeted next-generation sequencing of cancer genes in advanced malignant pleural mesothelioma: a retrospective study.J Thorac Oncol 2015;10(3):492-9*]. For this reason, the development of target treatment approaches in MPM has been more difficult and slower as compared to non-small-cell lung cancer (NSCLC), for example. However, many drugs have been tested, while others are currently under evaluation. Among the first studied agents, mTOR inhibitors failed to show activity in pre-treated MPM patients [*Ou SH, Moon J, Garland LL, et al.SWOG S0722: phase II study of mTOR inhibitor everolimus (RAD001) in advanced malignant pleural mesothelioma (MPM). J Thorac Oncol 2015;10(2):387-91*]. Enhancer of zeste 2 polycomb repressive complex 2 subunit (EZH2) is upregulated in MPM with *BAP1* inactivation and its inhibition showed to be synthethic lethal in *BAP1*-negative tumors. The EZH2 inhibitor tazemetostat demonstrated a 51% disease control rate (DCR) in 74 MPM patients (95% with *BAP1* inactivation) enrolled in a phase 2 study [*Zauderer MG, Szlosarek P, Le Moulec S, et al. Phase 2, multicenter study of the EZH2 inhibitor tazemetostat as monotherapy in adults with relapsed or refrectory (R/R) malignant mesothelioma (MM) with BAP1 inactivation. J Clin Oncol 36, 2018 (suppl.abstr 8515)*]. As *BAP1* loss leads to homologous repair deficiency, PARP inhibitors are currently being tested in this subgroup [NCT03531840; NCT03207347; NCT03654833]. Neurofibromin 2 (NF2) inactivation, which encodes for merlin, has been proposed to be synthetic lethal to focal adhesion kinase (FAK) inhibition. However, the COMMAND trial, exploring the use of the FAK inhibitor defactinib as a maintenance treatment after first-line chemotherapy in MPM patients stratified for merlin expression, failed to show any improvement as compared to placebo [*Fennell DA, Baas P, Taylor P, et al. Maintenance defactinib versus placebo after first-line chemotherapy in patients with merlin-stratified pleural mesothelioma: COMMAND-a double-blind, randomized, phase II study. J Clin Oncol 2019;37(10):790-798*]. Defactinib is currently under investigation in combination with anti programmed-death 1 (PD-1) monoclonal antibody pembrolizumab in a phase I/IIA clinical trial enrolling pretreated MPM patients along with pancreatic cancer and NSCLC ones [NCT02758587]. The identification of argininosuccinate synthetase 1 (ASS1) loss in MPM, leading to arginine auxotrophy, paved the way to the use of the arginine depletor pegylated adenosine deiminase ADI-PEG20 in a phase 2 randomized trial in 70 ASS1-deficient patients [*Szlosarek PW, Steele JP, Nolan L, et al. Arginine deprivation with pegylated arginine deiminase in patients with argininosuccinate synthetase 1-deficient malignant pleural mesothelioma: a randomized clinical trial. JAMA Oncol 2017;3(1):58-66*]. Among the 68 treated patients,

the drug improved progression free survival (PFS) as compared to best supportive care (BSC) (HR 0.56, 95% CI, 0-33-0.96), although by only 1.2 months (median PFS 3.2 vs 2.0 months for ADI-PEG20 and BSC, respectively; p=0.03). Currently, ADA-PEG20 is being explored in combination with first-line chemotherapy in biphasic and sarcomatous MPM only [NCT02709512]. Recent studies described novel prognostic MPM subsets with specific genomic characteristics that could further shape personalized treatment approaches, especially when looking at immunotherapic approaches [*Hmljak J, Sanchez-Vega F, Hoadley KA, et al. Integrative molecular characterization of malignant pleural mesothelioma. Cancer Discov 2018;8(12):1548-1565*]. Indeed, the high expression of V-domain immunoglobulin suppressor of T-cell activation (VISTA) negative immune-checkpoint in epithelioid MPM reported in this study, suggests a possible of role of specific inhibitors alone or in combination with other agents in advanced MPM.

MS14.01 MOLECULAR SUBSETS OF NEUROENDOCRINE TUMORS

C. Hann

Johns Hopkins University School of Medicine, Baltimore/United States of America

Small cell lung cancer (SCLC) is an aggressive tumor with one of the highest case-fatality rates among cancer. Clinically SCLC is hallmarked by early metastatic behavior and rapid development of therapeutic resistance. Over the past decades multiple research teams have used genomic, epigenomic, transcriptomic and proteomic approaches to further characterize SCLC. Long considered a relatively homogeneous tumor, these data have led to a deeper understanding of SCLC biology and support the concept that there are distinct biologic subsets of SCLC. Complementary work using patient-derived xenografts and genetically engineered mouse models have validated some of this data and these models serve as platforms for novel therapeutic development. These studies support translational efforts in SCLC focused on distinct vulnerabilities in subsets of this disease and the development of predictive biomarkers.

MS14.02 SUBCLONAL ARCHITECTURE AND GENOMIC EVOLUTION OF SCLC

J. Wang

Beijing Chest Hospital, Beijing/China

Small cell lung cancer (SCLC) accounts for 15-20% of all of lung cancer worldwide and it is a highly aggressive and rapidly progressive tumor with rapid growth speed and strongly associated with smoking. SCLC is divided to limited disease and extensive disease. The staging systems for SCLC are Veterans Administration scheme (VA), the AJCC TNM staging systemand NCCN staging, among of these VA is most commonly used. In recent several decades, chemotherapy combined radiotherapy is the main treatment for SCLC. The overall survival (OS) in patients with limited disease-SCLC and extensive disease were 15-18 months and 10-12 months, respectively. Immunotherapy is becoming a promising treatment for SCLC nowadays. Targeted therapy based on genotyping in non-small cell lung cancer is a main treatment. However, targeted therapy in SCLC is not successful and studies on the genomic evolution of SCLC are rare. ctDNA (circulating cell-free tumor DNA) is a good tool for monitoring the genomic changing in patients with malignant tumors, especially for monitoring acquired resistance of targeted therapy. ctDNA and CTCs are useful for genomic evolution of cancer. However, isolation and identification of CTCs are not satisfied in lung cancer, though there are more CTCs in small call lung cancer because of tumor cells are more easily to shed to blood stream in SCLC. ctDNA can provide more accurate genomic landscape of SCLC through overcome heterogeneity. We conducted a study that aimed to explore the genomic structure and gene evolution pattern of SCLC using next-generation sequencing and who had been followed by dynamic samples after chemotherapy or/and radiotherapy. We found that TP53 and RB1 are the most common mutations in SCLC, and NOTCH1-4, CREBBP, EG300, MYC, MYCL1, and MYCN are also frequently mutated genes and copy number alterations. We also compared the tissue and blood ctNDA genome and we found that a majority of mutations detected in tumor DNA were also detected in paired ctDNA samples suggesting ctDNA sequencing is sensitive and reliable for detecting mutations in SCLC patients. We used the average VAF (Variant allelic frequencies) of mutations from the major clones as a surrogate for overall ctDNA level. We found higher median ctDNA level was associated with shorter progression-free survival (PFS) and overall survival (OS). Dynamic ctDNA levels are correlated with tumor measurements on imaging suggesting that ctDNA sequencing has the potential for monitoring the clinical course of SCLC. The genomic profiles derived from pre-treatment ctDNA to the genomic profiles from ctDNA at different time points during treatment from post-treatment plasma samples available. Some new mutations that were not exist in pre-treatment blood samples. Immunotherapy is an important method for lung cancer. PD-L1 expression and tumor mutation burden (TMB) are two common predictors for immunotherapy. In our cohort, tumor mutation burden is not higher based on the large gene panel. PD-L1 expression is about more than 10% in SCLC. The treatment for SCLC is still highly challenging. TMB based on ctDNA is worth further investigation on predicting SCLC immunotherapy. A previous study showed that SCLC with high TMB had a better response to checkpoint inhibitors. Shedding of ctDNA is a complicated process affected by many factors. With the technique development and increasing understanding of tumor biology, the genome of SCLC will be a useful tool for guiding the treatment and predicting the prognosis of SCLC in the future.

MS14.04 TARGETING DNA DAMAGE AND REPAIR

T. Sen

Memorial Sloan-Kettering Cancer Center, New York/United States of America

Genomic profiling of small cell lung cancer has revealed nearly universal inactivation of the key tumor suppressor genes TP53 and RB1. Loss of these critical regulators of cell cycle entry and DNA damage response together results in selective sensitivity to DNA damaging agents, inhibitors of DNA damage repair, and inhibitors of the remaining late phase cell cycle checkpoints. Multiple preclinical studies and recent clinical data nominate these pathways as potential synthetic lethal vulnerabilities in small cell lung cancer. Recent study has also demonstrated that targeting DNA damage response can activate the anti-tumor immunity and potentiate the response of immune checkpoint blockade antibodies. This talk will review these recent studies, focusing on opportunities and future directions in investigational therapy for patients with small cell lung cancer.

MS14.05 DLL3 TARGETING AGENTS

J. Poirier

Memorial Sloan Kettering Cancer Center, New York/United States of America

Delta-like ligand 3 (DLL3) is a single-pass transmembrane Notch ligand that interacts with full-length, unprocessed NOTCH1 in the Golgi apparatus, inhibiting the pathway *in cis*. DLL3 is selectively overexpressed in the subtype of small cell lung cancer (SCLC) driven by the transcription factor ASCL1 (SCLC-A) that accounts for ~70% percent of SCLC diagnoses (95% CI [60 – 79])[1]. In one study immunoreactivity was observed in 1,040/1,363 (70.4%) of SCLC specimens, consistent with this incidence[2]. Overexpression of DLL3 leads to low-level cell surface expression of the protein on the order of 10,000 proteins per cell while expression in normal tissues is restricted to intracellular compartments: the same study demonstrated only low to moderate cytoplasmic or nuclear immunoreactivity in normal adult tissues[3]. High expression of DLL3 has also been reported in low-grade glioma[4,5], neuroendocrine prostate[6], and occasionally in other cancer types when neuroendocrine features are present[7,8]. The exquisitely selective expression of surface DLL3 on cancer cells presents an attractive target for a variety of therapeutic strategies. Rovalpituzumab teserine (Rova-T; SC16LD6.5) is an antibody drug conjugate consisting of a monoclonal antibody targeting DLL3, a cathepsin-cleavable linker, and a pyrrolobenzodiazepine (PBD) warhead[4]. The first-in-human clinical trial of Rova-T in recurrent SCLC demonstrated encouraging activity despite often severe side-effects attributable to the PBD warhead[9]; however, the phase 2 TRINITY study showed a disappointing 16% objective response rate while reporting a similar toxicity profile (NCT02674568). Subsequently, the phase 3 TAHOE study was halted due to shorter overall survival in the treatment arm. An active phase 3 trial of Rova-T in the maintenance setting (MERU) is ongoing (NCT03033511). Other DLL3-targeting therapies under active investigation include the bispecific T cell engager (BiTE) AMG 757 (NCT03319940), and a chimeric antigen receptor CAR-T AMG119 (NCT03392064). These agents have shown significant anti-tumor activity in preclinical models of SCLC; however, AMG 119 required direct delivery of the engineered T cells for activity. AMG 757 was therefore the more potent of the two strategies in preclinical models and may therefore be better suited to overcome known barriers to CAR-T activity in solid tumors. Alternative strategies remain under exploration including the use of ^{89}Zr-SC16, a PET radiotracer, for *in vivo* imaging and as a companion diagnostic to optimize the selection of patients for treatment with DLL3-directed therapeutic agents. ^{89}Zr-labeled-SC16 antibody successfully delineated normal tissue from subcutaneous and orthotopic SCLC tumor xenografts. Radiotracer accumulation in tumors was directly correlated with the degree of DLL3 expression and, also correlated with response to SC16LD6.5 therapy in SCLC patient–derived xenograft models. 1 Rudin, C. TUESDAY, SEPTEMBER 10 11:30–13:00

MS15.01 THE IMPORTANCE OF CESSATION AND "5AS" AS A FRAMEWORK FOR CESSATION

B. Faseru

University of Kansas Medical Center, Kansas City/United States of America

Almost two-thirds of newly diagnosed cancer patients have used or currently use tobacco. Evidence shows that continuous use of tobacco after cancer diagnosis adversely affects treatment outcomes among cancer patients compared to their counterparts who stop using tobacco. These outcomes include recovery, quality of life and survivorship. According to the United States Department of Health and Human Services clinical practice guideline for treating tobacco use and dependence, 5As include 1) Ask about tobacco use at every visit to identify and document tobacco use status of every patient 2) Advise every tobacco user to stop using tobacco – the message must be clear, strong and personal 3) Assess readiness to quit - implement strategies to motivate those who are not ready with 5Rs [Relevance, Risks, Rewards, Roadblocks and Repetition] 4) Assist those who are ready quit - develop (a) a quit plan using the STAR method [Set a quit date, Tell friends, family and co-workers and ask for their support, Anticipate challenges to the quit attempt, Remove all tobacco products] (b) recommend smoking cessation medication as indicated, provide counseling support and supplemental materials including information about the quitline where available 5) Arrange follow-up for additional support to avoid relapse. The efficacy of the 5As brief intervention recommendations have been described in the clinical practice guidelines. For example, clinicians who work in a setting where tobacco use status are easily captured are three times more likely to provide tobacco treatment to their patients OR 3.1 95% CI (2.2-4.2); physician advice to patients who smoke increases the odds of quitting compared to no physician advice OR 1.3 95% CI (1.1-1.6); and a combination of counseling and medication outperforms counseling alone OR 1.7 95% CI (1.3 - 2.1). This brief smoking cessation intervention approach using the 5As framework is feasible and cost effective. However, gaps in smoking cessation knowledge and practices in cancer care persist and tobacco use treatment remain suboptimal. During this mini symposium, we will discuss the effectiveness of 5As at various settings, examine other adaptations such as 3As, ABC, ABCD, AAR and identify ways to overcome the multi-level challenges of implementing evidence-based tobacco dependence treatment during cancer care. MS15.02 PHARMACOTHERAPY SUPPORTS CESSATION

C. Dresler

Action on Smoking and Health, USA, USA/United States of America

It should be acknowledged that smoking cessation is one of the hardest things the patient has ever tried to do. There are two key aspects to tobacco cessation: appropriate pharmacotherapy and behavioral modification. This abstract will address only the pharmacotherapy, but the practitioner must also try to provide or refer to behavioral modication interventions to amplify the effect of the pharmacotherapy. : The most common type of medication for quitting smoking is called 'nicotine replacement therapy' or 'NRT". NRT that has had regulatory approval comes as a gum, a lozenge, or a transdermal patch, or in a device that you 'smoke' like a cigarette' or a nasal spray. In the United States, the nicotine gum, nicotine lozenge and nicotine patch can be purchased without a doctor's prescription. The device that is 'smoked' (I call an inhaler or inhalator - as it is mostly absorbed by buccal mucosa) and the nasal spray must have a doctor's prescription. is a pill that is taken once in the morning and once in the evening. This medication requires a doctor's prescription. This drug does not yet (as of 2019) come in a generic form. To use varenicline – take 0.5 mg by mouth once in the morning for 3 days. On the fourth day – take 0.5 mg by mouth once in the morning and once in the evening. On the 7th day the person should QUIT SMOKING and use 1 mg by mouth once in the morning and once in the evening. Use varenicline for at least 3 months. A discussion between doctor and patient should occur if a longer term treatment period is needed to maintain cessation. is also taken as a pill once in the morning and once in the evening. This medication should not be taken if there is any risk of a seizure, alcoholism, or anorexia. This drug does come as a generic and requires a doctor's prescription. To use bupropion: Take 150 mg by mouth once a AM for 3 days. On the fourth day, take 150 mg by mouth once q AM and a PM. On the 7th day – quit smoking. Use bupropion for at least 3 months. A discussion between doctor and patient should occur if a longer term treatment period is needed to maintain cessation. Nicotine gum: the labeling on the box states that if more than 25 cigarettes per day are smoked, use the 4 mg dose and if less than 25 cigarettes are smoked per day, use the 2 mg dose. However, one can try either and see which dose works better in relieving or preventing cravings for a cigarette. It is very important to take the nicotine gum frequently! Most people do not take enough of the gum during the day to be effective. Instruct the quitter to use at least 9 pieces in the first days of quitting. One should SLOWLY taper down. Plan on having the quitter using the gum for at least 3 months! The worst day is the first day, and then the first week. After about 7-10 days, all of the nicotine and its breakdown products are cleared from the system and the body is starting to become normal again. It is probable that the quitter is still having cravings – and the nicotine gum will help prevent them and make the cravings more manageable. : The nicotine lozenge has a little bit different dosing instruction: if the first cigarette of the day is within 30 minutes after waking up in the morning – use the 4 mg nicotine lozenge. If the first cigarette of the day is had after 30 minutes after getting up – use the 2 mg nicotine lozenge. Again – one can try one and see how it works in relieving cravings without any side effects. If it doesn't seem to relieve cravings – try the other, higher dose. Follow the same instructions above for the gum. AGAIN – it is important to be sure and use enough lozenges per day – the most common problem is people NOT using enough lozenges per day. : The nicotine patch comes in a variety of doses and dosing instructions. Most commonly, people use the 15 mg dose (Nicotrol or generic patch) or the 21 mg patch (Nicoderm, Habitrol or generic). These patches should be put on an area of clean and dry skin. It can be put anywhere on the body, but it is best to put it somewhere on the upper body. Try to put it on a place that is not hairy – so it doesn't hurt when taken it off! Don't put it on the hips where one might sit on it, don't put it under the breast – these places are just common sense places NOT to put the patch. The best place is somewhere on the chest, upper back or arms. It is important to put the new patch on each morning in a DIFFERENT place than the patch before. Some skin redness is common, and it should resolve in the next day or so – but it is important to NOT keep using the same place to put the patch. After about 8 weeks on the highest dose patch, the quitter should start to 'step-down' the dose and use the 14 mg or the 7 mg patch. These decreasing doses are intended to help wean the quitter off of nicotine. Of course, the smaller amount of nicotine will also help with the decreasing cravings and withdrawal symptoms as they get further from the quit date. Even if there is a slip - the quitter has had even one puff – it doesn't mean failure. If there is a slip, work with the quitter, resolve to 'get back on the wagon' and not to have another cigarette. They should learn from the experience about what made that 'slip' occur and try and stay away from that temptation again.

MS15.03 SPEAKING WITH PATIENTS, MOTIVATIONAL INTERVIEWING DEMONSTRATION

D. Arenberg

University of Michigan Medical School, Ann Arbor/United States of America

Ongoing tobacco use accounts for significant treatment and disease related morbidity, mortality, and decreased quality of life among patients undergoing cancer treatment. A common misconception is that it is too late to pursue tobacco cessation for individuals with advanced lung cancer. Data from existing studies do not support this, yet support for tobacco cessation services among cancer centers is often lukewarm or frankly lacking. For individuals undergoing active cancer therapy, even brief interventions from their oncologist can have an enormous impact on their willingness, and motivation to make a quit attempt. The purpose of this presentation is to arm lung cancer clinicians with tools to help patient's find internal motivation to make quit attempts, and to support them with counseling, as well as cessation pharmacotherapy. Common misconceptions among both providers and their patients who use tobacco will be presented, along with strategies to undserstand and overcome ambivalence towards tobacco cessation.

MS16.01 GETTING TO THE TARGET: TRANSPARENCHIMAL APPROACHES

D. Gompelmann

Thoraxklinik at University of Heidelberg, Heidelberg/Germany

The Bronchoscopic Transparenchymal Nodule Access (BTPNA) is a guidance technique that provides to establish tissue diagnosis for peripheral pulmonary nodules. This method differs completely from other guidance techniques as it allows to access nodules via the healthy lung parenchyma and thus is independent on the need to have an airway leading into the lesion [1]. Prior to bronchoscopy, a virtual bronchoscopy navigation system is used that calculates the point of entry (POE) with a straight line, vessel-free access to the lesion and displays the tunnel path from the POE on the airway wall to the target nodule on the basis of the patient´s computed tomography scan. During the endoscopy, the POE is identified under virtual guidance. Then a coring needle is used to penetrate the airway wall and this hole is enlarged by a balloon dilator. Afterwards, a sheath is advanced through the lung parenchyma in order to create a tunnel to the target lesion under fluoroscopic guidance. Once the nodule is achieved, the stylet can be removed and a biopsy forceps is advanced through the sheath in order to sample the lesion. So far, the BTPNA is still investigational and different trials are ongoing to evaluate the diagnostic yield of the BTPNA. Up to date, two prospective trials confirmed the safety and feasibility of the BTPNA in 18 patients with peripheral lesions from suspected lung cancer or metastatic disease [2; 3]. The tunnel path was successfully created in 89% and adequate histological sampling was attained. The only adverse events were pneumothorax in two patients with

the need for chest tube insertion in one of them and a transient rise in troponin levels in another patient. In a further prospective trial of BTPNA that was presented on this year´s ATS congress a diagnostic yield of 83.3% was found. References: [1] Gompelmann D. Upcoming techniques. MS16.02 ROBOTIC BRONCHOSCOPY: DRIVELESS IP?

D. Fielding

Royal Brisbane and Womens Hospital, Brisbane/Australia

Introduction: Robotic bronchoscopy has been developed in response to challenges which face bronchoscopists in the diagnosis of peripheral pulmonary nodules. Further, such nodules are increasingly presented to bronchoscopists because of CT screening programs, and a general increase in the performance of chest CT in the community with resultant incidental detection of small nodules. Two platforms have undergone preliminary lab evaluations followed by in-human feasibility and safety studies. These are the Auris system and the Intuitive surgical system and the results of these studies are now published (1,2). Both have since had FDA approval and are undergoing post- marketing multicentre studies, the first as the Monarch system, the second as the Ion system. The challenges facing bronchoscopists are 1. The small size of nodules, 2. The peripheral nature of the nodules requiring small calibre scopes to reach them, 3. The complex anatomic pathways to reach them, and 4. The position of the nodules in relation to the airway, with many being "extrinsic" to the bronchus, making biopsy sampling difficult. Robotic bronchoscopy seeks to answer these challenges by integrating an array of components incorporating small size of the distal scope, excellent manoeuvrability of the distal end of the scope, real time display of CT-derived navigational assistance, and biopsy channel size in the distal end of the scope to allow good quality samples. Methods: The robotic aspect of the systems means robotic arms (2 with Auris and 1 with Intuitive) drive the scope into the airway under the direction of a physician operated console, as opposed to the hands of a physician holding the scope and advancing and directing the scope. Important in this regard is the system is not "automatic", meaning the physician is in control of the device at all times, directing the scope into pre-planned airways under direct vision provided by the system. The robotic aspect of the devices means that the driving and directing of the scope are much more precise and not prone to slipping out of airways between biopsy attempts, reducing the need to re-navigate back to a nodule. The main difference in the systems relates to the design of the catheter (Figs 1 and 2). The Auris system has a telescoping end, with a scope extending out of an outer sheath, while the Intuitive scope has a single catheter, within which a removable optic can be removed to allow deployment of biopsy instruments. Figure 1: Distal end of the Auris system incorporating a sheath (light blue) and an inner bronchoscope (dark blue). The outer sheath(6mm) is wedged in a segmental bronchus, then the inner bronchoscope (4.2mm) is advanced to the distal airways. Figure 2. The distal catheter tip of the Intuitive system (outer diameter 3.4mm), showing accompanying shape sensing image which is displayed real time, providing continuous position feedback. Results: The Auris study reported 15 patients, and the Intuitive study 29 patients, mean lesion size 26mm (1.0-6.3) and 12.2 ± 4.2 mm respectively. Bronchus was sign was absent in all cases with Auris (predefined) whereas 44% were bronchus sign absent in the Intuitive study. All patients were intubated and the procedure performed under general anaesthesia. Most patients were discharged the same day. Both systems reported no adverse events from the device itself. One SAE was reported in the Intuitive study which was an anaesthetic complication related to use of muscle relaxants from which there were no long term sequelae. Successful navigation to the nodule was made in 14 of 15 and 28 of 29 patients respectively. EBUS Guide sheath confirmation was allowed just before biopsy in the Intuitive study but not the Auris study. The devices allowed multiple samples to be taken quickly; the use of needle sampling was common in the Intuitive study because of the nature of the extrabronchial lesions. Malignancy was confirmed in 7 of 9 cases with the Auris device and 13 of 15 cases with the Intuitive device. Conclusions: Robotic bronchoscopy offers unique capability for a proceduralists in combing excellent navigation with thin scopes and stability at the biopsy tip. These early results of sampling difficult nodules need to be followed up in multicentre studies, but suggest a significant potential in dealing with small peripheral nodule biopsy. Further the large size of the biopsy channels and the stability of the tip of the instruments due to the robotics could allow further evaluation of these devices to permit endolumenal therapies for small peripheral lung cancers. MS16.03 BRONCHOSCOPY AND OPTICAL BIOPSY

L. Wijmans

GZO Wetzikon, Zurich/Switzerland

Diagnosing lung cancer in the absence of endobronchial abnormalities is challenging. Needle-based confocal laser endomicroscopy (nCLE) enables real-time microscopic imaging of cells. We assessed the feasibility and safety of using nCLE for real-time identification of lung cancer. In patients with suspected or proven lung cancer scheduled for endoscopic ultrasound (EUS), lung tumours and mediastinal lymph nodes were imaged with nCLE before fine-needle aspiration (FNA) was performed. nCLE lung cancer characteristics were identified by comparison with pathology. Multiple blinded raters validated CLE videos of lung tumours and mediastinal nodes twice. EUS-nCLE-FNA was performed in 22 patients with suspected or proven lung cancer in whom 27 lesions (six tumours, 21 mediastinal nodes) were evaluated without complications. Three nCLE lung cancer criteria (dark enlarged pleomorphic cells, dark clumps and directional streaming) were identified. The accuracy of nCLE imaging for detecting malignancy was 90% in tumours and 89% in metastatic lymph nodes. Both inter-observer agreement (mean κ=0.68, 95% CI 0.66–0.70) and intra-observer agreement (mean±sd κ=0.70±0.15) were substantial. Real-time lung cancer detection by endosonography-guided nCLE was feasible and safe. Lung cancer characteristics were accurately recognised

MS16.04 BRONCHOSCOPIC LUNG CANCER ABLATION

K. Yasufuku

Toronto General Hospital, University of Toronto, Canada/Canada

Lung cancer is the leading cause of cancer mortality in the western world. Around 80% of cases are classified as non-small cell lung cancer (NSCLC). Surgical resection by lobectomy is the standard of care for patients with localized and early stage NSCLC (1). However, patients with comorbidities may not tolerate standard surgery. With the aging population and the wide-spread use of CT scan for lung cancer screening, we are faced with increasing number of patients with early stage lung cancer who are medically inoperable. Currently, stereotactic body radiation therapy (SBRT) is the standard-of-care for treatment of early stage peripheral NSCLC in medically inoperable

patients (1). Although SBRT has become a standard option for treatment of peripheral NSCLC, it is still not clear whether the survival rates and recurrence rates are similar to those after standard curative surgical resection. SBRT also has risks such as radiation lung toxicity and therefore it not applicable to all patients as well as limited with location of the tumor (2). Percutaneous thermal ablation typically performed by interventional radiologist is an alternative approach for treatment of medically inoperable patients. Hot therapy such as radiofrequency ablation (RFA) and microwave ablation (MWA) are used for treatment of lung tumors. Cold therapy is also available using the cryotherapy (3). Although thermal therapy has shown good local control rates, complications related to percutaneous ablative approach including pneumothorax, BP fistula, bleeding, needle tract seeding cannot be ignored, since the majority of patients requiring such therapy in general do not have good lung function. A safer approach and therapeutic option for medically inoperable patients with NSCLC is desired. Recently we have seen advances in technology that allow bronchoscopists to navigate and approach peripheral lung cancer via transbronchial approach. Development of smaller bronchoscopes allow better manipulation of the scope to reach out to the peripheral lung (4). Navigational bronchoscopy aids bronchoscopist by providing actual pathway to the peripheral nodule (5). The radial probe endobronchial ultrasound (RP-EBUS) allow confirmation of the tumor location during peripheral transbronchial biopsies (6). Combining these bronchoscopic technologies with an ablation catheter that will fit through the channel of the flexible bronchoscope may allow minimally invasive transbronchial ablation of peripheral lung cancer. Fore real-time confirmation of probe positioning during transbronchial ablation, cone-beam CT scan is suitable even during bronchoscopy. The development of such technology is still in its infancy. Based on current publications including animal studies and human case studies, possible transbronchial ablative technologies include transbronchial RFA, MWA, cryotherapy, photodynamic therapy (PDT), photothermal therapy (PTT) and thermal vapor ablation (7). Although the evidence is not available yet, multiple clinical trials under way and hopefully these technologies will become available in the future. Details of each modality will be discussed in the presentation. Reference Postmus PE, Kerr KM, Oudkerk M, et al. MS16.05 OPTIMAL TREATMENT SELECTION FOR SCREEN-DETECTED LUNG CANCERS

N. Ikeda

Tokyo Medical University, Tokyo/Japan

In recent years, the number of early stage lung cancers, especially cases showing ground-glass opacity (GGO) has enormously increased mainly due to frequent use of chest CT in routine practice or screening purpose. The surgical approach has enormously changed to pursue both curability and minimal inavasiveness for such early disease. Increased number of VATS lobectomy and sublobar resection for selected patients is the international trend.Conventional bronchoscopic examination for screening detected tiny cancers shows low diagnostic rate therefore the combination of virtual bronchoscopic navigation (VBN) and EBUS guide-sheath has been employed. A total of 40000 lung cancers were resected in Japan in 2015 and 70% of surgeries were performed by video-assisted1). Although there are a few randomized controlled trial, the evidence of VATS lobectomy is supported many propensity-matched studies, several high quality meta-analyses as well as outcome studies2). Segmentectomy has been performed intentionally mainly for lung cancer 2cm or less in diameter. Several comparative studies between lobectomy and segmentectomy for tumors < 2cm showed no significant difference in survival3). Recently, segmentectomy is selected based on the size, location as well as the consolidation size in the primary lesion in preoperative high resolution CT (HRCT). The proportion of consolidation diameter to tumor diameter (C/T ratio) correlates with biological malignancy and the establishment of robust image criteria predicting non-invasive cancer is desirable to find candidates for segmentectomy. The Japan Clinical Oncology Group (JCOG) conducted a prospective cohort study to recognize the relationship between HRCT finding and pathological non-invasiveness (no lymph node metastasis or vessel invasion) in clicical stage IA cancer (JCOG0201)4). This study revealed that adenocarcinoma <2.0 cm with <0.25 consolidation to the maximum tumor diameter showed pathological non-invasiveness in 98.7% and this criterion could be used to as radiological non-invasive adenocarcinoma5). Based on the result of JCOG0201, two prospective studies were performed and finished recruitment, phase II trial of wide wedge resection for radiological non-invasive adenocarcinoma (tumor diameter 2cm or less and consolidation ratio<0.25) (JCOG0804) and randomised phase III trial for radiological invasive adenocarcinoma (tumor diameter 2cm or less and consolidation ratio>0.25) to evaluate non-inferiority in OS of segmentectomy compared to lobectomy (JCOG0802)6). The indication of segmentectomy will be demonstrated by the results of these studies. Although C/T ratio in the maximum plane of the tumor has been applied clinically as an index of malignancy, objective measurement is sometimes difficult due to the irregular shape of objectives. It should be more accurate to analyze the ratio of the consolidation part volume to whole tumor volume quantitatively by creating 3D-CT image. In our analysis of 252 cases of stage I lung cancer, the solid part volume of the tumor had a statistically significant correlation with prognosis7). In addition, PET-CT has been routinely used for the management of lung cancer and another approach to evaluate the biological aggressiveness. The standardized uptake value (SUV) of the main tumor is recognized to be as a predictor of the clinicopathological characteristics. Our data showed that more accurate prognosis of stage IA adenocarcinoma could be predicted by the combination of SUVmax and solid part volume of the primary tumor8). Since CT reflects the histologic grade of the tumor and SUVmax reflects the intratumoral metabolism, the combined use of these may be expected to evaluate nature of lung cancer more precisely than each alone.The information on the grade of malignancy obtained from preoperative images is useful for selecting appropriate treatment. In the near future, radiomics can analyze the radiologic images and extract important pathological and genomic information non-invasively before treatment. Advances in imaging and quantitative analysis will be powerful support to select interventions of screening detected lung cancer. MS16.06 SMOKING CESSATION IN A PULMONARY CLINIC

P. Lee
National University Hospital, singapore/Singapore

Lung cancer is the leading cause of cancer related death worldwide. NLST showed 20% reduction in mortality from lung cancer among long-term heavy smokers screened with low dose CT. However, screening for early stage lung cancers can be controversial as the number of lives saved through early diagnosis should be assessed against potential harms of invasive testing, over diagnosis of indolent tumors and surgery for benign conditions. Of the positive CT scans in NLST, 96.4% were false positives, and the risks of death and major complications pertaining to diagnostic tests for benign nodules are 4.1 and 4.5 per 10,000 respectively. The decision to pursue surveillance imaging or invasive evaluation requires careful assessment of the risk for cancer, access for biopsy, fitness for surgery and patient's preferences. When biopsy is required, the approach includes bronchoscopy, transthoracic needle biopsy or surgical lung biopsy. Selection of the appropriate intervention depends on lesion size and location, presence of lymphadenopathy, and local expertise. Bronchoscopy is safe but limited by its sensitivity which in turn depends on location and size of the pulmonary nodule. There has been substantial evolution in bronchoscopic approaches towards achieving access of these small peripheral pulmonary nodules, improved tools to acquire specimens necessary for early diagnosis so as to facilitate curative therapy not confined to surgical resection but heralds an era of innovative techniques performed in minimally invasive manner.

MS17.01 ROLE OF LIQUID BIOPSY IN THE PATHOLOGY DIAGNOSIS WORKFLOW (INCLUDING DNA, RNA AD EXOSOMES)

F. Lopez-Rios

HM Hospitales (Madrid, Galicia & Barcelona), Madrid/Spain

Although liquid biopsy approaches have considerable potential to improve patient care, integrating them into the pathology diagnosis workflow could be a challenge. In the presentation I will address the most frequent barriers for inmediate implementation of the recommendations released by the IASLC and other academic groups. Briefly, plasma is preferred over serum for ctDNA and ctRNA extraction. The choice of analytical methodology should balance availability, cost, turnaround time, sensitivity and specificity. Recent cross-platform comparisons will be presented because technical factors could explain both discordance between assays and with tissue-based genotyping. The results of liquid biopsies should follow the standards of molecular pathology reporting. Taking into consideration that the number of pathology and biomarker reports per patient will be growing over the next few years, it is important to integrate all of them before discussion of treatment options take place at the molecular tumour board. The recent tier classifications of molecular alterations released by professional organisations could help implement this strategy. Abbosh C, Birkbak NJ, Swanton C. MS17.02 MAJOR PATHOLOGICAL EVALUATION IN NEOADJUVANT IMMUNOTHERAPY

J. Ramirez

Hospital Clinic, Barcelona/Spain

The pathologists play different roles in the care of cancer patients. The main part of this activity is to make the diagnosis of the tumor type, followed by the support to the clinicians in the staging of the patient. In the group of patients that receive Chemotherapy (CT) and / or Radiotherapy (RT) before surgery, the pathologist has to evaluate the results of these treatments by evaluating the tumor bed and the response of the lung. There is a lot of experience in the literature referred to the different types of pathological response to lung cancer treatment after the use of either CT or RT. There are guidelines for the pathologists in order to give an objective evaluation of the treatment results (1). All of them ask the pathologists to evaluate the percentage of viable tumor cells, necrosis and stromal reaction. We can also find different attempts to find molecular markers useful for predicting survival after these traditional treatments (2). In order to have an objective evaluation of the lung cancer patients after CT in 2014 emerged the concept of Major Pathological Response (MPR) as a possible predictor of overall survival (3). This term was applied to describe those patients with a viability of 10% of the tumor cells after neoadjuvant CT. In this report, they propose the MPR as a surrogate endpoint. Since that, the concept of MPR has been used in different reports and assays, becoming a usual parameter for patients with lung resections after receiving chemotherapy. The percentage of viable cells became an important data that has to be evaluated with accuracy in order to avoid subjective results. One of the best ways is to use any of the commercial systems to make measurements on the slides. In our department, we use digital slides to get objective and reproducible data for this type of evaluation. The recent implementation of immunotherapy (IT) for NSCLC that is being applied to an increasing number of patients all over the world makes it necessary to study deeply its morphological effects over de tumor in lung specimens. As most of the patients will never go to the operating room, it becomes important to be aware of the limited knowledge that we have so far. There are some reports comparing the effects of the traditional chemotherapy with immunotherapy. One of these studies shows that the pathologist should look for the same features that are routinely evaluated in the cases after CT (4). The pathologist might evaluate the classic features (viable cells, necrosis and stromal reaction) and other characteristics such as macrophages, cholesterol clefts, lymphoid aggregates, giant cells and neovascularization. In this review, they did not find important differences between the type of morphological changes in both types of treatment, so they propose to use the same parameters in CT and in IT A recent report proposes the concept of Immuno related Pathological Response Criteria (irPRC) (5). They pay attention to the Immune activation with dense lymphoid infiltrate, macrophages and tertiary lymphoid structures as the main characteristics. They also evaluate the massive tumor cell death with destructive features such as cholesterol clefts and those indicative of tissue repair with neovascularization and fibrosis. Last year a review collected different assays done with neoadjuvant IT in patients with resectable lung cancer (6). There is no enough experience in these special groups of patients, as today the IT is given only to advanced lung carcinoma patients. Conclusions: At the present time there are no guidelines for the evaluation of lung tissues after IT. The pathologists have to be aware of the effects of these new biological treatments for lung cancer patients, in order to give as much information as possible in the short number of cases that are

seen in the real clinical situation. The previous experience in resected lungs after neoadjuvant therapy is not enough to evaluate the cases after IT. The data obtained from these lung specimens have to give more information in order to improve the knowledge of the effects of these new therapies. References: 1. Pataer A, Kalhor N, Correa AM et al. MS17.03 QUANTITATIVE IMAGE ANALYSIS, IMAGE-BASED PROFILING INCLUDING 3D DIGITAL PRINTING AND AI

S. Lantuejoul

Centre Léon Bérard, Lyon/France

Digital pathology and AI Digital pathology refers to the use of computer stations to analyze images of whole slides scanned at high resolution for teaching or research purposes; these images are analyzed by algorithms that allow standardization and reproducibility of the analyses. Recently, artificial intelligence has been used to build even more powerful algorithms. The idea is not to reproduce the visual analysis of pathologists but to improve it and to identify new predictive or prognostic morphological characteristics or to couple them with genomic analysis to better stratify tumours (1,2). Technical considerations The digital workflow requires specific equipement (slide scanner, image storage and digital pathology workstation). Image analysis needs well-standardized pre-analytical conditions, especially if IHC stainings are analyzed, where colour variations and absence of background noise must be controlled during different validation steps. Some methods exist to correct artifacts such as section fold, fuzzy area. SOPs (standardised operating procedures) and regulations must also be respected concerning the scanning platforms, which must be CE IVD or FDA approved, the construction of databases, anonymisation, sending and image analysis. Algorithms used for analyses perform different operations on digital images: quality improvement, filtering, recording and segmentation and they must also be validated by correlation measuring the reproducibility between pathologists and algorithms. In addition, The large amount of data requires significant computer processing with accelerated calculations by CNNs (Convolutional Neural Networks) and large image storage capacity. Applications:Quantitative analyses and Image-Based Profiling: most image analyses proposed by commercial softwares (VisionPharm, Definiens Tissue Studio, Indica Labs HALO), or open source softwares such as QuPath Open Source Software for Quantitative pathology or ImageJ, are area or cells-based measurements. Area- based measurements include quantification of stained zones (using IHC stain for example); cell_ based measurements require segmentation steps to delineate tissue compartments, to distinguish for example tumor from begnin regions or to identify subcellular structures (such as nuclei). Some modules or algorithms are CE-IVD or FDA approved such as those used to quantify the expression of ER, PR, Her2 and KI67 in breast cancers. Other algorithms enable the estimation of the percentage of tumour cells before molecular analysis for the detection of genes mutations (Tissue Mark, Philipps pathology). They can also enable to localise and quantify the immune infiltrate (CD3 and CD8+ T Cells) within the tumor stroma (Immunoscore, Laboratory of Integrative cancer Immunology INSERM Paris). Some machine Learning methods can also automatically differentiate tumor cells from stroma cells and inflammatory cells or identify lymph node metastases. In thoracic pathology, automated whole slide scoring of PDL1 has been proposed in NSCLC with an excellent agreement for tumor cells scoring and a good concordance for immune cells (3). Image based analysis has been used for quantification of immune checkpoints molecules co expression in NSCLC (4). Several studies have showed the interest of automatic image-based analysis for the optimization of histological or cytological classification of lung cancer and prediction of prognosis (5,6). Deep learning technology has been used to classify lung tumour subtypes from the virtual slides available in the TCGA (7), or to classifiy adenocarcinoma according to the predominant pattern with a kappa score of 0.525 and an agreement of 66.6% with three pathologists (8). Deep learning was also proposed for genomic profiling of tumours, with a prediction of STK11, EGFR, FAT1, SETBP1, KRAS and TP53 mutations from pathology images showing an AUCs ranging from 0.733 to 0.856 (9,10). Applications: 3D dimensions modeling and digital Printing Three-dimensional (3D) photogrammetry is a method of image-based modeling in which data points in digital images, taken from offset viewpoints, are analyzed to generate a 3D model. This technique can be used to generate 3D representation sof surgical specimens, for routine gross examination, in multidisciplinary meetings to improve clinicopathologic correlation between surgeon and pathologists, and for education purposes via 3D printing specimen models (11). MS17.04 MULTIPLEX IMMUNOHISTOCHEMISTRY

I. Wistuba, E. Parra, A. Francisco Cruz

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Multiplexed imaging platforms to simultaneously detect multiple epitopes in the same tissue section emerged in the last years as very powerful tools to study tumor immune contexture. These revolutionary technologies are providing a deep methodology for tumor evaluation in formalin-fixed and paraffin-embedded (FFPE) to improve the understanding of tumor microenvironment, new targets for treatment, prognostic and predictive biomarkers, and translational studies. Multiplexed imaging platforms allow the identification of several antigens simultaneously from a single tissue section, core needle biopsies, and tissue microarrays. In recent years, multiplexed immunohistochemistry, immunofluorescence, mass spectometry and other imaging modalities have improved the abilities to characterize the different types of cell populations in malignant and non-malignant tissues, and their spatial distribution in relationship to clinical outcomes. Multiplexed technologies associated with digital image analysis software offer a high-quality throughput assay to study cancer specimens, inc;luding lung cancer, at multiple timepoints before, during and after treatment. The aim of this resentation is to provide a review of multiplexed tissue imaging applied to lung cancer focusing in the use of multiplex immunofluorescence with tyramine signal amplification staining for lung cancer immune profiling and translational research.

Keywords: Multiplex immunofluorescence, immune-profiling, microenvironment

MS17.05 CONTROVERSIES IN PATHOLOGIC STAGING

M. Yotsukura

National Cancer Center Hospital, Tokyo/Japan

The 8th edition of the TNM classification system was implemented in January 2017, except in the United States, where it was delayed until January 2018. The 8th edition was proposed by the Staging and Prognostic Factors Committee (SPFC) of the International Association for the Study of Lung Cancer (IASLC), and accepted by the Union for International Cancer Control and American Joint Committee on Cancer. The SPFC's proposed changes from the 7th to 8th edition were essentially based on prognostic data from the IASLC database, which included 70,697 evaluable patients with non-small cell lung cancer and 6,189 patients with small cell lung cancer. Although the TNM system is the result of a scientific analysis of the anatomical extent of the tumor, some of the classification points are still controversial. 1. Ground glass opacity Regarding the T descriptor, the main issue revolves around ground glass opacity (GGO)-related matters. The invasive area can pathologically be well-defined under microscopic evaluation, sometimes in combination with Elastica van Gieson stain. However, the difference between pathological and clinical staging has been a problem. Clinical staging depends on how to measure the GGO component by computed tomography (CT), which has not been defined very well. Another point to be addressed related to GGO is the separation of GGO-containing tumors from solid tumors. For example, if a tumor has a solid component of 1.5 cm without any surrounding GGO component, it will be defined as clinical T1b, whereas if a tumor has a solid component of 1.5 cm along with 1.0 cm of surrounding GGO component (total tumor diameter of 1.5 + 1.0 = 2.5 cm), it would also be defined as clinical T1b. However, the malignant capacity of a purely solid tumor is reported to be worse than that of GGO-containing tumors. Thus, from a prognostic viewpoint, it might be better to consider these two types of tumors separately. 2. Visceral pleural invasion Another controversy regarding the T descriptor in pathologic staging involves visceral pleural invasion (VPI). First, data should be collected using a standardized definition. A standardized definition of VPI was incorporated into the 7th edition of TNM and maintained in the 8th edition. PL1, 2, and 3 are pathologically evaluated based on tumor invasion to the elastic layer, pleural surface, and parietal pleura. In case of doubt regarding VPI, the use of elastic stains is recommended. The collection of data using this definition and the use of elastic stains are important for accurate evaluation in future revisions. Second, the difficulty of clinical evaluation of VPI might be a problem. In the current staging system, clinicians have to speculate on the presence of VPI, based solely on the findings of CT imaging. A clear imaging-based definition of VPI might be beneficial. Third, in the current staging system, interlobar PL3 is classified as T2a. Since little is known about the prognosis of this interlobar PL3, data should be collected for use in a future revision of the TNM classification. 3. Nodal evaluation Regarding the N descriptor, as previously reported in the literature, tumors with nodal metastases to multiple lymph node stations have a worse prognosis than those with single-station metastasis. Counting the number of positive nodes instead of the number of stations might be considered as well, especially from the viewpoint of emphasizing prognostic impact. However, a standardized method for pathological nodal evaluation has been lacking. How should pathologic slides be made for an accurate evaluation of nodal status? The number of nodes that are incorporated on the same slide, and the number and depth of sections to be evaluated per slide, are not well defined. It is also not clear how to handle an intraoperatively separated node, when counting the number of metastatic nodes. It would be desirable to have some consensus about the evaluation methodology to achieve a more accurate prognostic analysis. 4. Molecular information There are some disagreements about how to use molecular information, in relation to TNM classification. Over the past decades, dramatic advances have been made in the fields of molecular diagnosis and precision medicine. The therapeutic strategy has been developed in detail depending on the molecular status, especially in advanced tumors. Accordingly, the prognosis has been influenced by the molecular status of the tumor, and thus molecular biomarkers have become some of the most important prognostic factors. In principle, the TNM classification describes the anatomic extent of tumors, arranged according to prognostic differences. From the perspective of the prognostic impact, molecular biomarkers might be as important as TNM staging. The combination of molecular status and TNM classification could be considered. However, based on the principal concept of the anatomic classification of the TNM system, it might be better to consider molecular factors as a different methodology of the classification system. Further discussions will be needed regarding the relationship between molecular markers and the anatomic TNM classification system. These issues reflect only some of the controversies surrounding the TNM staging system. Along with other issues, they are expected to be discussed in detail in the SPFC meetings for the forthcoming update of the TNM classification system.

MS18.01 EXHALED BREATH BIOMARKERS

N. Peled

Soroka University Medical Center, Beer-Sheva/Israel

The evoloving field of early detection of lung cancer is being implemented around the globe. Low Dose CT scans are standard of care in all guidelines, however real world implementation is stil lacking. Biomarker to support early detection is the current UNMET need, as well as non-invasive biomarkers to follow early disease recurrence and monitoring response to therapy. The exhaled breath approach is a growing field of interest, where several groups have contributed significant abount of data. There are numerous technologies available while clinical validation is varies between groups. This talk will score the current knoledge associated with the exhaled breath analysis associated with lung cancer. Surprizingly, the volatille signature is associated with disesae existance, disesae burden, response to therapy, disease profile and even the related mutatoins.

MS18.02 CIRCULATING NUCLEIC ACID BIOMARKERS

G. Sozzi, M. Boeri, U. Pastorino

Fondazione IRCCS Istituto Nazionale dei Tumori, Milan/Italy

Encouraging results in lung cancer (LC) mortality reduction were obtained by the introduction of low dose computed tomography (LDCT) for lung cancer screening. The results of Nelson screening trial showed a 26% reduction in lung cancer mortality in the LDCT arm thus confirming the benefit of LC screening with LDCT already published by the NLST group (1). In MILD trial we showed that at 10 years follow up the mortality reduction was even higher (-39%) proving that extended LDCT screening is effective in reducing lung cancer mortality (2). Nonetheless, the development of non-invasive complementary biomarkers could be helpful to improve the efficacy of LDCT screening by improving LC risk prediction and defining personalised LDCT screening intervals as well as to decrease false positives identified by LDCT and monitor disease evolution in patients after curative resection. The value of circulating tumor DNA (ctDNA) as a biomarker in advanced tumor stages is well established. However, its role in early lung cancer detection is still uncertain. The biggest technical challenge is sensitivity. Current efforts to develop next-generation sequencing (NGS) technologies to study ctDNA in the context of early detection might improve sensitivity in this context. The scientific community is awaiting the results of the Circulating Cell-free Genome Atlas (CCGA) Study for early cancer detection, enrolling 15,000 participants in the United States and Canada. Plasma samples collected at baseline and during 5 years of follow-up will be analyzed by whole genome sequencing(WGS) for copy number variation(CNV), targeted DNA sequencing (a 507-gene panel), and whole genome methylome profiling. Preliminary results in an observational case-control setting include 95% specificity, high sensitivity for advanced lung cancer in 54 patients (85% for targeted sequencing, 91% for CNV WGS, and 93% for methylome profiling), and modest sensitivity for 63 patients with stage I to III lung cancer (48% for targeted NGS, 54% for CNV WGS, and 56% for methylome profiling)(3). Therefore, the generalizability of these findings to the screening setting is uncertain. In order to implement lung cancer screening programs, we focused on circulating microRNAs which may reflect the contribution not only of the tumor but also of its microenvironment and the host. We developed a plasma miRNA Classifier (MSC) composed of 24 miRNAs which showed high performance in terms of sensitivity (87%) and specificity (81%) in 940 subjects enrolled in the MILD screening trial. The classifier was able to identify, in longitudinal plasma samples of the patients, a risk profile to develop LC up to two years before a significant tumor burden was visible at LDCT(4). These results prompted us to launch in 2013 a prospective screening trial, called bioMILD, to test the efficacy of a combined LDCT-MSC approach as forefront screening tests in a large cohort of 4119 smokers, 50 yrs or older. We succesfully completed the baseline of all the volunteers and executed a LDCT in 11,012 and miRNA test in 9,156 subjects. BioMILD has now reached the 3 yrs follow up for all subjects and 4.2 year median follow up for the all cohort. Analyses of the results are ongoing and will be presented. Concerning the origin of the 24 miRNA, since the classifier was able to identify a risk profile to develop lung cancer up to two years before the radiological diagnosis, we hypothesized that that such circulating miRNAs could be released not merely by cancer cells but rather by the damaged lung microenvironment and the host response that may sustain tumor development. Using *in vitro* models and clinical samples we showed that c-miRNAs originated mostly from blood cells, with activated neutrophils showing modulation of the 24 miRNAs overlapping that observed in plasma of MSC positive subjects(5). The role of immunity in modulating the risk of disease development remains to be elucidated, while it could have enormous impact in terms of prevention and early intervention. Therefore we characterized peripheral blood immune cell profiles as possible complementary biomarkers for risk assessment and analyzed their relationship with MSC. In a case control study of 40 lung cancer patients and 20 controls we found immune cell subpopulations differentially expressed between screening detected lung cancer patients and controls. Of interest an MSC high risk profile in patients was associated with specific circulating immune cell subsets including higher numbers of exausted T cells and monocytes/MDSC and lower cytotoxic T and NK cells. These findings suggest that MSC high risk profile might reflect an immunosuppressive status and prompted us to study the possible utility of MSC in lung cancer immunotherapy settings. Using a prospective cohort of 140 consecutive advanced NSCLC patients treated with immune checkpoints inhibitors we found that MSC either alone or in combination with PD-L1 expression in the tumor was associated with patients survival(6). Therefore, plasma MSC, reflecting an impaired tumor immune contexture, could supplement PD-L1 tumor expression to identify a subgroup of patients who do not benefit from immunotherapy. MS18.03 AMOLECULAR DIAGNOSTICS, INCORPORATING GWAS AND RISK MODELS: FUTURE APPROACHES TO THE IDENTIFICATION OF HIGH-RISK INDIVIDUALS

P. Brennan[1], C. Amos[2]

[1]*International Agency for Research on Cancer, Lyon/France,* [2]*Baylor College of Medicine, Texas/United States of America*

Role of Biomarkers in Lung Cancer Screening As a part of ongoing research to understand the etiology and early detection of lung cancer, the Integrative Analysis of Lung Cancer Etiology and Risk (INTEGRAL) consortium has been genotyping large numbers of lung cancer cases and controls and analyzing biomarkers from case cohort members prior to their diagnosis with lung cancer and matched controls. We are also assembling knowledge about predictors of lung cancer risk to identify biomarkers that will be applied along with radiomic features to select individuals at highest risk for lung cancer to enroll in screening studies and to assist in resolution of cancer risk among those found to have small nodules. To date we have analyzed genetic data from 29,266 patients and 56,450 controls of European descent(1) and curated genotyping information from 20 studies conducted in European descent, 14 from Asian descent and 1 study in African-American Populations(2). Ongoing imputation is allowing us to integrate most of these data for a further analysis that brings together world populations for genetic discovery. Results of these studies have identified 12 strongly replicated loci and an additional 38 loci that are highly significant in some studies but less well replicated. Among the variants that we identified, a variant in BRCA2 (1) is remarkable for conferring over 2 fold increased risk for lung cancer development independent of smoking behavior and thereby indicating a small subset of high risk individuals based on genotype. Further studies to identify rare variants that confer a high risk of lung cancer have identified mutations in ATM and KIAA0930 with odds ratios well over 2. The ATM variant is associated with loss of heterozygosity in tumors but does not cause Ataxia Telangiectasia in homozygotes. We have used genetic information to develop polygenic risk scores and a model that included 221 variants yielded the most improvement in accuracy. Results comparing models to identify individuals at high risk for lung cancer development based on risk scores compared with models based on demographic, clinical and smoking information show a modest increase in prediction accuracy, but identify selected individuals who are at high risk and for whom lung screening would be particularly indicated. The genetic information we have developed and curated can also be used with additional approaches to identify predictors of lung cancer risk using shared heritability and Mendelian randomization analyses. Shared heritability analysis identifies strong genetic correlations

with all measures of smoking behavior and also with primary biliary cirrhosis and schizophrenia. Mendelian randomization, which removes concerns about change in BMI during cancer development, shows that increased BMI is associated with squamous and small cell lung cancer and not associated with adenocarcinoma(3). Mendelian randomization studies found association of increased lung cancer risk with longer germline telomere length and increased risk associated with higher levels of vitamin B12(4). Further Mendelian randomization studies are underway to evaluate other biochemical factors that may associate with increased lung cancer risk. Cohort studies to identify biomarker signatures of risk have identified a reliable panel(5) comprising CEA125, CEA, CYFRA 21-1 and pro-SFTB that along with smoking behavior provide an area under the receiver operator curve of 83%, indicating that a strategy that seeks to identify high risk individuals using data from questionnaires about smoking along with biomarker analysis could substantially improve the yield of low dose spiral CT screening. Further studies of panels of biomarkers including microRNA and circulating cell-free DNA are underway to evaluate the utility of adding additional biomarkers to further identify higher risk individuals. 1. MS18 ROLE OF BIOMARKERS IN LUNG CANCER SCREENING
TUESDAY, SEPTEMBER 10 14:30–16:00

MS18.04 ALTERNATIVE AND PROMISING BIOMARKERS

R. Pio

Center for Applied Medical Research (CIMA), University of Navarra, IDISNA, Pamplona/Spain

Randomized controlled trials have demonstrated that lung cancer screening with low-dose computed tomography (LDCT) in subjects at risk is associated with a decrease in mortality (1-3). However, concerns regarding false positive findings, overdiagnosis, or selection criteria may limit their implementation and sustainability. The use of molecular biomarkers that help to overcome some of these limitations offers great potential. Biomarkers should be non-invasive, reproducible and improve the current standard of care for their intended use. Biomarkers could complement image-based screening in two different ways. First, they may allow refinement of screening selection criteria, independent of age and smoking habits, reducing the numbers of individuals exposed to screening and follow-up interventions. Worldwide collaborative efforts have been implemented to gain insights into the association between SNPs and common cancers (4). Lung cancer-associated single nucleotide polymorphisms (SNPs) identified in these studies may be integrated in risk models to limit the costs of lung cancer screening. Secondly, the combination of radiological findings with molecular biomarkers may facilitate the management of indeterminate pulmonary nodules (IPNs). The implementation of LDCT screening programs is rapidly increasing the detection of IPNs, which too often leads to unnecessary follow-up CTs, or even invasive procedures. Molecular markers may help to differentiate patients with malignant IPNs from the larger number of subjects with benign nodules. At present, no molecular biomarker of lung cancer is being used in routine clinical practice. The tremendous research efforts regarding the development and use of molecular biomarkers in lung cancer screening have recently been reviewed (5). Biomarkers can derive from cancer cells, the tumor microenvironment, or the immune response to cancer. They can be sampled from many different bodily sources, including whole blood, serum, plasma, airway epithelium, sputum, exhaled breath, or urine. Promising molecular candidates include proteins (e.g. cancer-associated antigens, autoantibodies or other immune-related markers), metabolites, microRNAs, epigenetic markers, DNA mutations or RNA signatures. Markers of this kind are at different phases of development, ranging from their analytical validation to the evaluation of their performance in the intended use population. Ultimately, evaluation of the biomarker in real clinical settings will determine its improvement of current standards and cost. Few biomarkers have reached the clinical testing phase. The application of an RNA-based signature in bronchial epithelial cell samples from the AEGIS-1 and AEGIS-2 prospective multicenter observational trials (NCT01309087 and NCT00746759) improved the diagnostic performance of bronchoscopy for the detection of lung cancer (6). In PANOPTIC (NCT01752114), a prospective multicenter observational study, plasma levels of two proteins, LG3BP and C163A, were used to discriminate benign from malignant nodules (7). The bioMILD study (NCT02247453) is prospectively evaluating the efficacy of a plasma microRNA profiling as a first line-screening test for lung cancer detection. The clinical utility of another microRNA-based signature is been validated in blood samples prospectively collected in the COSMOS-II lung cancer screening trial (8). ECLS (NCT01700257) is a randomized study aimed to assess the clinical and cost effectiveness of a test that measures a panel of seven tumor-associated autoantibodies in blood (9). The study has reached its 12,000-participant target, and initial results are expected soon. The DECAMP consortium is conducting two multicenter prospective observational trials (NCT01785342 and NCT02504697) designed to develop an integrated panel of airway and blood-based molecular markers. DECAMP-1 seeks to improve the discrimination between benign and malignant IPNs, whereas DECAMP-2 will test biomarkers to predict the development of lung cancer in screened asymptomatic high-risk individuals. Novel approaches to overcome sensitivity/specificity limitations are also being tested. Host responses to cancer based on activation of the immune system have proved to provide promising diagnostic and prognostic markers applicable in the context of lung cancer screening (10). A diagnostic signature based on the combined determination of complement-activation fragments and cancer-associated proteins has shown a notable capacity to discriminate those patients with malignant IPNs. Next-generation sequencing technologies are also starting to be applied. The CCGA study (NCT02889978) has recently concluded the enrollment of 15,000 participants (more than 10,000 of them with a diagnosis of cancer) from whom longitudinal plasma samples are being collected and analyzed by DNA sequencing and methylation profiling. This study will provide valuable information about the potential application of deep sequencing technologies in circulating cell-free DNA for the early detection of lung cancer. Finally, deep learning approaches will allow the integration of several levels of information (e.g. radiographic features, clinical characteristics and molecular biomarkers) for the generation of more accurate predictive models. In conclusion, molecular biomarkers are potentially useful adjuncts to LDCT screening for lung cancer, either by refining risk prior to LDCT or by assessing malignancy. A remarkable amount of discovery and clinical validation work is ongoing. However, more evidence is still needed to support the implementation of any of the proposed biomarkers in the routine clinical practice. Further development of emerging biomarkers, new technological and integrated approaches, better metrics of clinical utility, and innovative trial designs will be required to speed up the development of lung cancer early detection biomarkers. MS18.05 SPUTUM BIOMARKERS, DYSPLASIA AND CHEMOPREVENTION

R. Keith

Univ of Colorado/RMRVAMC, Aurora/United States of America

The most dramatic improvements in lung cancer survival will emerge from both early detection and the prevention of disease development. Low dose CT screening trials (NLST and NELSON) have shown significant improvements in survival and advances in lung cancer screening will rely on our ability to better define at risk populations and to more personalize the management of indeterminate pulmonary nodules. This includes identifying and validating biomarkers of risk. The NIH defines biomarkers as 'characteristics that are objectively measured and evaluated as indicators of normal biologic processes, pathologic processes, or pharmacologic responses to therapeutic interventions'[1]. The ideal biomarker has excellent sensitivity and specificity and applications to lung cancer screening will mostly focus on two specific areas. The first is improving the selection of at-risk subjects to be screened, and the second is to guide the management of screening detected pulmonary nodules. Biomarkers of lung cancer risk can include a variety of potential biospecimens, ranging from sputum and exhaled breath condensates to endobronchial and peripheral lung biopsies. Expectorated sputum has long been viewed as a 'window to the central airways' and cytologic changes have been observed in sputum samples to predict the presence of lung cancer[2]. While sputum cytology can also predict the presence of pre-malignant central airway lesions, sputum collection has largely fallen out of favor due to perceived difficulties in collecting and interpreting specimens, and advances in analyzing other specimens like blood, urine and exhaled breath. Sputum is a readily available resource, and recent methodological advances, most notably automated 3-dimensional morphologic analysis of sputum[3], are currently being studied to determine the presence of cancer or pre-malignant lesions. It may also help risk stratify subjects with suspicious LDCT findings. Additional studies have also focused on sputum samples. For example, selected gene promoter methylation in exfoliated cells from sputum has been shown to predict cancer up to 18 months prior to diagnosis[4]. Other groups have examined sputum miRNA, and their stability make them potentially attractive biomarkers. One study conducted qRT-PCR studies of sputum from subjects with indeterminate pulmonary nodules and found a panel of 3 miRNAs (miRs 21, 31, and 210) with good sensitivity and specificity for identifying malignant nodules[5]. More recently, a pilot study using metagenetic sequencing of the sputum microbiome suggests there may be bacterial biomarkers indicating the presence of lung cancer[6]. Exhaled breath condensate is an additional biospecimen that has been studied as an adjunct to screening protocols, and the subject is extensively reviewed in a recent publication[7]. For NSCLC, specific pre-malignant histologic lesions have been used as biomarkers of risk and modifiable endpoints in chemoprevention trials. For adenocarcinoma, atypical adenomatous hyperplasia (AAH, a lesion more commonly found now that more ground glass opacities are noted during LDCT screening) can progress to adenocarcinoma in situ and eventually adenocarcinoma. Multiple studies are currently profiling AAH lesions with a goal of better understanding those that progress to invasive cancer. Lung squamous cell carcinoma (SCC) develops in the central airways where pre-malignant lesions progress through advancing levels of dysplasia (mild, moderate, and severe), followed by carcinoma in situ and ultimately invasive SCC. Change in endobronchial histology has been the primary endpoint in multiple SCC chemoprevention trials[8], and longitudinal research has revealed an increased cancer risk in subjects with multiple lesions that persist or progress over time[9]. Endobronchial dysplasia that regresses (i.e. fails to become invasive cancer) is associated with specific immune responses and ongoing studies are characterizing the lesional immune microenvironment of bronchial dysplasia. This will allow for a better understanding of progressive lesions and advance the field of precision chemoprevention. 1. MS18.06 CAPTIVE AUDIENCE, TEACHABLE MOMENT - INTEGRATING TOBACCO CESSATION IN LUNG CANCER SCREENING

M. Tammemagi

Brock University, St. Catherines/Canada

Cigarette smoking causes more than 480,000 deaths each year in the United States.[1]Smoking has been causally linked to cancers of the oropharynx, larynx, esophagus, trachea, bronchus, lung, stomach, liver, pancreas, kidney, ureter, cervix, bladder and colorectum and acute myeloid leukemia, as well as to stroke, blindness, cataracts, age-related macular degeneration, periodontitis, aortic aneurysm, early abdominal aortic atherosclerosis, coronary heart disease, pneumonia, atherosclerotic peripheral vascular disease, chronic obstructive pulmonary disease, tuberculosis, asthma, diabetes, reproductive disorders, ectopic pregnancies, erectile dysfunction, hip fractures, rheumatoid arthritis and immune dysfunction.[1]Lung cancer screening is most effective when applied to individuals at high risk.[2]Using NLST data, Figure 1 describes how the number of competing-causes deaths, primarily smoking related, increases with lung cancer risk, primarily driven by smoking, and how competing-causes deaths exceeds lung cancer deaths. Successful smoking interventions have the potential to greatly reduce morbidity and mortality in lung cancer screenees. It is likely that smoking cessation interventions in lung cancer screening programs will be cost-effective and may lead to health benefits that exceed those of the lung cancer mortality reduction benefits. Current, U.S. guidelines recommend providing smoking cessation interventions for current smokers in lung cancer screening programs. However, which type of smoking cessation program in the lung cancer screening setting is most effective is unknown. Lung cancer screenees generally have longer and more intense smoking histories so they may be more intractable to cessation interventions. On the other hand, screening may provide a *teachable moment*, which may lead to greater rates of cessation.[3]The proportion of current smokers selected for screening is greater when selected by risk prediction model, than when selected by NLST-like criteria. The proportion of current smokers in the NLST was 48.2%, in PLCO NLST-eligible participants was 40.4%, and in the Pan-Canadian Early Detection of Lung Cancer Study and Cancer Care Ontario (CCO) pilot, both of which have eligibility criteria of PLCOm2012 6-year risks ≥2%, were 62.8% and 65.4%, respectively. Two recent reviews concluded that evidence is lacking to recommend specific tailored smoking cessation approach in the lung cancer screening setting and recommend more research.[4,5]Currently, in the U.S., 8 trials in the SCALE (Smoking Cessation within the Context of Lung Cancer Screening) collaboration are underway that are investigating different smoking cessation interventions within lung cancer screening programs.[6]Some of the factor under study in SCALE include the following[6]:participant eligibility criteria, baseline versus annual screen, participant's interest in stopping smoking, treatment delivery method and dose, incorporation of positive and negative screening results, perceived risk of lung cancer, and costs of treatments.Results of SCALE are expected after 2021. Recently, Cadham and colleagues conducted a meta-analysis of smoking cessation interventions in samples that were similar to those in lung

cancer screening programs.[7] At 6-month follow-up, smoking cessation had the following associations with interventions: Electronic/web-based (odds ratio [OR] 1.14, 95% CI 1.03-1.25) Telephone counseling (OR 1.21, 95% CI 0.98-1.50) In-person counseling (OR 1.46, 95% CI 1.25-1.70) Pharmacotherapy (OR 1.53, 95% CI 1.33-1.77). CCO's *Lung Cancer Screening Pilot for People at High Risk*started low dose computed tomography screening in three sites on June 1, 2017. In the first year of screening, 1624 individuals received LDCT scans and current smokers were enrolled in an "opt-out" in-hospital smoking cessation programs. Of scanned participants 88.8% attended in-hospital smoking cessation counselling, and 95.2% were satisfied with their cessation services. In conclusion, several intervention approaches appear to be associated with smoking cessation. Multiple approaches appear better than single approaches. Pharmacotherapy and in-person counseling interventions appear to be superior to electronic/web-based or telephone counseling. Successful enrollment into in-person cessation programs is achievable. 1. JCSE01.02 THE OPPORTUNITY OF DRUGS DEVELOPMENT ON IMMUNOTHERAPY IN CHINA

Q. Zhou

Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangzhou/China

Immunotherapy gets the breakthrough after almost 100 years of silence. PD1/PD-L1 inhibitors as the representative have been extensively studied in various human malignant tumors and get promising long term response with relatively fewer adverse events. The first PD1 inhibitor indication was approved for melanoma in Japan on July 2014. Up to now, the US Food and Drug Administration had approved several PD-1 pathway blockade treatments including nivolumab, pembrolizumab and atezolizumab using in first line and second line of NSCLC. In China, nivolumab was approved for second line setting for advanced NSCLC and pembrolizumab combined with chemotherapy were approved for first line setting of advanced NSCLC. Two novel PD-1 inhibitors from Chinese pharmaceutical companies were approved for melanoma and lymphoma by National Medical Products Administration (NMPA) of China. And, a lot of clinical trials about domestic novel PD-1 and PD-L1 inhibitors from Chinese pharmaceutical companies are now ongoing. IO arena faces intense in-class competition from both MNC (Multi-National Corporation) and domestic pharmaceutical company in China. Now there are more than 20 IO antibodies from 10 MNCs and 16 pharmaceutical companies in China. Besides PD1/PD-L1 and CTLA4, other hot IO drugs such as IDO or Lag3 et al are also under investigation. Clinical trials about some novel combination, for example, CMET inhibitor plus IO, anti-angiogenesis drugs plus IO, et al, are also ongoing. There are special questions which need to be settled in China. Chinese population has relatively high rates of hepatitis B virus infection and much higher proportion of EGFR mutation. The delightful changing recently is some studies emerging to consider the characteristics of the Chinese or Asian populations. Some clinical trials are trying to answer these questions. Besides clinical trials for advanced NSCLC, Clinical trials focus on local advanced NSCLC, early stage NSCLC and SCLC are also ongoing. New adjuvant and adjuvant IO trials have started in China. Most importantly, some novel combinations overcoming previous IO resistance are now on the way, which will give more interesting results in the near future. Research about Chinese IO treatment remains in their early stage and further efforts are needed to improve the design of future clinical trials and translational research. Meanwhile, the other hot IO drugs and phase I studies need to speed up in China.

JCSE01.03 ANY DIFFERENCE ON EFFICACY AND TOXICITY BETWEEN EAST AND WEST?

J. Hu

Zhongshan Hospital, Fudan University, Shanghai/China

Lung cancer is now the most commonly diagnosed cancer and the leading cause of cancer related mortality, taking about 1.6 million lives each year. There has been long evidenced that different population display differential sensitivity and safety profiles on different treatment. in addition, many other factors can also influence therapeutic response of patients, such as lifestyle, metabolism, dietary etc. Here we try to explore the impact and underlying mechanism of ethnic difference on response and tolerance of various therapeutic regimens such as cytotoxic chemotherapy, TKIs, antiangiogenic drugs and ICIs. Treatment patterns of lung cancer has been transformed over the years, leading to the better outcomes of patients. The 5-year overall survival (OS) rate of advanced NSCLC is less than 5% in the standard chemotherapy era. Although widely used of tyrosine kinase inhibitors (TKIs) prolonged progression-free survival (PFS) and OS in patients harboring driver gene mutations, the long-time survival rate was still low due to acquired drug resistance. Over the last five years, emergence of immune checkpoint inhibitors (ICIs) has greatly improved outcomes of NSCLC with objective response rate (ORR) about 20% and 5-year OS rate nearly 16% in previous treated patients based on multiple clinical trials data. A retrospective review of the SEER database found that Asian population presented with higher percentage of metastatic lung cancer but significantly greater overall survival rate among nine different ethnic groups. Furthermore, among the total Asian population, Chinese has the highest percentage of adenocarcinomas (69.4%). The latest data show mutation rate of epidermal growth factor receptor (EGFR) in Adenocarcinoma is 40.3-64.5% and 75% in certain clinically enriched population such as non-smoking adenocarcinoma. These data can fully explain the better outcomes of TKIs in Asia population. There has evidence that different population has different sensitivity and toxicity to different anti-tumor regiments. Studies showed that hematological toxicities of docetaxel were more frequently observed in Japanese compared to US/European patients. In addition, it is reported that docetaxel-induced grade 3/4 neutropenia is higher in Asian clinical trials than non-Asian trials. On the other hand, the discrepancy of dosage regimen between Japanese (60 mg/m^2) and western population implies ethnic difference in PK. Similar data of carbo-platin/paclitaxel and irinotecan-based regimens have been reported in many phase 3 or phase 2 trials. Meanwhile, there are many studies compared the adverse events of TKIs in different ethnics and data suggested that incidence of ILD caused by gefitinib and erlotinib is higher in Japan (1.2-5.4%) than in the rest of the world. Despite promising outcomes of ICIs, the clinical trials for Asia population is still rare now. Checkmate 078 was the first trial to predominantly recruit Chinese NSCLC patients, the ORR of Chinese population was 17%, which is in accordance with Caucasian population. However, according to PMS study of Japan and several published meta-analysis results, Asian patients were more likely to develop pneumonitis with the incidence rate 5.7-9.6% in ICIs mono-therapy and these rate would be increased significantly when combined with other drugs. Many genetic studies have revealed the prevalence of genetic polymorphisms (i.e. mutation of SFTPC, ABCA3; telomere-associated genes like TERT, TERC, RTELI, PARN; SNP of MUC5B etc.) was associated with susceptibility to ILD in Japanese. Understanding characteristics of genomic profile will be of no doubt to facilitate the selection of targeted population of ICIs. Except for the toxicity of ICIs, we should pay attention to the drug response of particular groups of population, which were excluded from clinical trials according to the entry criteria of RCT. Among these HBV-infected NSCLC patients seemed to be more emergency as HBV infected population of Asia is accounted for 62% of global HBV burden, therefore, efficacy and toxicity of ICIs on HBV infected NSCLC patients will be discussed based on many clinical trials or real world data. In a word, ethnic difference can influence efficacy and toxicity of different treatment options. More genomic mapping and preclinical research should be implemented to explore the relationship between ethnic diversity and varying degrees of response. Key word: ethnic, efficacy, toxicity, TKIs, ICIs

Keywords: ethnic, efficacy, toxicity, TKIs, ICIs

JCSE01.04 NEO-ADJUVANT IMMUNOTHERAPY IN LUNG CANCER

N. Wu

Peking University Cancer Hospital & Institute, Beijing/China

Immune checkpoint inhibitors (ICIs) therapy have been recommended as the standard of care in the first-line treatment strategy of selected advanced non-small cell lung cancer (NSCLC) patients. Effective therapies also needed for NSCLC patients in early-stage, whose failure arises both local relapse and remote metastasis after surgery. Lavin et al revealed that an immunosuppressive microenvironment had developed even in stage I disease, which promoted the investigation of immunotherapeutic regimens in early stage population[1]. The success of ICIs in the metastatic disease has also generated enthusiasm to initiate clinical trials to evaluate the utility

of ICIs as neoadjuvant therapy in the setting of resectable NSCLC[2]. Theoretically, immunotherapy in patients with early-stage NSCLC may have more favorable antitumor effects due to lack of T cell function depletion and less tumor clonal heterogeneity. However, there are lots of details need to be discussed, and this necessitates a review regarding neoadjuvant immunotherapy topic. The fundamental premise on the application of neoadjuvant immunotherapy is the safety and feasibility. In a cohort of 21 patients, Forde et al revealed neoadjuvant nivolumab was associated with well tolerance and few side effects, did not delay surgery and induce a major pathological response (MPR) in 45% of resected tumors[2]. MPR rate is associated with long term survival outcomes, thus it is considered as a surrogate endpoint for recurrence and survival[3].Radiologic assessment of treatment cannot predict pathological response accurately after ICIs therapy. Chest CT might underestimate response rate accurate after neoadjuvant ICIs therapy compared with pathological assessment (10% vs. 45%)[2]. This phenomenon was postulated to be related with T-cell infiltration and peritumoral inflammation during the early stage of treatment, which was defined as "pseudo-progression" by some experts[4]. Bott et al analyzed operative details and postoperative outcomes in this cohort. Unexpected perioperative morbidity and mortality was not observed. The rate of conversion was moderately high because of hilar inflammation and fibrosis, which might develop as a result of response to treatment[5]. The surgical outcomes proved the feasibility and safety of pulmonary resection after neoadjuvant nivolumab monotherapy and encouraged the execution of following neoadjuvant immunotherapy trials relevant to surgical practice. In the setting of resectable NSCLC, what is optimal sequence of immunotherapy and surgery? There is no straight evidence available to clear the issue right now. However, differing from perioperative chemotherapy, the administration of ICIs in the preoperative phase while the tumor is in situ might provide greater therapeutic efficacy in terms of elevated and sustained peripheral tumor-specific immune responses compared with adjuvant immunotherapy[6]. Liu et al proved it through utilizing a murine model of triple-negative breast cancer (TNBC). Therefore, the utilization of ICIs prior to surgery has been presumed to be capable of potentially eliminating micrometastatic disease and thus decrease the risk of recurrence in resectable NSCLC. It was also interesting that mice given neoadjuvant chemotherapy displayed no significant anti-tumor benefit over adjuvant chemotherapy in the same murine model, which was consistent with the results of clinical trials[7]. The optimization of neoadjuvant schemes is underway in resectable NSCLC patients. Since the combination of nivolumab plus ipilimumab showed encouraging clinical activity characterized by a high response rate and durable response in setting of advanced NSCLC[8-9], the combination of double ICIs has been incorporated into the neoadjuvant care of resectable NSCLC patients. The NEOSTAR trial randomized patients to receive nivolumab or nivolumab plus ipilimumab before surgery[10]. The combination therapy was associated with an increased number of tumor-infiltrating lymphocytes compared to monotherapy, suggesting superior therapeutic efficacy in doublet ICIs group. However, higher proportion of patients did not receive scheduled surgery (doublet 23.8% vs monotherapy 8.7%) was a problem need attention. ICIs in combination with chemotherapy (ICI-CT) was another direction of neoadjuvant immunotherapeutic schemes. Safety and tolerability of neoadjuvant ICIs combined with platinum-based doublet chemotherapy has been proved in the KEYNOTE-189 trial[11]and KEYNOTE 407 trial[12]. NADIM trial is an ongoing phase II, single-arm, open-label multicenter study of resectable stage IIIA N2-NSCLC patients with ICI-CT as a neoadjuvant treatment[13]. In NADIM trial, pathological response rate was also higher than that assessed by RECIST. Neoadjuvant ICI-CT yields an unprecedented response rate prompting the regimen as the most promising neoadjuvant scenario. All the oncologists are eager to observe the long-term outcomes of NADIM, which would finally revise the standard pathway of curing early stage NSCLC. In this new era of immunotherapy for NSCLC, multiple questions remain regarding the integration of immunotherapy and traditional therapy protocol. For instance, whether concurrent chemoradiotherapy combined with ICIs could be a neoadjuvant regimen for resectable stage IIIA (N2) NSCLC? Accrued evidence indicates that radiation could stimulate the immune system via upregulating tumor-associated antigens, augmenting MHC class I surface expression, increasing T-cell tumor-specific CD 8+ T cells, et al[14]. PACIFIC trial has delineated ICI significantly prolonged overall survival among patients with stage III, unresectable NSCLC following concurrent chemoradiotherapy[15]. If irradiation could produce systemic effects under ICI and contribute to the development of a broader range of cancer treatments[16], surgery would be asked to perform a better local tumor control. Surgery for advanced NSCLC are increasingly expanding in setting of partial or complete treatment response after immunotherapy[17]. It will indeed take years before we exactly know how to most effectively incorporate ICI into other traditional therapies, including surgery. It is always attractive to predict which individuals will have a long-lasting response. Fortunately, neoadjuvant therapy allows for an assessment of treatment effect, as well as pathological response due to the convenience of specimencollection after surgery. Optimal biomarkers should be capable to improve patient selection for ICI treatment. Therapeutic selection based on actionable genomic alterations can clearly delineate patients who will receive survival benefit from a given therapy. However, the same scenario cannot certainly happen for immune-based biomarkers. Some experts deem deescalating therapy of single agent checkpoint blockade should be approached with caution regarding the lack of transformative immune-based biomarker[18]. Except PD-L1 express and TMB, dynamics of the immune system need to be standardized to ensure the accuracy of results and uniformity across clinical trials[19]. To capture a perfect biomarker to predict clinical responses to ICIs is an unrealistic goal in the short-term. Further studies are desiderated to identify biomarkers associated with improved survival.

JCSE01.05 BIOMARKER IN IMMUNOTHERAPY: MYTH OR REALITY?

A. Addeo

Hôpitaux Universitaires de Genève, Genève/Switzerland

Background: NSCLC treatment landscape has rapidly evolved with several immune checkpoint inhibitors (ICIs) approved initially in second line as monotherapy and subsequently in first line as either monotherapy or in combination with chemotherapy. The recent presentation at the ASCO 2019 of the 5 years overall survival (OS) of the Keynote 001 has further strengthened the importance and impact of ICIs on patients with NSCLC, showing unprecedented 5 years overall OS. However up to 50-60% of NSCLC patient does not benefit from such a treatment. The need to validate and find out new effective biomarker (BM) remains crucial. Discussion: PD-L1 expression is the only approved BM in NSCLC that proved to be predictive of better OS for anti-PD1 (Pembrolizumab). Despite several advantages such as short turnaround time (TAT), relatively simple IHC assay (gone through an harmonized process in the blueprint2) there are several limitations: PD-L1 non expresser could still be responders and benefit form ICIs or in driven mutated NSCLC the PD-L1 level might be very high, generally mediates by the JAK3 pathway, but not being responsive to ICIs for the rarity of T cell infiltrations. A new promising BM is the tumour mutation burden (TMB). The prevalence of somatic mutation varies between 0.01 mut/Mb to 400 mutations/Mb. Some of these mutations led to the translation of novel peptide epitopes or neoantigens that should enhance the immunogenicity of the tumour by eliciting T cell repertoire. The hypothesis then is that in case of high TMB ICIs should work better than chemo. So far this has been partially seen in some studies in term of response rate (RR) an progression free survival (PFS) but no study has been designed yet as having primary endpoint better OS in High TMB patients. Furthermore there are several aspects to consider about TMB: TAT is at least 2 week (it the first studies were conducted by using whole exome sequencing), high cost, no clear cut-off, unclear if it should be performed on cancer tissue or circulating tumour DNA (ctDNA) and the most important one the prospective trial has ever validated TMB as predictive of better OS compared to chemotherapy. There are several new BM in embryonic phase: role and importance of TILs, immune gene signature, INFgamma relatedmRNAbased signatures, myeloid-derived suppressor cells(MDSCs) or the neutrophil-to-lymphocyte ratio (NLR) at baseline. None of them is ready for prime time but there are ongoing studies that hopefully will validate useful BM to adopt in clinical practice Conclusion: are BMs reality? Yes we already have a reliable predictive BM which remains PD-L1 expression. TMB might represent a possible alternative to identify a different subgroup of NSCLC patients. PD-L1 high and high TMB might partially overlap but they highly likely correspond to 2 different patients populations. There is indeed room for improvement and more BMs are needed: possibly simple to adopt in clinical practice, with short TAT and most important showing OS benefit, to definitively move from the myth to the reality.

JCSE01.06 NEW ERA BEYOND PD-1/PD-L1

L. Paz-Ares

Hospital Universitario 12 de Octubre, Madrid/Spain

Over the past few years, targeting immune checkpoints such as PD-1/PD-L1 (and in some extend CTLA-4) has changed the landscape of lung cancer therapy and largely impacted patients with notable therapeutic benefits. However, not all lung cancer patients respond to immune checkpoint inhibitors and actually only some 15-20% of those with metastatic disease achieve long term survival, reflecting to the complexity of immune checkpoints and daunting tumor resistance. In order to broaden the possibilities of lung cancer immunotherapy, we need to seek alternative immune checkpoints beyond PD-1/ PD-L1, test novel combination strategies of immune checkpoint inhibitors and more conventional treatments, and increase the predictive potential of biomarkers to optimally guide clinical practice. Meanwhile, there are a number of unsolved questions that may require our attention for future better clinical performance. The wide range of immune-related adverse effects (irAEs) that accompany immune checkpoint inhibitors can complicate this efficacious immunotherapy and restrict its use in cancer patients. The precise pathophysiology underlying irAEs is frequently unknown, but may be related to breaking the balance of immunologic homeostasis. Although any organ system is possibly influenced, irAEs most commonly involve the gastrointestinal tract, endocrine glands, and skin. Most of the toxic effects are reversible, but deaths due to severe irAEs such as myocarditis and pneumonitis can occur. The serious problem of irAEs particularly requires to define optimal strategies for multidisciplinary and collaborative management, and ad-hoc education programs. Of note, recent data suggest that prophylactic TNF blockade uncouples efficacy and toxicity in dual CTLA-4 and PD-1 immunotherapy. The clinical therapeutic efficacy of immune checkpoint inhibitors remains controversial. Tumor resistance, primary and acquired, is a daunting challenge that limits the responsiveness to immunotherapy, and deserves intensive investigation. Hyperprogressive disease (HPD) following immunotherapy also deserve adequate attention. Evidence suggests that MDM2 family amplification or EGFR, KEAP and LKB1 aberrations may lead to poor clinical outcomes on IO treatment and may account for the risk of HPD. Preclinical and clinical testing of alternative immune checkpoints is mandatory, particularly in programs that coupled a biomarker driven strategy. It is noteworthy that tumor infiltrating T cells can simultaneously express PD-1/ PD-L1 along with other immune checkpoints. Also, evidence has delineated that upregulation of compensatory inhibitory molecules such as LAG-3, VISTA, and TIM-3 may mediate tumor resistance to immune checkpoint inhibitors. Understanding the precise molecular mechanisms of different immune checkpoints will benefit the design of effective combination therapies and overcome potential resistance. More well-designed combination strategies (antiangiogenics, targeted therapies, chemotherapeutics,..) that can yield remarkable and synergistic clinical benefits are critical for immune checkpoint therapy. To optimize the combination therapies, we should carefully explore effective and safe doses of treatments, sequencing of the agents, appropriate timing, and so on. There is a pressing need to study the indepth mechanisms of the interaction between chemo-radiotherapy or targeted therapy and the immune system. In addition, identifying more combinations of immune checkpoint inhibitors and new treatment approaches such as by-specific antibodies, chimeric antigen receptor T cell (CAR-T) immunotherapy, TILs, modulating the microbioma and tumor vaccines is a tantalizing option. Finally, due to the complexity of the immune system, developping and validating a multiparametic model of predictive biomarkers is much required. As mentioned earlier, PD-L1 expression can inform treatment decisions, but its clinical value still needs confirmation in different patient cohorts. Meanwhile, certain genomic tumor aberrations, TMB and TME are future directions for routine clinical practice. Different TIL phenotypes, diverse TCRs, immune gene signatures, and genetic features derived from blood monitoring or TME hold high potential, but are ready for clinical use as yet. Background: The role of PD-L1 expression in 2nd line and beyond non-small cell lung cancer (NSCLC) remains controversial. Camrelizumab (SHR-1210) is a potent anti-PD-1 monoclonal antibody and has shown promising activity in NSCLC in Phase I studies. We report results from the SHR-1210-201 study (NCT03085069), a phase II umbrella

study of camrelizumab monotherapy in different PD-L1 expression cohorts in Chinese patients with previously treated advanced or metastatic NSCLC. **Method:** Patients who progressed during or following platinum-based doublet chemotherapy were enrolled and assigned to one of 4 cohorts based on PD-L1 expression. Patients with EGFR or ALK genomic alterations were eligible provided they had disease progression with at least one approved tyrosine kinase inhibitor and with ≥50% PD-L1 expression in tumor. All enrolled patients received camrelizumab at 200 mg IV Q2W until loss of clinical benefit. The primary endpoint was objective response rate (ORR), other endpoints included progression-free survival (PFS) and overall survival (OS). **Result:** As of Aug 1st 2018, of all the 259 patients who underwent screen, 229 cases could be pathologically evaluated. PD-L1 expression were 47.6% (109/229) in PD-L1 < 1%, 27.1% (62/229) in PD-L1 ≥1-<25%, 8.7% (20/229) in ≥25-<50% and 16.6% (38/229) in ≥50%. A total of 63.8% (146/229) patients were enrolled. 89.0% of patients had stage IV NSCLC and 54.8% had non-squamous tumor histology. ORR was 18.5% (95%CI: 12.6%–25.8%) in ITT population. Subgroup analysis showed increased PD-L1 expression was associated with better response rate (Table 1). No response was observed in patients with EGFR mutation. The responders had durable response (median: 15.1 months; 95%CI: 5.5–not reached). Median PFS was 3.2 months (95%CI: 2.0–3.4) and median OS was 19.4 months (95%CI: 11.6–not reached) (Table 1). Treatment-related adverse events (AEs) occurred in 87.7% of patients (all Grade); 20.5% had ≥G3 related AE; and 15.8% had related SAE. 21.2% of AEs led to dose interruption and 7.5% led to treatment discontinuation.

Conclusion: In Chinese patients with previously treated advanced/metastatic NSCLC, camrelizumab demonstrated improved ORR, PFS, and OS compared with historical data of the 2nd line chemotherapy. The efficacy in patients with PD-L1 <1% is similar as the 2nd line mono-chemotherapy, while patients with higher PD-L1 expression derived greater benefit from camrelizumab, the ORR, PFS and OS in patients with PD-L1 ≥25% was comparable to the 1st line doublet chemotherapy in advanced NSCLC. Camrelizumab was well tolerated. This phase 2 data warrant further clinical studies of camrelizumab in NSCLC.

Keywords: advanced/metastatic non-small cell lung cancer, camrelizumab, PD-L1 expression

Table 1 - Efficacy data in subgroups

Population	No of pts	ORR, % (95%CI)	PFS (month), median (95%CI)	1YOS, % (95%CI)	OS (month), median (95%CI)
PD-L1<1%	74	12.2% (5.7%, 21.8%)	2.1 (1.9, 3.2)	47.1% (33.8%, 59.2%)	11.6 (7.8, NR)
PD-L1 ≥1% and < 25%	31	19.4% (7.5%, 37.5%)	3.1 (1.8, 4.9)	76.7% (57.2%, 88.2%)	NR (NR, NR)
PD-L1 ≥25% and < 50%	11	45.5% (16.7%, 76.6%)	6.0 (1.9, NR)	81.8% (44.7%, 95.1%)	NR (2.9, NR)
PD-L1 ≥50% (without EGFR mutation)	25	28.0% (12.1%, 49.4%)	7.6 (3.3, 11.4)	55.2% (32.3%, 73.2%)	NR (8.6, NR)
PD-L1 ≥50% (with EGFR mutation)	5	0	1.7 (1.2, NR)	40.0% (5.2%, 75.3%)	10.3 (1.2, NR)
ITT	146	18.5% (12.6%, 25.8%)	3.2 (2.0, 3.4)	56.6% (47.3%, 64.9%)	19.4 (11.6, NR)

Background: NSCLC patients who have potentially resectable disease often subsequently relapse after surgery. New therapy that prevents relapse after surgery is desperately needed. In this study, we tested the efficacy and safety of neoadjuvant sintilimab, an anti-PD-1 antibody, for patients with resectable sqNSCLC in China. **Method:** All patients had treatment-naïve resectable sqNSCLC (stage IB-IIIA) that was confirmed by histopathology. Patients received two cycles of sintilimab (200 mg IV) on Day 1 and 22. Surgery was performed between Day 29-43. An enhanced PET/CT was obtained at baseline and seven days prior to surgery. Preliminary analysis of safety profile and efficacy was planned after at least 20 patients had received operation. **Result:** As of Jan. 28, 2019, 22 patients (20 males and 2 females) with sqNSCLC received two doses of sintilimab followed by radical resection. The median age was 61.5 yr (range, 48 to 70). Six (27.3%) and four (18.2%) patients experienced neoadjuvant treatment emergent adverse events (TEAEs) and neoadjuvant treatment-related AEs (TRAEs), respectively. Most of the TEAEs and TRAEs were grade 1 or 2. Three patients achieved radiological partial response: an ORR of 13.6% based on RECIST 1.1. Ten patients (45.5%) achieved a major pathologic response (MPR, ≤10% viable tumor cells), including four (18.2%) had complete pathologic response (no viable tumor cell). There was a direct correlation between pathological response and decrease in the standardized uptake values (SUV) in the primary tumor. Among nine patients with > 30% decrease of SUV, eight had MPR, compared with no MRP response in the 11 patients with ≤30% decrease of SUV. **Conclusion:** Neoadjuvant sintilimab for sqNSCLC patients was tolerable and the 45.5% MRP rate is encouraging. A decrease in SUV may be predictive of pathologic response after PD-1 therapy in sqNSCLC.

Keywords: squamous NSCLC, Sintilimab, neoadjuvant

JCSE01.11 EFFICACY AND SAFETY OF SINTILIMAB WITH ANLOTINIB AS FIRST-LINE THERAPY FOR ADVANCED NON-SMALL CELL LUNG CANCER (NSCLC)

B. Han[1], T. Chu[2], R. Zhong[2], H. Zhong[2], B. Zhang[1], W. Zhang[3], C. Shi[1], J. Qian[2], Y. Han[2]

Background: Given the synergy effect of immunotherapy and anti-angiogenic therapy in advanced NSCLC, FDA approved atezolizumab plus bevacizumab and chemotherapy as first-line treatment. However, chemo-free first-line strategy of PD-1/PD-L1 inhibitor combining angiogenesis modulator remains to be explored. This is the first trial evaluating sintilimab (anti-PD-1) plus anlotinib (multi-target TKI against tumor angiogenesis and proliferation) in treatment-naive advanced NSCLC patients and is one arm of Phase II anlotinib-based trial (NCT03628521). **Method:** Treatment-naive, stage IIIB/IV NSCLC patients aged 18-75 with ECOG PS 0-1 were eligible. Patients with EGFR, ALK or ROS1 mutations were excluded. Participants were given intravenous sintilimab (200mg q3w) and oral anlotinib (12mg/d 2 weeks on/1 week off) until progression or unacceptable toxicity. The primary endpoints were ORR and safety. The secondary endpoints included DCR, PFS and OS. AEs were graded according to CTCAE v4.0. **Result:** From Septembe-2018 to February-2019, 22 patients were enrolled. All are under treatment and have received at least one tumor assessment as of Apr-8th-2019. Most were male (95.5%), former/current smokers (63.6%) and squamous cell histology (54.5%). 4 had baseline brain metastases. Among all, 15 achieved PR (7 confirmed, the rest waiting for next assessment), 7 achieved SD, ORR was 68.2% and DCR was 100%. Two grade 3 TRAE occurred with no grade 4/5 observation. The most common TRAE were hematuria, hyperuricemia, hypertension, increased ALT and rash, etc. No unexpected AE observed. Of 21 PD-L1-evaluable patients, 13 (61.9%) were PD-L1+ and showed higher ORR than PD-L1- patients. 16 patients got TMB status (details in table). Notably, 7 of 9 patients achieved SD developed cavities, suggesting a synergetic anti-tumor effect from combination regimen.

Table 1. Response rates

Best Overall Response	Overall (n=22)	PD-L1 + (n=13)	PD-L1 - (n=6)	TMB ≥ 10 (n=6)	TMB <10 (n=10)
CR, n (%)	0	0	0	0	0
PR, n (%)	15 (68.2%)	9 (69.2%)	5 (62.5%)	5 (83.3%)	5 (50%)
SD, n (%)	7 (31.8%)	4 (30.8%)	3 (37.5%)	1 (16.7%)	5 (50%)
PD, n (%)	0	0	0	0	0
ORR, n (%)	15 (68.2%)	9 (69.2%)	5 (62.5%)	5 (83.3%)	5 (50%)
DCR, n (%)	22 (100%)	13 (100%)	8 (100%)	6 (100%)	10 (100%)

Conclusion: In this interim analysis, sintilimab plus anlotinib showed high ORR (68.2%) and DCR (100%) with good tolerability, supporting worthy of further development from this convenient usage of chemo-free regimen in first line setting.

Keywords: PD-1 inhibitor, multi-target angiogenesis agent, advanced NSCLC

JCSE01.14 HIGHER PREVALENCE OF EGFR MUTATIONS SIGNIFICANTLY CORRELATES WITH LOWER PD-L1 EXPRESSION IN CHINESE LUNG ADENOCARCINOMA

S. Wen[1], Y. Jiang[2], J. Guo[3], X. Fan[4], X. Pan[5], Y. Dai[5], D. Chen[5], K. Wang[6], X. Dong[5], S. Zhang[5]

[1]*Fourth Hospital of Hebei Medical University, Shijiazhuang/China,* [2]*Shandong Provincial Hospital Affiliated to Shandong University, Jinan/China,* [3]*Xingtai People's Hospital, Xingtai/China,* [4]*Qilu Hospital Qingdao Branch, Qingdao/China,* [5]*Origimed, Shanghai/China,* [6]*The Second Hospital of Zhejiang University, Hangzhou/China*

Background: *EGFR* mutations are more prevalent in lung adenocarcinoma compared with other non-small cell lung cancer and are more prevalent in East Asians compared with the other populations. At the same time, we observed lower PD-L1 Tumor Proportion Score (TPS) in Chinese lung adenocarcinoma patients (pts) compared with that in Chinese lung squamous cell carcinoma pts and we also observed the proportion of PD-L1 positive (TPS >= 1%) in Chinese lung adenocarcinoma pts was lower than that in other multicenter cohorts. Then we hypothesize that the higher prevalence of *EGFR* mutations in Chinese lung adenocarcinoma pts correlates with lower PD-L1 expression. **Method:** The Origimed-based lung adenocarcinoma cohort was a retrospective cohort consisted of more than one thousand Chinese lung adenocarcinoma pts who underwent both NGS panel sequencing and PD-L1 immunohistochemistry (IHC) in a College of American Pathologists (CAP) certified and Clinical Laboratory Improvement Amendments (CLIA) certified laboratory during the year 2017 and 2018. Antibodies used in the PD-L1 IHC assay included 28-8 (sample size = 883) and 22C3 (sample size = 158). Tumor Proportion Score (TPS) was applied. All the slides were reviewed by the same senior pathologist. All the *EGFR* mutations were manually reviewed in Integrated Genomics Viewer for confirmation. After confirmation, each pts was assigned to *EGFR* positive group or *EGFR* negative group. Fisher' s exact test and Student' s t-test were applied. **Result:** For antibody 28-8, PD-L1 IHC was positive (TPS >= 1%) in 18% (66/370) *EGFR* positive pts and was positive in 35% (180/513) *EGFR* negative pts (fisher exact test p value = 1.6e-5). For antibody 22C3, PD-L1 IHC was positive (TPS >= 1%) in 14% (9/64) *EGFR* positive pts and was positive in 45% (42/94) *EGFR* negative pts (fisher exact test p value = 3.8e-3). And we observed a significantly lower PD-L1 TPS in *EGFR* positive pts for both antibodies (t-test p value = 3.5e-11 for PD-L1 antibody 28-8; t-test p value = 6.0e-5 for PD-L1 antibody 22C3). **Conclusion:** The observation demonstrated that lower PD-L1 TPS in Chinese Lung Adenocarcinoma pts was significantly correlated with East-Asian-specific high prevalence of *EGFR* mutations. The observation reassured that *EGFR* mutation status should be examined simultaneously with PD-L1 IHC in lung adenocarcinoma pts because it was a confounding factor for predicting immunotherapy outcome using PD-L1 TPS. The observation partly explained the generally higher PD-L1 TPS in Chinese lung squamous carcinoma pts compared with that in Chinese lung adenocarcinoma pts.

JCSE01.15 LIVER METASTASES PREDICTS POORER PROGNOSIS IN ADVANCED NSCLC PATIENTS WHO RECEIVING NIVOLUMAB MONOTHERAPY

G. Zhang[1], R. Cheng[2], H. Wang[1], Z. Ma[1]

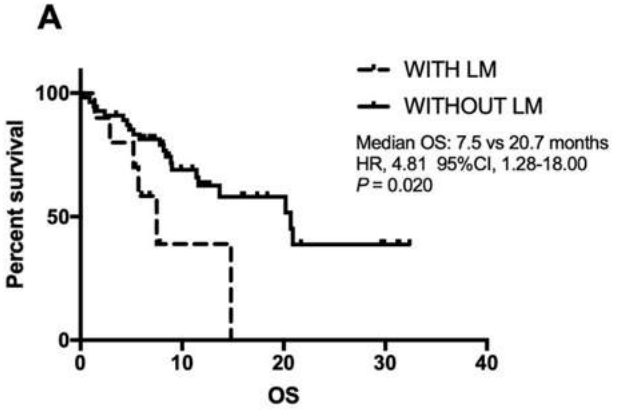
[1]*The Affiliated Cancer Hospital of Zhengzhou University, Zhengzhou/China,* [2]*The First Affiliated Hospital of Zhengzhou University, Zhengzhou/China*

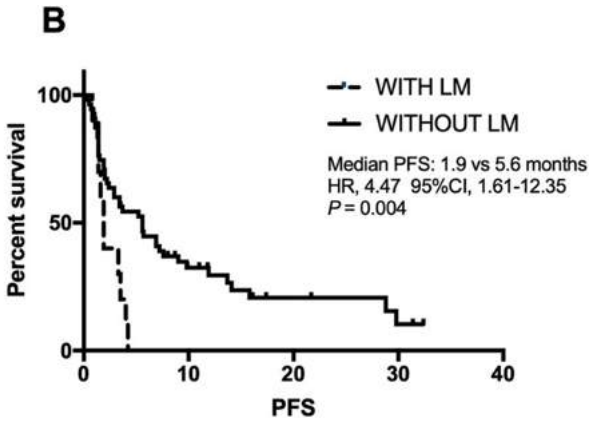
Background: Nivolumab is a fully human IgG4 monoclonal antibody targeting the programmed death-1 (PD-1). It's a standard second-line treatment for advanced NSCLC. Liver metastases(LM) is one of the worst prognostic NSCLC metastatic sites, but the attention to LM is far lower than brain metastases and bone metastases. **Method:** Patients with stage IIIB-IV NSCLC treated with second-line or later nivolumab monotherapy were retrospectively collected from January 2016 to July 2018. The patients were divided into two cohorts based on the presence or absence of LM at the time of first dose. Study endpoints included OS and PFS. **Result:** 65 patients

were included, including 10 patients with and 55 patients without LM. Baseline characteristics of the two cohorts were comparable, as shown in the below table.

Characteristic	*All*	*LM (n=10)*	*Without LM (n=55)*	*P-Value*
Sex(Female/Male)	16/49	2/8	14/41	0.999
Mean age (years)	59.0±10.2	60.1±8.0	58.8±10.5	0.713
ECOG PS				0.999
0-1	59	9	50	
≥2	6	1	5	
Histologic subtype				0.203
Squamous carcinoma	26	2	24	
Adenocarcinoma	36	7	29	
Others	3	1	2	
Stage				0.999
IV	62	10	52	
IIIB/IIIC	3	0	3	
Lines of therapy				0.673
2nd Line	53	9	44	
≥3rd Line	12	1	11	
Driver gene status				0.580
EGFR mutations	4	0	4	
KRAS mutations	4	1	3	
Other mutations	5	0	5	
Driver gene negative	27	6	21	
Unknown	25	3	22	
Other metastatic sites				0.958
Central nervous system	24	4	20	
Bone	20	2	18	
Adrenal gland	6	0	6	
Intrathoracic	47	6	41	
Other/unspecified	9	1	8	

The median OS of the patients with and without LM was 7.5 and 20.7 months, respectively(HR =4.81;95%CI, 1.28-18.00;p=0.020). Their median PFS was 1.9 and 5.6 months, respectively(HR =4.47;95%CI, 1.61-12.35;p=0.004). COX multivariate regression analysis suggested LM was an independent prognostic factor. Kaplan-Meier curves of OS and PFS were shown in the below figure.





Conclusion: The outcome of advanced NSCLC patients with LM treated with Nivolumab monotherapy is relatively poor compared with those without LM.

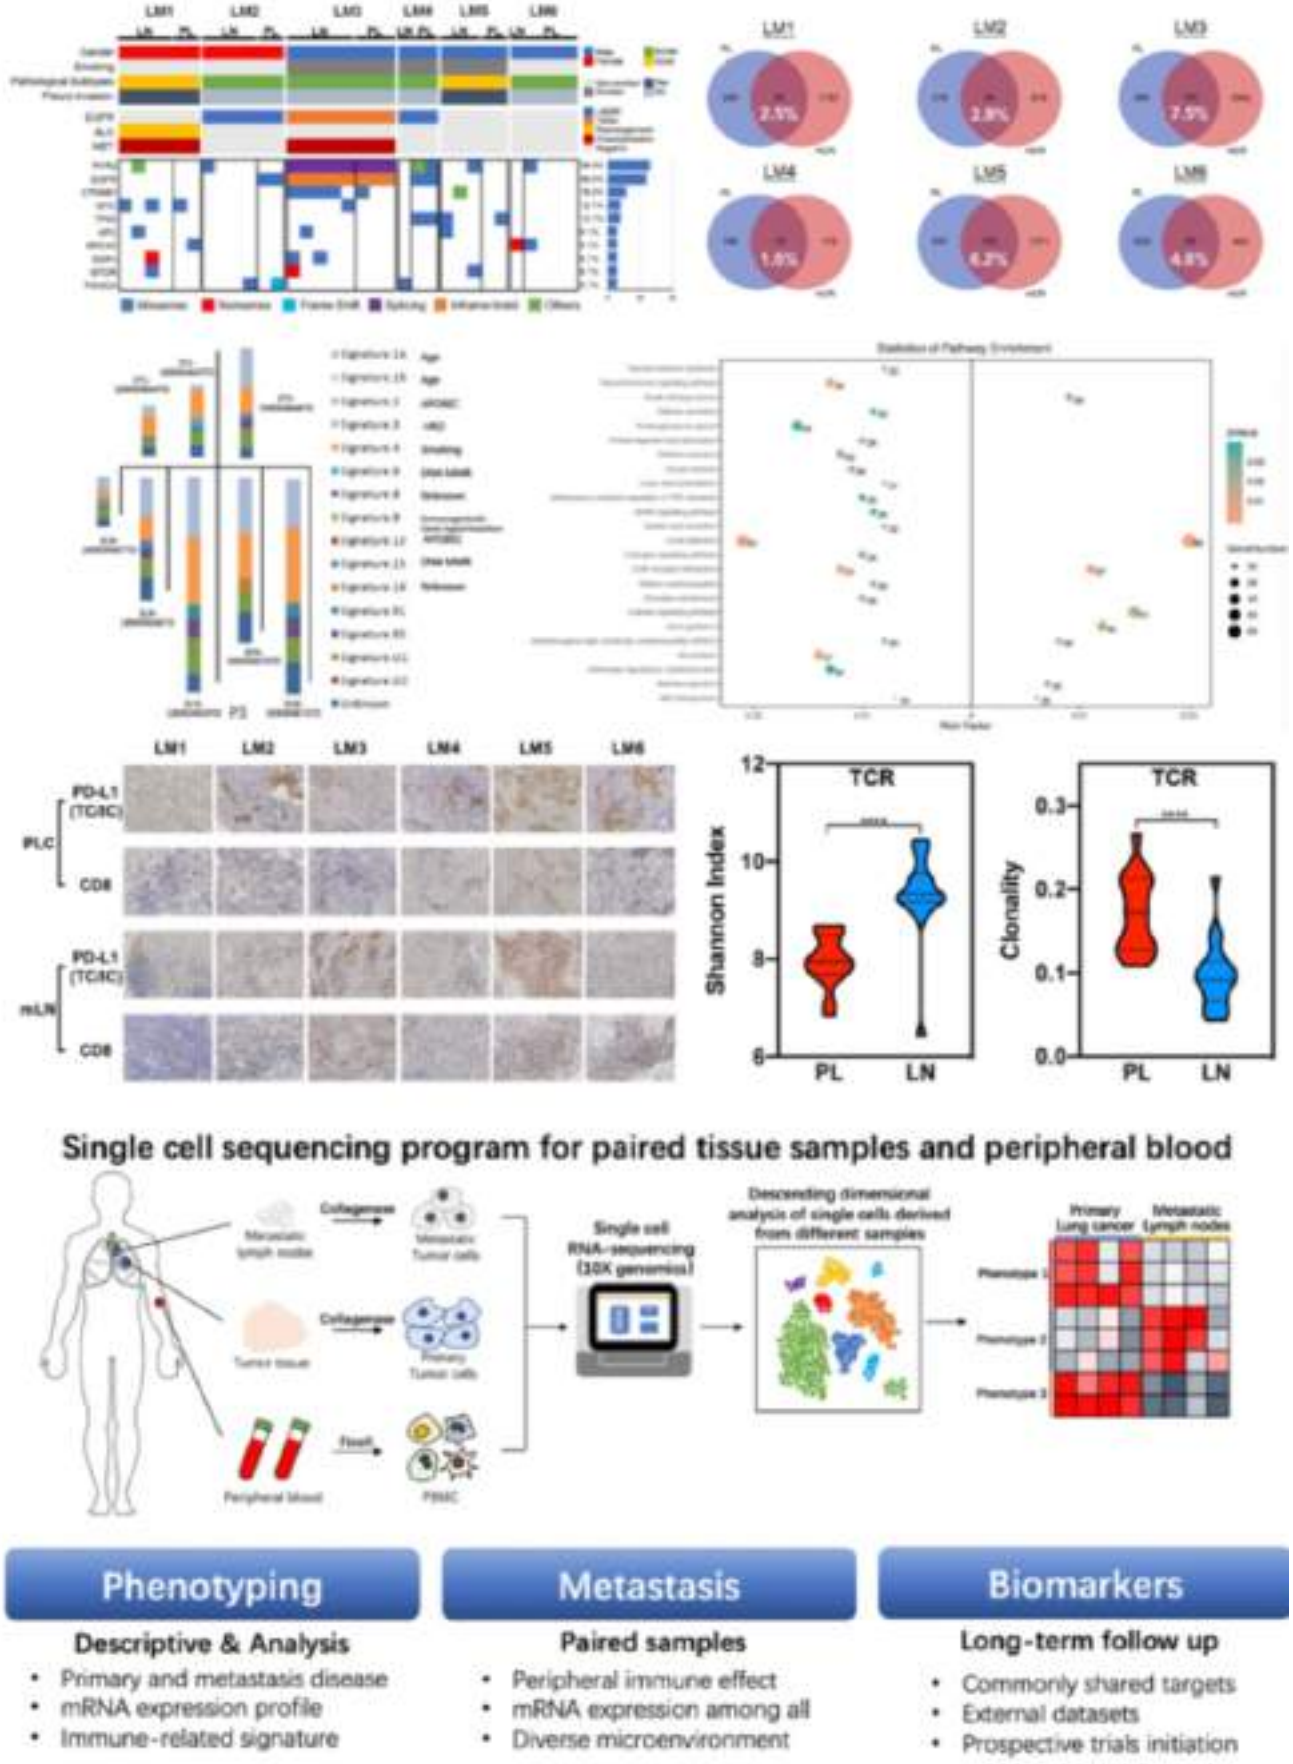
JCSE01.16 METASTATIC LYMPH NODES AS HIGH IMMUNOGENICITY MEDIA FOR PERIOPERATIVE IMMUNOTHERAPY IN LOCALLY ADVANCED NSCLC

C. Zhang[1], S.-Y. Liu[1], J. Su[1], X. Gao[2], L.-P. Chang[2], Y.-F. Guan[2], H.-Y. Tu[1], J.-J. Yang[3], X.-C. Zhang[4], W.-Z. Zhong[5]

[1]Guangdong Lung Cancer Institute, Guangzhou/China, [2]Geneplus-Beijing Institute, Beijing/China, [3]Guangdong Lung Cancer Institute (GLCI), Guangdong Provincial People's Hospital (GDPH), Guangzhou/China, [4]Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangzhou, P.R.China/China, [5]Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangzhou, P.R.China/China

Background: Perioperative chemotherapy showed limited survival benefit and increased toxicities while neoadjuvant immunotherapy achieved great success in early phase trials. Both inter/intra-tumoral heterogeneity (ITH) between primary lesion and metastatic lymph nodes (mLNs), and rationale of superior efficacy for immunotherapy remained poorly explored in locally advanced non-small cell lung cancer (NSCLC). **Method:** We retrospectively collected 6 locally advanced lung adenocarcinoma (LUAD) patients. 15 tissue samples were performed multi-region whole exosome sequencing and TCR repertoire analysis as well as 18 matched metastatic lymph nodes (mLNs). **Result:** 290 somatic mutations in average were identified in primary LUAD (PL) and 441.6 for mLNs. Tumor mutation burden as well as tumor neoantigen burden was significant higher in mLNs than in primary LUAD (median value, 6.6mut/Mb vs. 3.4mut/Mb, P=0.0376; 229.5 neo counts vs. 165 neo counts, P=0.0287). Increased transversion ratio was found in mLNs compared to primary lesions. The genomic concordance between primary lesions and mLNs was 58.4%±12.5% and 33.3% for EGFR-mutation. 87 copy number variants were detected in 14 samples with 3q, 8q and X chromosome as frequently mutated cytobands. Small cell lung cancer functional pathway was enriched in mLNs exclusively. Both expression of PD-L1 and CD8 revealed high level (median value 20% and 40%) and consistence (5/6, 83.3%) between primary and metastatsis lesions. TCR clonality was 17.2% and 9.1% for primary and metastasis lesions, respectively with higher T cell diversity and intra-tumoral heterogeneity of TCR found in mLNs.



Conclusion: Extensive genomic and TCR ITH was found between primary LUAD and mLNs which may lead to mixed response to perioperative treatment. mLNs may serve as a better immunogenicity media for perioperative immunotherapy suggesting a potential adjuvant modality of immunotherapy performing lymph nodes sampling during surgery. Results of an initiated single cell sequencing program including paired samples were pending to further provide insights of diverse immune-microenvironment.

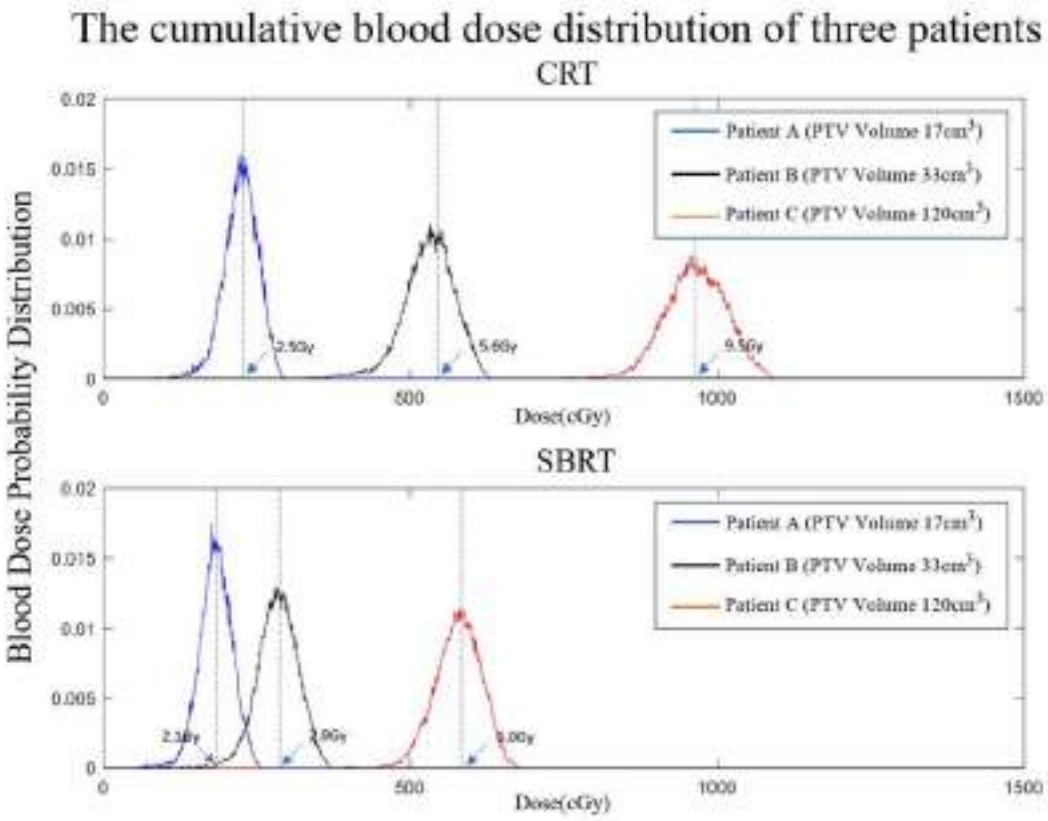
Keywords: locally advanced lung cancer, intra-tumoral heterogeneity, perioperative immunotherapy

JCSE01.17 MODELLING THE IMMUNOSUPPRESSIVE DIFFERENCE OF SBRT AND CRT BY SIMULATING THE DOSE TO CIRCULATING LYMPHOCYTES IN NON-SMALL CELL LUNG CANCER

Y. Shen, Y. Meng, X. Tang, P. Gu, C. Yu, W. Wang, F.-M. Kong, H. Yang

Radiation Oncology Institute of Enze Medical Health Academy, Affiliated Taizhou Hospital of Wenzhou Medical University, Taizhou/China

Background: Radiation-dose delivered to circulating lymphocyte (CL) has detrimental effect on immune system for cancer patients. Our study established a model to compare the cumulative dose on CL of patients with conventional fractionation radiotherapy (CRT) and stereotactic body radiation therapy (SBRT) in lung cancer with different target volume. **Method:** The improved model is based on convolution algorithm suggested by Yovino(Cancer Investigation, 2013). The current blood DVHs of each organ were multiplied with treatment field DVH to generate original DVHs. During one second, 0.6% of whole-body blood circulates through each organ and rest body according to blood circulating pattern and then new DVHs of organ were generated. The new DVHs would be used for next second's calculation with treatment field DVH. Conventional fractionated non-small cell lung cancer plan 60Gy (30 fractions*2.0Gy) and SBRT plan 50Gy (5fractions*10Gy) are constructed for three patients with different target volumes. The primary endpoint is peak cumulative blood dose (PCBC). **Result:** PCBC of three patients with CRT and SBRT were calculated as Figure 1. PCBC with CRT to circulating lymphocyte (CL) were 2.5Gy, 5.6Gy, 9.5Gy in PTV-volume 17cm^3, 33cm^3, 120cm^3, respectively. And PCBC with SBRT to circulating lymphocyte (CL) were 2.1Gy, 2.9Gy, 6.0Gy in PTV-volume 17cm^3, 33cm^3, 120cm^3, respectively. PCBC gap of SBRT to circulating lymphocyte (CL) was decreased 0.4Gy, 2.7Gy, 3.5Gy in PTV-volume 17cm^3, 33cm^3, 120cm^3, respectively.



Conclusion: An improved simulation-model was established, SBRT, compared to CRT, will lead to decreased cumulative dose on CL, which may cause less impact on immune system with the enlargement of PTV-volume.

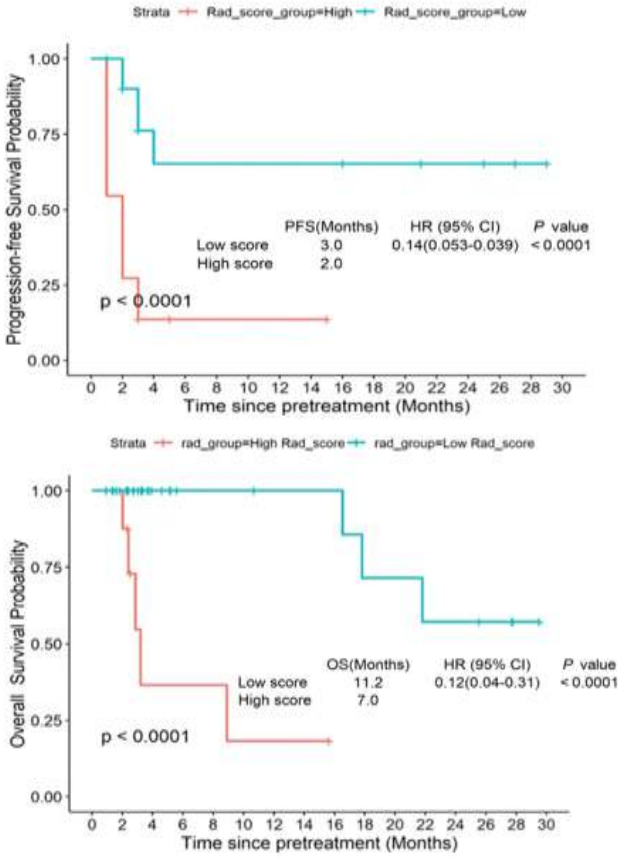
JCSE01.18 A CT-BASED RADIOMICS APPROACH TO PREDICT PD1 INHIBITOR RESPONSE IN NON-SMALL-CELL LUNG CANCER

J. Wang, S. Wang, H. Yu, C. Liu, X. Zhao, S. Sun, J. Chang, J. Qiao, X. Wu

Fudan University Shanghai Cancer Center, Shanghai/China

Background: The purpose of this study was to investigate the use of radiomics features as predictive parameters of clinical outcomes of non-small-cell lung cancer (NSCLC) patients treated with PD1 inhibitor. **Method:** Forty-three stage IIIB/IV NSCLC patients without EGFR mutation or ALK rearrangement who received nivolumab were enrolled between Apr 2016 and Jan 2019. High-dimensional quantitative feature analysis via Pyradiomics was applied to extract 852 radiomics features of pre-anti-PD1 treatment CT. A radiomic score model was constructed from these features with the use of least absolute shrinkage and selection operator (LASSO) Cox regression. The radiomic score for each patient was computed using an equation in which the coefficients were derived from the LASSO Cox model to subgroup patients by progression-free survival (PFS). The median value of radiomic score was used as the cut-off value to cluster patients into high or low score groups.



Result: We developed a radiomic signature for PFS that included seven variables. The median value of radiomic score was 0.23. The objective response rate (ORR) was 16.3% (7/43), the median PFS was 2 months and median overall survival (OS) was 3.2 months of all 43 patients. A low radiomic score was associated with a higher ORR (33.7% vs 0%, p= 0.0036), improved PFS (median: 3 months vs 2 months; HR 0.14, 95% CI 0.053-0.39, P<0.0001) and longer OS (median: 11.2 months vs 7.0 months; HR 0.12, 95%CI 0.04-0.31, p < 0.0001). Multivariate analysis also showed that a low radiomic score was related to better PFS (HR 0.12, 95% CI 0.041-0.32, P<0.0001) and OS (HR 0.11, 95%CI 0.03-0.28, p < 0.0001). **Conclusion:** The radiomic signature as an imaging predictor provided a promising way to predict clinical outcomes for NSCLC patients treated with PD-1 inhibitor.

JCSE01.19 TUMOR MUTATION SCORE IS MORE POWERFUL THAN TUMOR MUTATION BURDEN IN PREDICTING RESPONSE TO IMMUNOTHERAPY IN NON-SMALL CELL LUNG CANCER

Y. Li[1], Z. Chen[2], L. Wu[3], W. Tao[3]

[1]*Fudan University Shanghai Cancer Center, Shanghai/China,* [2]*Tongji Hospital, Huazhong University of Science and Technology, Wuhan/China,* [3]*Renmin Hospital of Wuhan University, Wuhan/China*

Background: Tumor mutation burden (TMB) and PD-L1 expression are the two important biomarkers for immune checkpoint inhibitors (ICIs) in lung cancer. However, growing evidences are showing that not all mutations, such as EGFR mutation, are favorable factors in predicting clinical outcome of ICIs and the power of TMB, which is unselective, might be attenuated. Therefore, we developed tumor mutation score (TMS) as better biomarker for response of ICIs in non-small cell lung cancer (NSCLC). **Method:** TMS was defined as the number of genes with nonsynonymous somatic mutations. Mutations were detected by targeted next-generation sequencing (NGS) in 240 NSCLC patients treated with anti-PD-(L)1 monotherapy or in combination with anti-CTLA4. Durable clinical benefit (DCB) was defined as complete response (CR)/partial response (PR)/stable disease (SD) that lasted 6 months. TMS, TMB and PD-L1 expression were compared among DCB and no durable benefit (NDB) NSCLC patients. **Result:** The total TMS was significantly correlated with TMB (R=0.98, P<0.001) and performed almost equally to TMB in the analysis. 12 genes and 11 genes (5 sharing genes) were significantly associated with longer progression-free survival (PFS) and response (DCB vs NDB), respectively. The number of mutated genes within these 18 genes were defined as TMS18. In the survival analysis of PFS, the HRs of the high group were TMS19 (HR=0.307, P<0.001), TMB (HR=0.455, P<0.001), and PD-L1 expression (HR= 0.403, P=0.02), separately. Moreover, patients with DCB had significantly higher TMS18 (P<0.001), TMB (P=0.006), and PD-L1 expression (P=0.032). High TMS18 group had highest proportion of CR/PR/SD patients, which was 74.1% (CR/PR/SD: 3/17/20), especially in distinguishing CR patients. Taken together, TMS18 was more powerful than TMB and PD-L1 in predicting response of ICIs in NSCLC. **Conclusion:** Simple transformation from unselective TMB to selective TMS greatly enhanced the power of mutations-based biomarkers. TMS in combination with PD-L1 expression might yield better efficiency in predicting response of ICIs in NSCLC with future validation in larger cohorts.

Background: Tumor immune microenvironment plays an important role in immunotherapy and prognosis. However, the differences and the clinical significance between non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC) is still largely unknown. **Method:** Resected lung cancer FFPE specimens and matched peripheral blood mononuclear cells (PBMC) from six patients with NSCLC (three adenocarcinoma, three squamous cell carcinoma) and three patients with SCLC were collected. All of the nine patients underwent stage III disease. Tumor mutation burden (TMB) was evaluated by hybridization capture based next-generation sequencing with 1021 cancer associated genes. Tumor infiltrating lymphocytes (TILs) were assessed by immunohistochemistry using multiple immune markers and meanwhile the intratumoral T-cell repertoires were analyzed via high-throughput sequencing of TCR β-chain. **Result:** Typical EGFR mutations in adenocarcinoma (2 in 3), NSCLC and RB1

mutations in SCLC (3 in 3) were observed. SCLC patients showed significantly higher TMB than NSCLC. Regarding to the tumor immune microenviroment, SCLC tumors exhibited lower infiltration of CD3+ and CD8+ TILs (P< 0.05). Furthermore, we found that SCLC patients tended to have lower TCR Shannon index (P= 0.167) and higher Clonality index (P= 0.095). Interestingly, patients with higher Shannon index exhibited better Overall Survival (OS) while Clonality was potentially associated with decreased OS. However, further study with more patients is needed to confirm the results. **Conclusion:** Tumor immune microenvironment varies between NSCLC and SCLC patients. Specifically, less prevalent and lower diversity of TILs were observed in SCLCs. This might potentially influence survival outcomes.

Keywords: Lung cancer, T-cell receptor repertoire

JCSE01.21 CHANGES OF PERIPHERAL BLOOD SPD-L1 IN PATIENTS WITH SMALL CELL LUNG CANCER DURING CHEMOTHERAPY AND ITS CLINICAL SIGNIFICANCE

H. Tian[1], X. Kang[2], L. Yang[1], H. Zhu[2], W. Guo[3], X. Song[2]

[1]*Shanxi Medical University, Taiyuan, Shanxi/China,* [2]*Shanxi Tumor Hospital, Taiyuan, Shanxi/China,* [3]*National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing/China*

Background: As a new immunotherapeutic target, the inhibitors of programmed death 1 (PD-1) and programmed death ligand-1 (PD-L1) pathway have been used to treat a variety of tumors including small cell lung cancer (SCLC). However, the biomarkers now used to predict the efficacy of SCLC immunological checkpoint inhibitors are still in the exploratory phase. The aim of this prospective study was to investigate the prevalence and prognostic roles of soluble PD-L1(sPD-L1) protein in the blood of patients with lung cancer. **Method:** A total of 94 patients with SCLC who were diagnosed by histopathology or cytopathology between March 2018 to November 2018 were enrolled. Blood samples plasma were collected at the time of diagnosis. 17 samples of healthy subjects matching in sex and age from the Health care Center of the hospital were also studied as control. The level of sPD-L1 protein in the blood was measured using an enzyme-linked immunosorbent assay (ELISA). And the correlation of sPD-L1 expression with tumor stage, distant metastasis, and pro gastrin releasing peptide (ProGRP) was analyzed. **Result:** Expression of sPD-L1 in SCLC patients was significantly higher than healthy people(P<0.05).A cut-off value of 1.362ng/ml was distinguished in patients according to Receiver operating characteristic curve (ROC). Dynamic changes of sPD-L1 are associated with progressive disease(PD)[a], partial response(PR)[a] and stable disease(SD)[b] in SCLC patients([a] P<0.01,[b] P>0.05).The expression of sPD-L1 in serum was positively correlated with ProGRP.

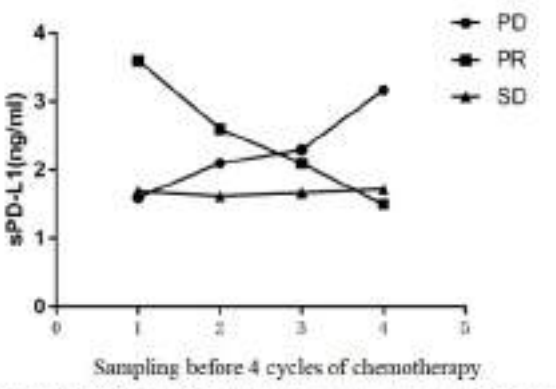

Figure 1 Trend of sPD-L1 in patients with small cell lung cancer during treatment

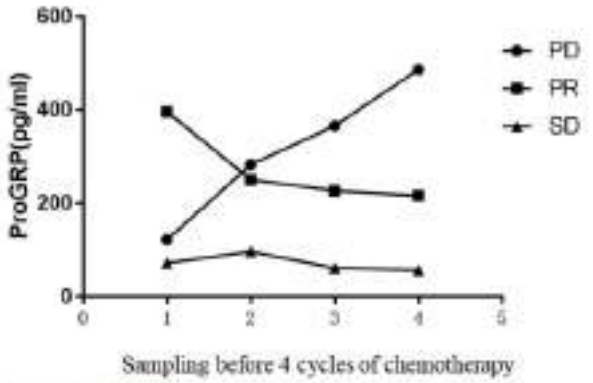

Figure 2 Trend of ProGRP in patients with small cell lung cancer during treatment

Conclusion: Our results indicated that changes of plasma SPD-L1 levels in SCLC patients are associated with prognosis. Plasma sPD-L1 protein is a great biomarker in SCLC and may play an important role in sifting the beneficiaries of immunotherapy.

Keywords: small cell lung cancer (SCLC), soluble programmed death ligand 1 (sPD-L1), pro gastrin releasing peptide (ProGRP)

Background: Primary pulmonary lymphoepithelioma-like carcinoma (LELC) is Epstein-Barr (EB) virus related subtype of non-small-cell lung cancer. Evidence of immunotherapy in LELC is scarce. The role of immune markers in tumor microenvironment and their relation with the efficacy of PD-1/PD-L1 inhibitors in LELC remain poorly explored.Primary pulmonary lymphoepithelioma-like carcinoma (LELC) is Epstein-Barr (EB) virus related subtype of non-small-cell lung cancer. Evidence of immunotherapy in LELC is scarce. The role of immune markers in tumor microenvironment and their relation with the efficacy of PD-1/PD-L1 inhibitors in LELC remain poorly explored. **Method:** A total of seventeen patients treated with PD-1/PD-L1 inhibitors in Guangdong Lung Cancer Institute were enrolled. We detected multiple immune markers including PD-L1, IDO1, TIM3, LAG3, CD4 and CD8 by immunohistochemistry in eleven of these patients. Dynamic changes of the checkpoint biomarkers in two patients (#10 and #11) treated with PD-1 inhibitors were analyzed. Tumors with 1% TPS (tumor proportion staining) were defined as PD-L1 positive. H-score of PD-L1, IDO1, TIM3 and LAG3 was calculated by multiplying percentage of positively stained cells and intensity score (0, absent; 1, weak; 2, moderate; 3, strong). For CD4 and CD8, the H-score equals the percentage of staining positive lymphocytes among all nucleated cells.

TIM3	0	16
LAG3	9	3

	pretreated	posttreatment
PDL1	50	3
IDO1	15	1
TIM3	10	15
LAG3	0	1

Result: In the 17 patients, most of them suffered from lines of chemotherapy (only two patients (2/17, 11.8%) received PD-1/PD-L1 inhibitors as the first line therapy). There are eight males and nine females. The median age was 47 years (range from 13 to 63). All of them were stage IIIB and IV. Thirteen of seventeen patients received single agent PD-1/PD-L1 inhibitor. PD-1/PD-L1 inhibitor showed an 82.4% disease control rate and 17.6% objective response rate. The median progression free survival was 7.4 months. The overall survival was not reached. Biomarkers of IDO1, LAG3, and TIM3 were not mutually exclusive with PD-L1, and could be highly expressed in responder patients to PD1/PD-L1 inhibitors. Notably, TIM3 expression was up-regulated at disease progression in two patients treated with PD-1 inhibitor. **Conclusion:** PD-1/PD-L1 inhibitors had preliminary good activity, and TIM3 up-regulation might be a mechanism of resistance to PD-1 inhibitors in advanced pulmonary LELC.

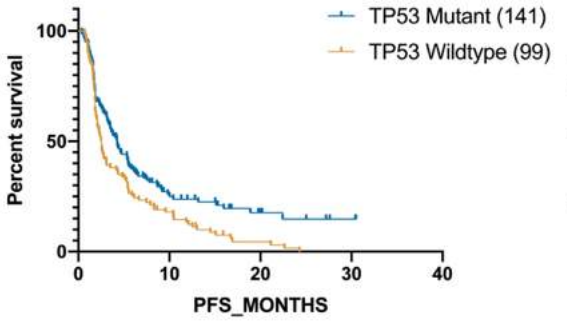
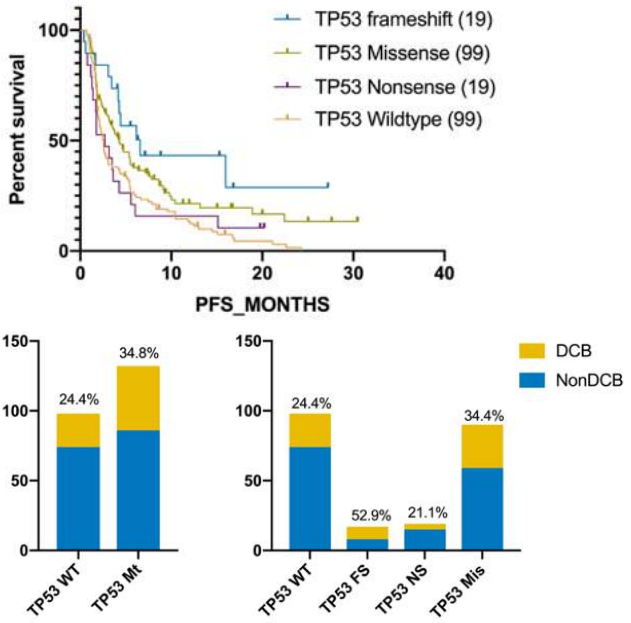
JCSE01.23 SPECIFIC TP53 MUTATION SUBTYPES AS BIOMARKER FOR RESPONSE TO PD-1/L1 BLOCKADE IMMUNOTHERAPY IN NSCLC

H. Sun[1], S.-Y. Liu[2], J.Y. Zhou[3], M. Zheng[2], J.J. Huan[4], Y.F. Guan[4], R. Gao[4], X. Yi[5], Y.-L. Wu[6]

[1]*Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangdong/China,* [2]*Guangdong Lung Cancer Institute, Guangzhou/China,* [3]*Guangdong Provincial People's Hospital, Guangzhou/China,* [4]*Geneplus-Beijing Institute, beijing/China,* [5]*Geneplus-Beijing Institute, Beijing/China,* [6]*Guangdong Lung Cancer Institute, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangzhou/China*

Background: Although TP53 co-mutation with KRAS have been proved to have predictive value for response to PD-1/L1 blockades, not all TP53 mutations are equal in this context. TP53 subtypes as independent factors to predict the response to PD-1/L1 blockade have not yet reported. **Method:** We performed an integrated analysis on the multiple-dimensional data types including genomic and clinical data from cohorts of NSCLC public (240 from MSK database) and local databases (224 patient with PD-L1 IHC score, 1986 NSCLC with TMB data). Durable clinical benefit (DCB) was defined as partial response/stable disease that lasted more than 6 months. **Result:** The presence of mutant TP53 was associated with longer median progression free survival (mPFS) in NSCLC taking PD-1/L1 blockade therapy compared with TP53 wild-type group in the MSK-cohort (4.3 *vs*2.6 months, P=0.0027, HR=0.6409, 95%CI, 0.49 to 0.88). TP53 frameshift seemed to predict longer mPFS (6.6 months, P=0.0159, HR= 0.41, 95%CI, 0.26 to 0.65) than TP53 wild-type, TP53 missense (mPFS=4.27 months, P=0.17) and TP53 nonsense status (mPFS=2.7 months, P=0.002).NSCLC with TP53 frameshift mutation had a 52.9% rate of DCB, which was higher than TP53 missense (34.4%) and nonsense (21.1%) group. Besides, in the MSK cohort, five of six patients with TP53 truncated mutation in proline-rich (PR) domain (residues 58--101) achieved DCB, and one patient achieved 5.5 months of PFS and did not progress. Fractions of PD-L1 low-positive (1% - 49%) and PD-L1 high-positive (≥50%) tumors between each TP53 mutation subtype and wild-type groups are analyzed based on local data. The TP53 mutation rate was significantly higher in NSCLC with PD-L1 score >50% (P=0.004). But NSCLC with TP53 frameshift showed lower fractions of PD-L1 high-positive (12.5%, 2/16) compared with TP53 missense group (27.5%, 33/120) and TP53 nonsense group (25.8%, 8/31). PD-L1 low-positive rate is also lower in TP53 frameshift group (25.0%, 4/16) than TP53 missense (30.8%, 37/120) and nonsense group (29.0%, 9/31). Among 1986 NSCLC patients with TMB data, each TP53 mutation subtype is associated with significantly higher TMB than TP53 wildtype, especially among NSCLC with TP53 truncated mutation in PR domain (median TMB= 9 mut/Mbs). But no significant difference was found between TP53 mutation subtypes in TMB.





Conclusion: Our study demonstrated heterogeneity among TP53 mutations in predicting the response to PD-1/L1 blockade therapy. TP53 frameshift mutation may contribute to better PD-1/L1 blockade therapy response beyond PD-1/L1 IHC status. And the truncated TP53 mutation in PR domain may contribute to DCB.

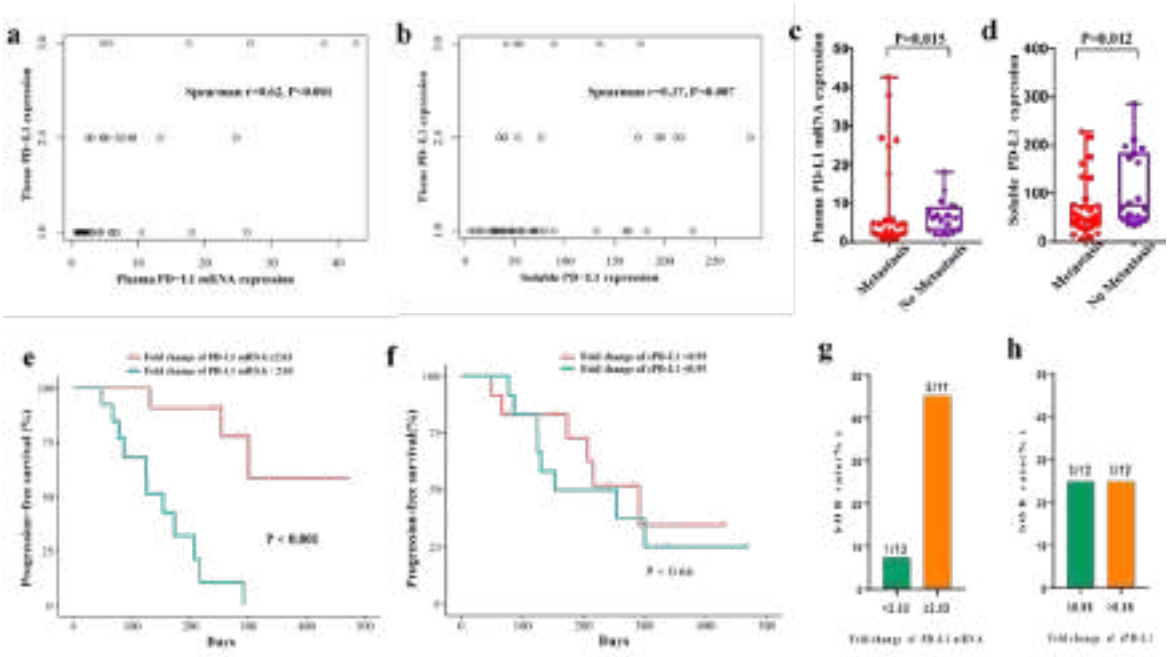
JCSE01.24 DYNAMIC CHANGES OF PLASMA PD-L1 MRNA EXPRESSION PREDICT RESPONSE TO ANTI-PD-1/ANTI-PD-L1 TREATMENT IN MALIGNANCIES

J. Sun, Q. Yang, M. Chen, J. Gu, L. Zheng, Y. Yu, F. Li, L. Zhang, K. Niu

Cancer Institute of People's Liberation Army, Chongqing/China

Background: PD-L1 expression in malignant tumor tissues is a rational biomarker to predict the efficacy and prognosis of anti-PD-1/anti-PD-L1 treatment, but few studies focus on the role of blood PD-L1 expression. **Method:** Fifty-one paired tissue samples and blood samples, as well as clinicopathologic features, were collected from patients with diverse malignancies to investigate the correlation among tissue PD-L1 (tPD-L1) expression, plasma PD-L1 mRNA expression, soluble PD-L1 (sPD-L1) expression and clinicopathologic features. Tissue PD-L1 were measured by immunohistochemistry. PD-L1 mRNA and self-designed plasma inner reference PLACON were measured by quantitative real-time PCR. Soluble PD-L1 were detected by ELISA kit. Then, dynamic changes of blood PD-L1 expression (at baseline and within 2 months) were measured to evaluate the efficacy of patients with malignancies (n=24) who received anti-PD-1/anti-PD-L1 treatment. **Result:** Moderate correlation between tPD-L1 and PD-L1 mRNA (r=0.62, *P*<0.001), weak correlation between tPD-L1 and sPD-L1 (r=0.37, *P*=0.007) and weak correlation between PD-L1 mRNA and sPD-L1 (r=0.32, *P*=0.02) were found. Most clinicopathologic features had no significant correlation with PD-L1 mRNA and sPD-L1 expression. Interestingly, patients without metastasis had higher PD-L1 mRNA and sPD-L1 expression than counterparts. Further, patients with over 2.03-fold PD-L1 mRNA increase (n=11) during treatment experienced improved progression-free survival (PFS) than those with less than 2.03-fold increase (n=13), these patients also had higher best overall response (bOR) rate (45.45% vs. 7.69%). By comparison, the dynamic changes of sPD-L1 expression had no significant correlation with PFS and bOR.



a, The correlation between tPD-L1 and plasma PD-L1 mRNA (n=51). b, The correlation between tPD-L1 and sPD-L1 (n=51). c, Plasma PD-L1 mRNA expression in patients with (n=33) and without (n=18) metastasis. d, sPD-L1 expression in patients with (n=33) and without (n=18) metastasis. e, Kaplan–Meier PFS of patients with high (n = 11) and low (n = 13) fold changes of plasma PD-L1 mRNA within 2 months. f, Kaplan–Meier progression-free survival of patients with high (n = 12) and low (n = 12) fold changes of plasma sPD-L1 within 2 months. g, bOR rate for patients with high and low fold changes of plasma PD-L1 mRNA . h, bOR rate for patients with high and low fold changes of plasma sPD-L1. tPD-L1, tissue PD-L1; sPD-L1, soluble PD-L1; PFS, progression-free survival; bOR, best overall response.
* Tissue PD-L1 expression were measured by immunohistochemistry with SP142 (1.0 : <1%, 2.0 : 1%–49%, 3.0 : ≥ 50%). Plasma PD-L1 mRNA and self-designed plasma inner reference PLACON (Reference: 10.16016/j.1000-5404.201812172) were detected by quantitative real-time PCR. Plasma soluble PD-L1 expression were measured by ELISA kit.

Conclusion: Our study demonstrates that plasma PD-L1 mRNA expression was significantly correlated with tissue PD-L1 expression, and provides proof for the application of plasma PD-L1 mRNA as a predictor for anti-PD-1/anti-PD-L1 treatment.

Keywords: dynamic changes, anti-PD-1/anti-PD-L1 treatment, PD-L1 mRNA

JCSE01.25 TP53/KMT2C CO-MUTATION AS A NOVEL BIOMARKER FOR IMMUNOTHERAPY IN NON-SMALL CELL LUNG CANCER PATIENTS

Q. Zhou[1], X. Peng[1], W. Wang[2], W. Wang[2], L. Zhang[2], K. Wang[2], S. Zhang[2]

[1]*Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong Provincial People's Hospital & Guangdong Academy of Medical Sciences, Guangzhou/China,* [2]*OrigiMed, Shanghai/China*

Background: Immune checkpoint inhibitors (ICIs) have shown remarkable antitumor effects in non-small cell lung cancer (NSCLC), however only a subset of patients respond. Genomic alterations (GAs) detected by targeted next-generation sequencing (NGS) is increasingly used in clinical practice, but its correlation with recognized immune biomarkers and predictive value for ICIs response in NSCLC is unclear. **Method:** FFPE tumor and matched blood samples of 637 NSCLC patients (84 squamous cell and 553 non-squamous cell) were collected for targeted NGS panel sequencing from December 2017 to January 2019. GAs including single nucleotide variations, short and long insertions/deletions, copy number variations and gene rearrangements were assessed. TMB high (TMB-H) was defined as ≥10 muts/Mb. Positive PD-L1 expression was defined as ≥1% of tumor cells with membranous staining (22C3/28-8, DAKO). Genomic data and ICIs treatment outcome from a 240 NSCLC patient cohort was derived from cBioPortal (MSKCC, J Clin Oncol 2018). **Result:** In 637 NSCLC patients, the prevalence of PD-L1≥1% was 26.5% and the median TMB was 4.6 muts/Mb (IQR, 2.3-10). Recurrent *TP53*, *KRAS*, *LRP1B* and *KEAP1* mutations were significantly correlated with higher TMB (p value). *TP53*, *KRAS* and *KEAP1* mutations were significantly enriched in the TMB-H/PD-L1+ subset while *STK11* mutations were enriched in TMB-H/PD-L1- subset (p value). *KMT2C*, also known as *MLL3*, belongs to the mixed-lineage leukemia (MLL) family of histone methyltransferases and its GAs was found in 5% of our cohort. Tumors with *KMT2C* and *TP53* co-mutations (co-MUT) had a significantly higher TMB (15.1 muts/Mb) than *TP53/KMT2C* single-MUT (8.7 muts/Mb) and *TP53/KMT2C* co-WT (3.1 muts/Mb) tumors. Moreover, TMB-H/PD-L1+ subset was enriched in *KMT2C* and *TP53* co-MUT (25%) comparing to *TP53/KMT2C* single-MUT (14.7%) and *TP53/KMT2C* co-WT (3.3%) tumors. Survival analysis from public clinical trials confirmed that patients with *TP53/KMT2C* co-MUT had remarkable clinical benefit to ICIs in both progression free survival (PFS) and durable clinical benefit (DCB). The median PFS was 7.3, 4.2 and 2.5 months for *TP53/KMT2C* co-MUT, *TP53/KMT2C* single-MUT and *TP53/KMT2C* co-WT patients, respectively (p=0.0032). *TP53/KMT2C* co-MUT was an independent variable of PFS (*TP53/KMT2C* co-MUT vs. *TP53/KMT2C* co-WT, HR: 0.47, 95%CI: 0.25-0.89, p=0.0199). Furthermore, *TP53* with *KMT2C* or *KRAS* co-MUT expanded the patient population benefiting from ICIs (mPFS = 7.2 months, p=0.00042; DCB = 51.2%, p= 0.0195). **Conclusion:** This study provides evidence that *TP53/KMT2C* co-MUT may serve as a predictive biomarker for ICIs in NSCLC. GAs detected by targeted NGS could illuminate insight for immunotherapy.

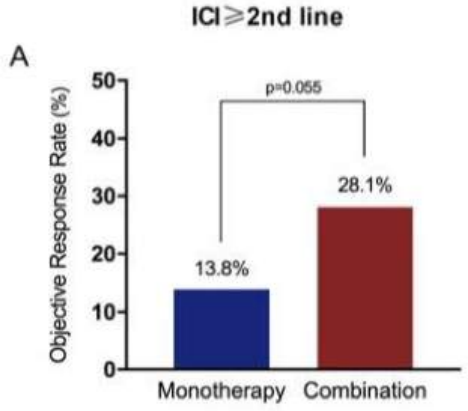
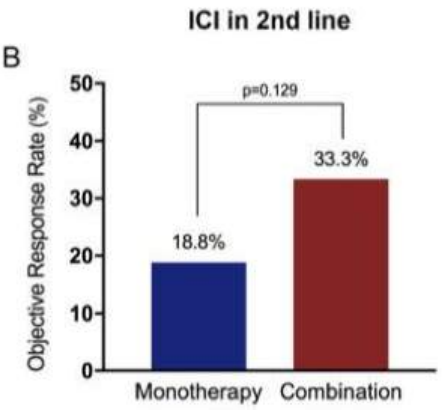
JCSE01.26 PD-1 INHIBITOR PLUS CHEMOTHERAPY AS 2ND/SUBSEQUENT LINE SETTING DEMONSTRATE SUPERIOR EFFICACY OVER PD-1 INHIBITOR ALONE IN PTS OF ADVANCED NSCLC

S. Ren[1], Y. Liu[2], F. Zhou[3], T. Jiang[4], C. Su[4], X. Chen[5], C. Zhou[6]

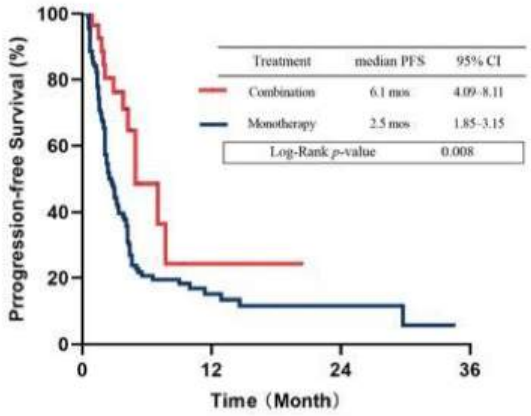
[1]*Shanghai Pulmonary Hospital, Thoracic Cancer Institute, Tongji University School of Medicine, Shanghai/China,* [2]*Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/China,* [3]*Shanghai Pulmonary Hospital, Tongji University School of Medicine, SHANGHAI/China,* [4]*Shanghai Pulmonary Hospital, Shanghai/China,* [5]*Shanghai Pulmonary Hospital, Tongji University, Shanghai/China,* [6]*Shanghai Pulmonary Hospital, Tongju University, Shanghai/China*

Background: PD-1/PD-L1 inhibitors have become standard of care as the 2nd-line setting and also approved as 1st line setting when combined with doublet chemotherapy in patients with advanced NSCLC. This study aims to compare the efficacy of PD-1 inhibitor plus chemotherapy with PD-1 inhibitor alone as 2nd/subsequent lines setting in patients with advanced NSCLC **Method:** Patients who received PD-1 inhibitor monotherapy or PD-1 inhibitor plus chemotherapy as 2nd/subsequent lines setting in Shanghai Pulmonary Hospital, Tongji University were retrospectively collected. Detailed clinicopathologic characteristics and therapeutic outcomes were analysis. **Result:** From January 2016 to February 2019, 148 patients who meet the criteria were included. Among them, 116 were in PD-1 inhibitor monotherapy group and 32 were in PD-1 inhibitor plus chemotherapy group. Chemotherapy regimens were pemetrexed(n=9), docetaxel(n=2), nab-paclitaxel(n=18) and gemcitabine(n=3). The baseline characteristics such as age, gender, smoking status, histology, PD-1 mono-antibodies, line of therapy were similar in the 2 groups. Combination group showed a favorable ORR (28.1% vs. 13.8%, p=0.055) and a significantly longer PFS(median 4.9 vs 2.5 months, p=0.005) compared with ICI monotherapy. Overall survial (OS) data was immature in the cutoff date of follow up. In the subgroup of 96 patients (monotherapy group n=69/ Combination group n=27) who were included as 2nd line setting, PD-1 inhibitor plus chemotherapy had significantly higher ORR(ORR:33.3% vs 18.8%, p=0.129) and longer PFS(median PFS: 4.9 vs 2.9 months, p=0.041).

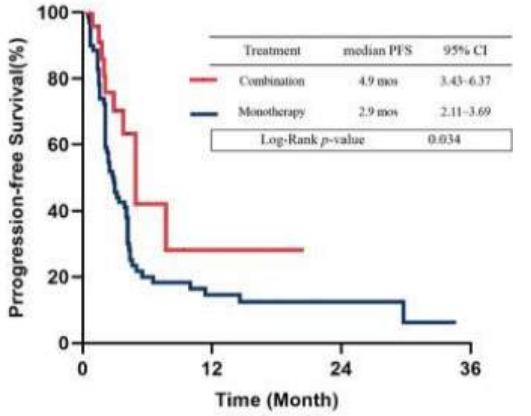




C



D



Conclusion: PD-1 inhibitor plus chemotherapy as 2nd/subsequent lines setting demonstrated superior efficacy over PD-1 inhibitor alone in patients with advanced NSCLC.

Keywords: Chemotherapy, NSCLC, Immunotherapy

Background: To investigate the potential value of peripheral blood programmed cell death 1 (PD-1)$^{+}$CD8^{+}Tcell receptor (TCR) repertoire profiling in predicting the clinical outcomesof immune checkpoint blockades (ICBs) for patients with non-small cell lung cancer (NSCLC). **Method:** The study comprised two independent cohorts (A and B). Cohort A (n=25) was used for the discovery of TCR diversity in the prediction of response to ICBs, and cohort B (n=15) was used as an independent validation set. A total of 40 out of 51 patients with stage IIIB-IV NSCLCs undergoing anti-PD-1/PD-ligand 1 (PD-L1) therapy between March 14th, 2017 and May 2nd, 2018were ultimately recruited.Pre- and post-ICB (4-6 weeks from the timepoint of the first imaging evaluation) peripheral blood samples were prospectively collected, and PD-1^{+}CD8^{+}T cells were isolated by flowcytometry for TCR sequencing. The diversity and clonality of the TCR repertoire were calculated for biomarker exploration. **Result:** In cohort A, patients with a high pre-ICB PD-1^{+}CD8^{+}TCR diversity had better response rate and longer progression-free survival (PFS) to anti-PD-1/PD-L1 therapythan those with a low diversity (6.4 months vs. 2.5 months, HR, 0.39, 95% CI, 0.17-0.94,*P*= 0.021), which was validated in cohort B. In a merged dataset from cohorts A and B, pre-ICB PD-1^{+}CD8^{+}TCR diversity achieved an optimal Youden's index of 0.81 with a sensitivity of 0.87 and a specificity of 0.94 in stratifying clinical response of ICBs [partial response (PR) + stable disease (SD) vs. progressive disease (PD)]. Patients with an increased PD-1^{+}CD8^{+}TCR clonality after treatment demonstrated significantly improved PFS (7.3 months vs. 2.6 months, HR, 0.26, 95% CI, 0.08-0.86,*P*= 0.002) compared to those with a decreased TCR clonality. Interestingly, two patients with initial pseudo-PD exhibited similar changes of TCR clonality and expansion of dominant TCR clones with those with PR but not PD. **Conclusion:** Pre-ICB TCR diversity and early change of TCR clonality after treatment based onperipheral PD-1^{+}CD8^{+}TCR repertoire sequencing are biomarkers to predict the response and survival to anti-PD-1/PD-L1 therapy, which provide a promising non-invasive approach to stratify NSCLC patients for ICB treatment.

Background: EGFR-TKI was the standard care for metastatic NSCLC patients harboring positive EGFR mutation, which might inhibit EGF signaling pathway and consequently have effect on differentiation, maturation and rehabilitation of neural cells. For the first time, we evaluated the dynamic changes of white matter lesion (WML) and gray matter volume (GMV) among such patients based on series of MRI images. **Method:** We retrospectively identified 778 patients with pathologically diagnosed advanced NSCLC receiving first-generation EGFR-TKIs in our hospital from 2010 to 2017, and 75 patients without brain metastasis and else comorbidity (hypertension, *etc.*) were analyzed. The modified Scheltens visual scale were performed to evaluate the changes of WML based on the series (baseline, 12 months' point and 24 months' point) of MRI images, and CBM (cluster-based morphometry) method based on SPM12 were adopted to identify GMV loss. The statistical methods were performed using SPSS software 22.0. **Result:** During the 24-month EGFR-TKI treatment, the patient's WML visual scores showed a progressive worsen. Comparing to the baseline (6.680±3.636), the scores were significantly changed at the 12 months' point (8.650±3.857; Mean scores increasing 1.973, 95% CI 1.595-2.352, p<0.001) and changed more obviously at the 24 months' point (10.110±3.854; Mean scores increasing 3.427, 95% CI 2.979-3.874, p<0.001), respectively. Also, the significant GMV loss were found in subregions of the right occipital lobe (mean decrease 76.714, 95% CI 40.739-112.690), left occipital lobe (mean decrease 93.476, 95% CI 37.483-149.469) and left basal ganglia (mean decrease 37.571, 95% CI 21.576-53.567), respectively (all *p*<0.005, the cluster level FDR<0.05). **Conclusion:** Dynamic structural analysis of series brain MRI images showed the significant worsen of the WML and GMV loss in patients with advanced NSCLC receiving EGFR-TKIs chronically. Perspective studies are warranted to verify its impact on the cognitive deficiency and hypomnesis among these patients in future.

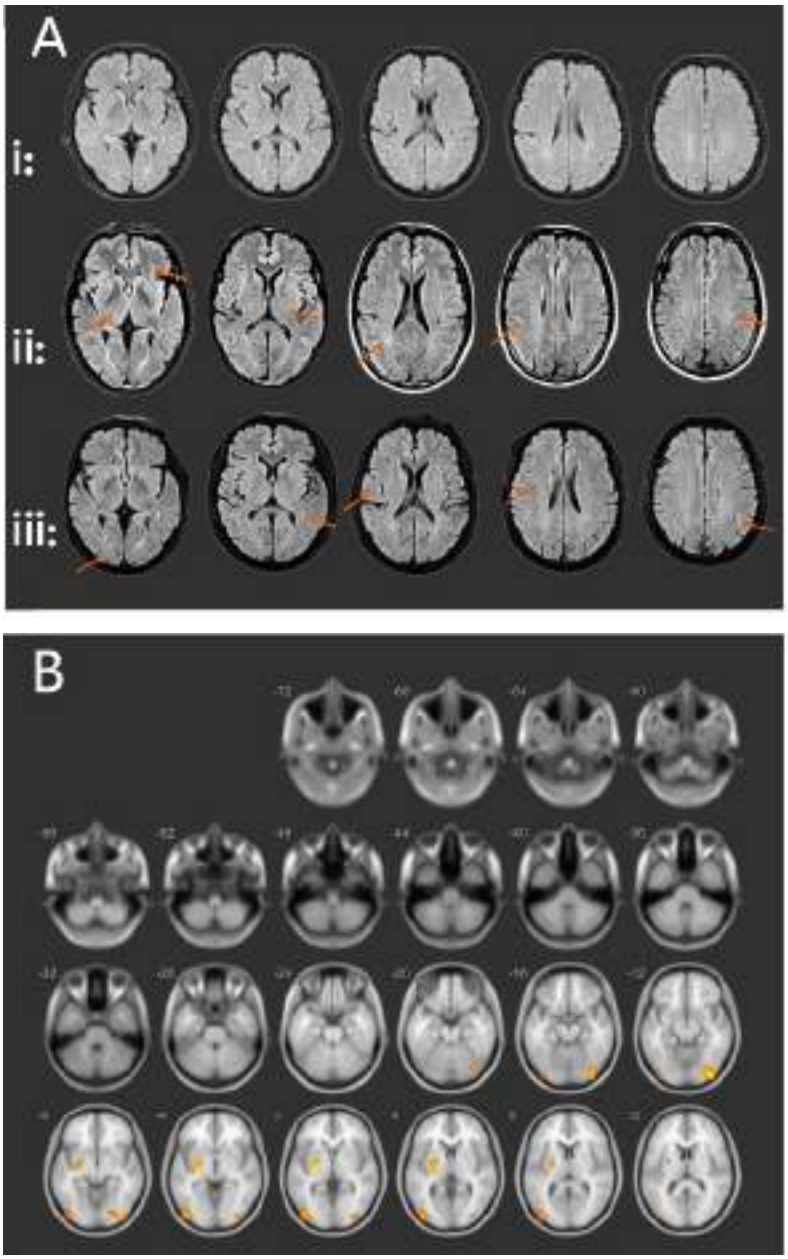

Figure. A. Series MRI images of one representative patient receiving long-term EGFR-TKI. (i. Baseline; ii. 12 months' point; iii. 24 months' point). New white matter lesions were identified in T2 FLAIR images (with yellow arrows). B. Significant loss of gray matter volume (colored areas) was identified by cluster-based morphometry method in the brain subregions among the studied population.

S01.02 INTRODUCTIONS & WELCOME

J. Mulshine[1], J. Field[2]

[1]*Rush University, Chicago/United States of America,* [2]*The University of Liverpool, Liverpool/United Kingdom*

The Five-year Vision for Lung Cancer Screening

The goal of lung cancer screening is to increase the detection of asymptomatic, localized cancers that can more frequently be cured. Given this prospect, it is with a sense of urgency that we explore strategies that allow us to benefit as many willing candidates to receive this service. In addition, there is an obligation to ensure that this cancer detection service is delivered in a fashion that conveys maximal benefit while minimizing harms. Thinking strategically, what steps and in what sequence should we pursue implementation of lung cancer screening to optimize improvement of lung cancer outcome in the five-year window? First, we expect results from a number of currently ongoing studies of smoking cessation studies integrated into lung cancer screening to be completed which may provide insight how to enhance cessation rates long-term smokers. This would be critical information to rapidly disseminate as risk of smoking harms rise so steeply in later life and since tobacco causes not only premature death but also profound economic costs (1, 2). Resources to accelerate screening research are currently an intense focus of developmental efforts. Over the next five years, collaborative mechanisms such as the IASLC's Early Lung Imaging Confederation will be fully functional and providing imaging cases with associated metadata to allow a robust number of research questions to be rapidly addressed (3). Many believe that from an outcome's perspective that "you get what your measure". Currently, there are no established panel of metrics that define excellence in screening. This must be rapidly addressed. A strong measure of screening success would be the reality within five years that clinicians and subjects have easy access to information regarding critical outcomes at a lung cancer screening facility. Such annual metrics for a screening facility may include, screening number, rate of lung cancers detected in screening, frequency of Stage I/II/III/IV, frequency of symptom-detected lung cancer, frequency of true positive lung case detection, operability rate, non-malignant thoracic resection rate, surgical morbidity/mortality rate, compliance with subject follow-up and smoking cessation rate. Armed with such information, subjects as well as clinicians can make well-informed decision about selection of site of care. Five years from now the clinical community may also come to consensus on a reliable and economical approach to access the biological potential of a resected tumor from a screen-identified cancer patient. The goal being to identify aggressive Stage I lung cancers based on mechanistic signatures derived from molecular analysis of the resected tumors identifying cancers that are unlikely to be cured with surgery alone. Appropriate target therapy can be match based on tumor characteristics so that immediate adjuvant therapy may be administered to preserve the possibility of a curative option for that subset of screen-detected cancers. The key to the remarkable progress in lung cancer screening outcomes has been fueled by the rapid advances in reliably imaging of small non calcified lung nodules. Further progress in improving the efficiency of lung cancer screening management has been made possible by actually measuring changes in the volume of lung nodules over time to specifically identify clinically aggressive lung nodules. Reliably measuring lung nodule volume in the range of 6 mm in diameter is a challenging task, but the work of the Quantitative Imaging Biomarker Alliance (QIBA) has worked out a quality conformance process that greatly improved the reliability of using imaging as a quantitative biomarker in this context (3). As screening is rolled out, the QIBA quantitative measurement can be disseminated through a cloud-based infrastructure such as the environment being developed by IASLC to support the imaging quality aspect of lung cancer screening (4, 5). A key to sustain innovation in this regard is to continue to cultivate collaborative efforts in an open research environment so that investigators from many nations can participate and innovate, as IASLC has demonstrated with its impressive contributions to both lung cancer pathology and staging.

S01.03 SESSION I: 2019 STATUS OF THE INTERNATIONAL MATURITY OF CT TRIAL OUTCOMES AND THEIR IMPLICATIONS

J. Mulshine[1], J. Field[2],

[1]*Rush University, Chicago/United States of America,* [2]*The University of Liverpool, Liverpool/United Kingdom*

Outstanding issues in lung cancer screening: Implementation Research Programmes The Lung cancer community now have the results from two large international RCTs, NLST and NELSON (1, 2), recent confirmatory data from the MILD trial (3), as well as from large international cohort studies (4-7) and smaller RCTs in Europe (8), all of which provide evidence to start the implementing lung cancer. The recent European consensus statement on lung cancer screening provides a very strong argument for the implementation of lung cancer screening (9). However, the actual implementation a cancer screening modality quite often only occurs 10-15 years after the large clinical trials, due to a range of issue which includes the allocation of long term funding, approval from national organisations, clinical agreement regarding the screening protocol and design of the implementation programmes, as well as national service delivery and staffing issues. All the evidence indicates that one would start to save lives now if lung cancer screening was implemented and even though there are acknowledged harms, the benefits outweigh the harms, as recently demonstrated in the NLST infographic (10). The number of deaths per year from lung cancer is still a major public health issue and has to be tackled with a well -structured and integrated smoking cessation and lung cancer screening programmes. This does not infer we are currently in a position to undertake lung cancer screening to its optimum, we still have a great deal to learn and we need to plan for future 'Implementation Research Programmes'. Figure 1 provides the basis for continued improvements in screening over the next 20 years and are the subject of this presentation." We need to have conversations with the public, as to who benefits from lung cancer screening and discuss the basic concept of 'early detection with early treatment, saves lives'. Future Implementation Projects. • Patient engagement / compliance.• Identification of patients in primary care- availability of risk data, integrated Information technology development.• Quality assurance of imagining CT platforms. • Use of liquid biopsies / breath tests in remote populations. • Patient selection utilising risk prediction models – optimising risk models. • Risk of lung cancer in females – re-evaluate based on NELSON mortality data. • Lung cancer Risk in non-smokers, new approaches required. • LDCT scans utilising volume & VDT – improve methodology / reporting. • Coronary Calcium assessment, working with cardiology on treatment pathways. • Use of AI reading of scans - quality control and future Radiology reporting. • Central CT Screening scans reading nationally / internationally. • Identification of the Indeterminate nodules – care pathway utilising integrated radiomics and biomarkers. • Referral to MDT in centers of excellence – potential for spoke & hub care with far-reach communities. • Treatment options / non-surgical – required clinical trials for small CT Screen detected nodules. • Developing new innovative interventive treatment trials in the lung cancer screening pathway, which will be required over the future 20-year

screening programmes. • Continuously monitor mortality and cost effectiveness to improve the service. • Significant other findings/ unexpected findings, integrated pathway of care with primary care for CT screened patients. • Annual / biannual repeat screening based on initial CT Scan reports and patient underlying risks – re-evaluate with new data. • Smoking cessation programmes – review success and adapt for differing populations.

S01.04 LUNG CANCER SCREENING: 2019 – TAKING GLOBAL IMPLEMENTATION FORWARD

H.J. De Koning, C. Aalst

Public Health, Erasmus Mc University Medical Centre Rotterdam, Ca/NL

With 338,000 EU-deaths annually, lung cancer is a devastating problem. Computed Tomography (CT) screening has the potential to prevent ten-thousands of lung cancer deaths annually. The positive results of the Dutch-Belgian screening trial (NELSON), with relatively low referral rates, and the NLST in the USA provided conclusive evidence. However, implementation is likely to be limited, slow and of variable quality throughout Europe, and current guidelines could easily require up to 25 million CT screens annually. The most optimal strategy in risk-based lung and thoracic screening is still unknown regarding the optimal and most cost-effective (e.g., targeted) strategy 1) to recruit, 2) to include smoking cessation and co-morbidity-reducing services in the context of screening, and 3) to determine the (risk-based) screening interval. Personalised regimens based on the baseline CT result can potentially retain 85% of the mortality reduction achievable through screening at 45% less screens, thus potentially saving much unnecessary harm associated with screening, and 0.5-1 billion Euros per year. But we do not know whether it is safe to have risk-based less intensive screening intervals after a negative baseline CT. Various methods to improve participation of hard-to-reach individuals have to be assessed in different healthcare settings. Innovative co-morbidity reducing strategies have to be tested including other markers on CT imaging, as Calcium Score and COPD. Such implementation research is needed to form the evidence base for risk-based lung cancer screening with huge benefits for the EU, on health outcomes, cost savings, and innovation in the long run.

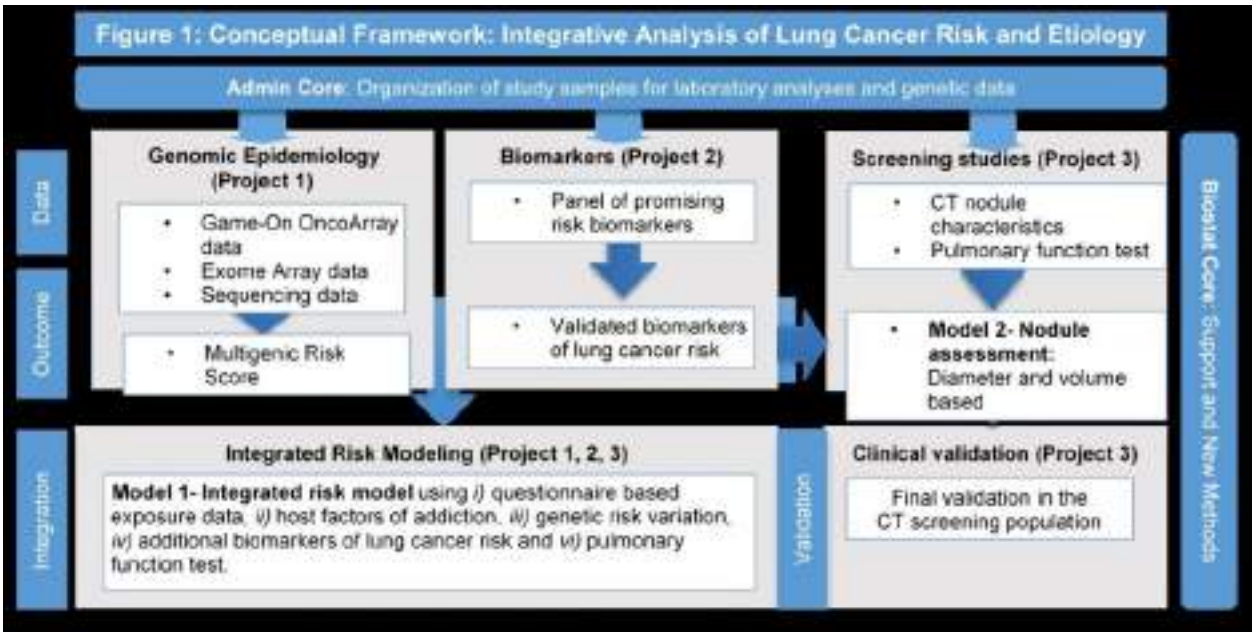
S01.07 THE U19 PLANS FOR INTEGRATION OF BIOMARKERS INTO FUTURE LUNG CANCER SCREENING

C. Amos[1], R.J. Hung On Behalf Of The International Lung Cancer Consortium[2], P. Brennan[3]

[1]*Baylor College of Medicine, Houston/United States of America,* [2]*Lunenfeld-Tanenbaum Research Institute, Sinai Health System and University of Toronto, Toronto/Canada,* [3]*International Agency for Research on Cancer, Lyon/France*

The goal of the U19 Integrative analysis of Lung Cancer Etiology and Risk (INTEGRAL) consortium is to develop biomarkers that characterize individual risk for development and progression from lung cancer. We are using a comprehensive strategy, depicted below in Figure 1, for this analysis and we are drawing on world-wide resources and expertise. There are three projects focusing on i) genetics of smoking behavior and lung cancer risk, ii) biomarker discovery and validation for identifying individuals at highest risk for developing lung cancer and iii) evaluation of these biomarkers in screening cohorts along with radiographic analaysis to evaluate risk for lung cancer development and nodule behavior. There are also administrative and biostatistics cores. We will discuss strategies and novel findings from these projects. For Project 1, to assist in genetic analysis, we have reimputed all the available data from lung cancer cases and controls using the haplotype reference consortium to bring together a data lake comprising data from over 100,000 individuals. The consortium provides data to its members and to collaborators who would like to evaluate hypotheses related to lung cancer by providing access for analyses and we currently are supporting 107 projects evaluating lung cancer risk. Additionally, consortium members from the University of Laval have performed transcriptomic analysis of normal lung tissue from over 500 participants undergoing surgery for lung cancer treatment. We are also studying the role that genetic factors have in influencing smoking behavior by collaborating with other large consortia and by studying multiethnic variation using Hawaiian multiethnic populations. Analyses of the genetic data and further extension to the UK Biobank have identified novel genetic loci that contribute to risk. Interaction analysis of the *CHRNA3/A5/B4* cluster with all other genomic regions identifies interactions with the 15q25.1 nicotinic receptors that influence lung cancer risk. Results identified genes in the neuroactive ligand receptor interaction pathway as playing a key role in increasing lung cancer risk. A cross-ethnicity analysis identified genetic factors in the major histocompatibility complex (MHC) that affect risk for lung cancer. We imputed sequence variation for 26,044 cases and 20,836 controls in classical HLA genes, fine-mapped MHC associations for lung cancer risk with major histologies and compared results among ethnicities. Independent and novel associations within HLA genes were identified in Europeans primarily affecting risk for squamous cell histology including amino acids in the HLA-B*0801 peptide binding groove and an independent HLA-DQB1*06 loci group. In Asians, associations are driven by two independent HLA allele sets affecting adenocarcinoma risk primarily that both increase risk in HLA-DQB1*0401 and HLA-DRB1*0701; the latter was better represented by the amino acid Ala-104. These results implicate several HLA-tumor peptide interactions as the major MHC factor modulating lung cancer susceptibility. A rare variant analysis yielded a mutation of the ATM gene that is rare in all populations except individuals of Jewish descent that primarily increase risk for adenocarcinoma and has highest risk in nonsmoking women. Analyses of smoking and genetic data have identified gene-smoking interactions that contribute to lung cancer risk, and particularly several genes that protect at-risk smokers from lung cancer development. Mendelian randomization and mediation analyses are underway to evaluate novel biomarkers that can be further studied in project 2. This effort found a surprising result that elevated levels of vitamin B12 increase risk for lung cancer development. Project 2 has been bringing together an approach to analyzing biomarkers using data from existing cohort consortia, which have collected samples prior to the clinical presentation of lung cancers. Results of an initial study showed that analysis of 4 circulating proteins (CEA125, CEA, CYFRA 21-1 and pro-SFTB) yielded an area under the receiver operator curve accuracy of 83%. This level of accuracy is sufficient to consider the panel for recruitment of individuals for screening studies, but we anticipate that adding additional biomarkers will further improve the accuracy of risk prediction. Biomarkers that are being further considered include additional protein markers along with micoRNA species, the inclusion of polygenic risk scores and additional serum-derived biomarkers like vitamins B-6 and B-12 that have been shown in mendelian randomization studies to help in identifying high risk subjects. Project 3 is focused on the establishment and validation of the models in the LDCT screening programs. In collaboration with National Lung Screening Trial, Canadian LDCT screening programs, NELSON and United Kingdom Lung Study (UKLS), we have begun the data harmonization across LDCT studies, including clinic-epidemiological data as well as nodule characteristics. We have established a pipeline of feature extractions for the radiomics analysis and compared the inter-reader variability. The intraclass correlation coefficients are >0.75 for the majority of the radiomics features extracted. We will conduct cross-study validation for the model building to ensure the maximum generalizability of the model. We will start the work on biomarkers and assess their added values in these models.



Keywords: biomarkers, genetics, early detection

S01.11 FRAMING CURRENT STATUS

D. Yankelevitz

Icahn School of Medicine, NY/United States of America

CT screening has gained increased acceptance due to results from recently reported randomized controlled trials. Nevertheless, there continues to be concerns regarding the benefits. Articles continue to appear describing a very marginal benefit versus harms. This concern has likely impacted its uptake both in the US and globally. There is a strong need to rethink what is the relevant information to provide to a person interested in screening. The most obvious answer would related to their frequency of being diagnosed with a potentially life threatening cancer and then how curable it would be if found early by screening versus later when symptom prompted. Without knowing these specifics there is no rational way to make a decision. Nevertheless, this type of information is not routinely available and is commonly misrepresented in the literature. It is vital that people understand that lung cancer can be found early in the majority of cases and that surgery is curative in the majority of them as well. Another aspect of screening that directly affects the overall usefulness relates to the management of screen detected findings. Currently there are several different protocols that are being used. It will be important to be able to learn from each of these how well they perform and in particular, which aspects of the protocols work best. Some standardized measure that compares their efficiency would be useful. This not only would apply to the management schemes but also to the various software that is being applied. The use of volumetrics has been gaining continued acceptance, but it has different roles, it can be used for setting size thresholds and also looking for change over time. Each of these represent important areas that can have a large impact and both aspects need to be studied separately. Finally there is continued advancement in our ability to look for other findings on the same basic scan. The overall benefits that are likely to come about as a result of the screening process will extend to other illnesses and how this will be integrated into an overall assessment of benefit should be a high priority for those interested in screening.

S01.14 LUNG CANCER MDT

D. Baldwin

Nottingham University Hospitals, Nottingham/United Kingdom

The Lung Cancer MDT David R Baldwin Consultant Respiratory Physician and Honorary Professor of Medicine Nottingham University Hospitals and University of Nottingham, UK Multidisciplinary Team (MDT) meetings or “Tumour Boards” are increasingly becoming a central component of lung cancer services. Management of lung cancer patients through diagnosis, staging, fitness assessment and treatment is a multidisciplinary endeavour. Good communication between disciplines means that the goal of personalised treatment can be realised because of the complexity of modern management, not least the rapid change in treatments. Many lung cancer services have a meeting of professionals at key points along the clinical pathway that is commonly at the point of decision to treat and where diagnosis and/or staging is complex. There are a number of documents that describe the membership of the MDT and how the meetings should function. Key is that all relevant professional groups are represented and that there is a clear record of the discussion. Despite the widespread adoption of MDT meetings, there remains limited evidence for their effectiveness. This is because the integration of MDTs into the lung cancer services has evolved as management has become increasingly complex. It would be difficult to devise an experiment to test the efficacy of the MDT as they are now so embedded in services. With respect to lung cancer screening, it is important that MDTs adhere to guideline-driven management so as to reduce the harms that may accrue. The place of the lung cancer MDT is in relation to a high probability of cancer. In screening it is probably better to have a separate MDT to advise on the management of nodules and incidental findings, again using guideline-driven management. All MDTs should record data for audit, quality improvement and research.

S01.15 SERVICE REQUIREMENTS; STAFF AND PLATFORMS AVAILABILITY

H. Schmidt

University Health Network, Alberta/Canada

Lung cancer screening encompasses a pathway that includes several integral elements. It starts with the active recruitment of individuals and their risk assessment. The pathway continues into radiology, with the actual scanning using low dose computed tomography (LDCT), as well as standardized reporting that focuses on the follow up of both lung nodules and incidental findings. At the end of the pathway is the seamless integration into a diagnostic assessment program for confirmation and timely and appropriate treatment of the detected lung cancer. High quality, and quality assurance of the radiology performance is the central piece in this pathway, to decrease the harm from radiation and false positives. Since lung cancer screening is most often a newly established program in an institution, this presents a unique opportunity to build robust quality standards for radiology. Radiology quality assurance comes with requirements regarding acquisition, interpretation and reporting of the low-dose computed tomography (LDCT) scans. The facility standards need to provide equipment that does allow low dose data acquisition. Scanning protocols need to be defined, and protocol compliance needs to be assured, radiation exposure needs to be regularly measured with phantoms, and image storage needs to be properly identified. Personnel requirements cover both the technologists and the reporting radiologists. Both have to provide the necessary training and certification. Radiologists need to document their ongoing experience in chest reporting, participate in a workshop or alternative training regarding nodule follow up, and get familiar with the respective reporting template. Radiologists training programs have received positive feedbackon content, their goal is to increase confidence in reading lung cancer screening LDCTs and appropriate recommend follow up for screen-detected nodules. Complex cases are collected and their discussion fosters mutual learning. Ongoing quality assurance measures include peer review and double reads, to minimize false positive. An adjudication process can provide expert opinion and support learning where consensus can not initially be reached. Report completeness should be confirmed with regular audits. All these requirements should be available and met by a facility planning to engage in lung cancer screening using LDCT. All above standards are available; they need to be monitored, must be met at baseline and during tailored annual assessments, ensuring compliance across screening sites. In summary, the implementation of a robust quality assurance program assures a high standard around the radiology workflow, from LDCT scanning to image interpretation and follow up recommendations. Radiologist training programs, centre minimum requirements, and standardized reporting can ensure that quality standards are consistently high

S01.17 SMOKING CESSATION

R. Murray

University of Nottingham, Nottingham/United Kingdom

More than 85% of cases of lung cancer are caused by tobacco smoking, and stopping smoking, at any age, significantly reduces lung cancer risk. Despite positive findings reported by the National Lung Screening Trial (NLST) and the Dutch-Belgian Randomised Lung Cancer Screening Trial (NELSON), a number of important questions remain regarding the best way to implement lung cancer screening (LCS), including how most effectively to embed smoking cessation interventions (SCI) into these programmes. One concern that has been raised around LCS for current smokers is the potential 'moral hazard' arising from a negative (i.e. reassuring) screening result, which may reduce motivation to quit. Conversely, attendance at a lung cancer screening programme offers a 'teachable moment' for smoking cessation, occurring at a time when participating smokers may be particularly receptive to offers of help to quit. Indeed, a negative screen result has been reported as being perceived as a 'clean slate' as a motivator to stop smoking. Evidence suggests that smoking cessation and low dose computed tomography (LDCT) screening have additive effects on survival; an analysis of participants in the NLST reported a 38% reduction in lung cancer mortality with the combination of smoking abstinence at 15 years with LDCT screening. Further, research has indicated that adding SCIs to LCS improves the cost effectiveness of such programmes. It is, therefore, essential that any lung cancer screening programme provides smoking cessation support for participants. Clinical guidelines regarding delivery of smoking cessation interventions in the context of LCS have been produced by the Association for the Treatment of Tobacco Use and Dependence and The Society for Research on Nicotine and Tobacco, but this document acknowledges the paucity of data and need for future research specific to this patient population. Participants in LCS are unlikely to be representative of the general population of smokers, and evidence regarding smoking cessation outcomes in a lung cancer screening (LCS) context is variable. There is some evidence to suggest that participation in LCS alone may increase smoking cessation rates above that of the general population, influenced by screening outcomes. However, comparisons between smoking cessation outcomes in screened and control populations in a number of studies have reported inconsistent findings. There is limited proven effectiveness of low intensity SCIs delivered as part of LCS programmes. When comparing such interventions delivered to smokers attending for LCS, there appears to be no difference between standard written advice, internet resources, quitline details or brief advice. However, more intensive interventions such as telephone-based counselling sessions have been shown to be more effective than self-help cessation resources and a combination of cognitive behavioural therapy and pharmacotherapy have shown further promise. Little research exists as to the potential benefits of e-cigarettes for cessation in this setting but given their increasing popularity as a cessation aid this requires further attention. Delivery of a more intensive intervention at the time of screening may be viable; one recent study reported that it was feasible to deliver a single tailored session of motivational interviewing counselling on the day of screening. Smoking cessation studies from other settings mayprovide learnings transferrable to the LCS setting. Personalised interventions for smoking cessation are generally more effective than standard approaches. the presence of emphysema and coronary artery calcification may be incidental findings from LDCT scans that could be used as part of an SCI in the LCS setting. This may be particularly pertinent where participants are fit, relatively asymptomatic and hence potentially more susceptible to a message that lung damage had already occurred but clinical impact could be reduced by stopping smoking (as may be the case in LCS attendees). Relatively few studies have tested interventions for smoking cessation in LCS settings, and are subject to large variations in timing, setting, participants, SCI and outcome measures which does not allow direct comparison between studies and makes it difficult to draw conclusions regarding optimal interventions. However, it is likely that higher intensity interventions will be more effective and the use of incidental scan findings should be considered. Much research into the best way to integrate SCIs into LCS is now ongoing in an attempt to answer the outstanding implementation questions. The SCALE (Smoking Cessation within the Context of Lung Cancer Screening) collaboration in the US consists of eight clinical trials which seek to build an evidence base for effective interventions in LCS, using a common core of data collection measures to allow pooling of data and comparison across studies. In the UK, the Yorkshire Enhanced Stop Smoking study (YESS) seeks to test the delivery of an intensive SCI, co-located with the Yorkshire Lung Screening Trial (YLST) and personalised to the LCS result. Data from these studies will hopefully add clarity to the question of how best to reduce morbidity and mortality amongst those presenting for LCS.

S01.18 COST EFFECTIVENESS

B. Pyenson

Milliman, Inc., New York City/United States of America

There is broad consensus that lung cancer screening with low-dose CT is cost-effective. However, there has been slow take-up in the US where it is covered by commercial insurance and by the federal Medicare program. One way to optimize LC screening is to consider screening as part of an integrated program that specializes in population health for the cluster of smoking-related illness. There are four components of this, LC screening centers can provide high-quality screening and systematic follow-up and appropriate referrals Imaging for LC screening can quantify cardiac calcification, COPD, and osteoporosis, all of which may be associated with smoking LC screening centers can operate as a center for smoking cessation, exercise counseling, and adherence support For the 1.5 million annual indeterminant pulmonary nodules in the US, LC screening centers can provide appropriate follow-up. The vast majority of such cases receive no follow-up. There are both economic and financial consequences for integrated screening. The economic consequences are measured in cost-effectiveness. The financial consequences are attracting high-utilizing people away from lower-quality providers, which can offset the loss of income from treating late stage lung cancers.

Keywords: screening cost-effectiveness financial

S01.19 BIOMARKERS

P. Brennan, M. Johansson, H. Robbins

International Agency for Research on Cancer, Lyon/France

Improved risk stratification has the potential to enhance the ratio of benefit to harm for lung cancer screening. Risk biomarkers for lung cancer have been identified that have the potential to contribute to risk stratification, and efforts in this area are ongoing, although whether they are practical or cost-effective remains to be clarified. Recent progress in the use of biomarkers for lung cancer risk stratification and their cost-effectiveness will be discussed. S01 IASLC CT SCREENING SYMPOSIUM: FOREFRONT ADVANCES IN LUNG CANCER SCREENING (TICKETED SESSION)
SATURDAY, SEPTEMBER 7, 2019 07:00–12:00

S01.20 HOW WILL SUCCESS WILL BE JUDGED

K. Fong[1,2], H. Marshall[1]

[1]*University of Queensland, Chermside/Australia,* [2]*The Prince Charles Hospital, Chermside/Australia*

For instance, for a screening proponent, the implementation of a population based CT screening program may signify success, whereas the opposite conclusion will be drawn by those not swayed by the available evidence on lung cancer screening. From a technical viewpoint, as screening refers to the application of a test to a population which has no overt signs or symptoms of the disease in question, to detect disease at a stage when treatment is more effective. The technical effectiveness of CT screening can be viewed as its ability to detect the presence or absence of lung cancer, sensitivity, specificity, True and False positives, True and False negatives. From a CT screening program perspective, the metrics may include: · Participation (where it relates to an appropriate level of access and participation of people in the target and eligible population) · Cancer detection rates · Safety and harm minimisation (potential harm, either physical or emotional, is minimised) · Timeliness (providing access to screening and assessment services in a timely and efficient manner) · Client focused From an economic point of view, success may be a measure of the balance of the costs of screening (costs of the test and subsequent diagnostic tests and the costs associated with any hazard of the test as well as the costs of over-treatment) to reduced costs of therapy (costs associated with less expenditure on the treatment of the advanced disease, and the economic value of the additional years of life gained) For the policy maker, the metrics of success will include budgetary management, degree of realised benefit for the population targeted in the context of health care funding for other conditions (eg incidence and mortality), opportunity costs and population health measures, and adherence with their national screening policy Here we discuss the nuances of selecting metrics for lung cancer CT screening to inform our considerations for the multiple circumstances that make up the pragmatisim of real life.

S01.23 EVOLUTION OF ELIC

R. Avila

Accumetra, LLC, Clifton Park/United States of America

The Early Lung Imaging Confederation (ELIC) Hub & Spoke Environment (H&SE) is a new globally distributed and open source lung cancer imaging database and computational analysis environment designed to significantly improve the cost, time, and quality of lung cancer imaging research. This IASLC led initiative and computational infrastructure project, when fully deployed, will allow clinical research groups (Spokes) to securely make their locally stored de-identified lung cancer imaging collections available for computational analysis by other research groups (Clients), all coordinated by a central IASLC managed server (Hub). Clinical sites will be able to make lung cancer imaging data available for specific types of computational analysis without transmitting the imaging data over national boundaries to other groups and losing control over how the data is used and further distributed. This allows lung cancer screening research groups to more easily make available datasets to large global lung cancer imaging research studies with far more control over data use. This federated data storage and analysis approach will allow the ELIC H&SE to scale to much larger data sizes than a traditional centralized database, one day allowing lung cancer imaging researchers to quickly and easily perform quantitative analysis on global lung cancer imaging studies with larger collections of high quality, standardized data than is attainable today. This is viewed as a critical next step for the development of next generation Artificial Intelligence algorithms for lung cancer imaging, which require large amounts of data for algorithm development and performance evaluation. In preparation for the 2018 IASLC WCLC meeting in Toronto, Canada, a proof-of-concept ELIC Hub and Spoke Environment was developed and set up using Amazon Web Services (AWS) cloud resources. A hub was set up on a Virginia AWS cloud instance and 10 spokes, each pre-populated with an identical set of 100 de-identified CT lung scans, were set up at 10 globally distributed AWS cloud locations including Mumbai, London, Frankfurt, Montreal, Sydney, Tokyo, Paris, Seoul, Sao Paulo, and Virginia (on a separate cloud instance). Two open source lung cancer imaging algorithms, one that automatically computes lung volume for a thoracic CT scan and another for volumetric measurement of small lung nodules, were made available for use by the 10 spoke instances. Live demonstrations of the proof-of-concept system were shown at the 2018 WCLC meeting including the ability to launch computational experiments and receive back quantitative results from the 10 globally distributed spokes. Figure 1 shows the global distribution of the hub and spokes for the 2018 WCLC ELIC proof of concept demonstrations. The live demonstrations showed that the ELIC H&SE could be used to select globally distributed datasets available on the spokes for analysis, run specific computational algorithms on those datasets, and have all of the results aggregated in real-time for viewing on the hub, as shown in Figure 2. The ELIC

H&SE infrastructure is now undergoing further development in 2019 to bring it from a proof-of-concept demonstration to a functional globally distributed database and computational environment capable of performing useful quantitative lung cancer imaging studies. References to tools and resources for performing data de-identification and encryption are being added to support research groups that will be uploading lung imaging datasets and metadata into the ELIC H&SE. Standards for lung cancer screening data representation, starting with a lung cancer screening data dictionary developed by the VA-Partnership to increase Access to Lung Screening (VA-PALS) project, are also being added to ensure that global analyses can be performed with common terminology and data formats. In addition, the Radiological Society of North America's Quantitative Imaging Biomarker Alliance (QIBA) small lung nodule conformance certification phantom, specifications, and methods are being used to help lung cancer screening sites prospectively collect, monitor, and optimize lung cancer imaging studies for high quality volume measurements. All of these resources and formats are planned to be reviewed with all ELIC stakeholders on a quarterly basis to receive feedback and refine the systems and methods. There are numerous functionality advantages for spokes that use local cloud computing resources including significantly improved security for both clients and spokes, improved computational efficiency through on-demand cloud resourcing, and continuously updated hardware and infrastructure. Additional software development is underway that will allow ELIC to achieve these advantages for cloud-based deployments. Live demonstrations are again planned for the 2019 IASLC WCLC meeting in Barcelona, Spain showing an early demonstration of a new iaslc-elic.org website capable of supporting both spokes and clients performing globally distributed lung cancer imaging research studies.

Figure 1: The global distribution of the hub and spokes for the 2018 WCLC ELIC proof-of-concept demonstrations.

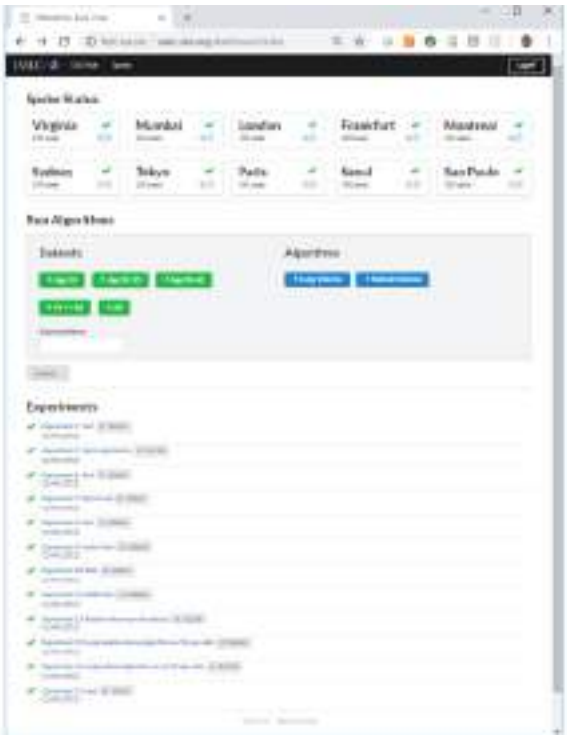

Figure 2: ELIC H&SE live demonstration screenshots showing the ability to view spoke status, select globally distributed datasets for analysis, and view a list of completed experiments (left) as well as drill down and view statistical experiment results including computationally generated images (right).

SATURDAY, SEPTEMBER 7, 2019 17:30–19:00

S02.01 INTRODUCTION

I. Wistuba

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Dr. Adi Gazdar was a scientific pioneer, a groundbreaking pathologist, loyal friend and inspiring mentor. Dr. Gazdar was born in India; he earned his medical degree from Guy's Hospital Medical School at the University of London and completed residencies in pathology at Peter Bent Brigham Hospital and New England Deaconess Hospital in Boston before joining the NCI in 1968. During his remarkable five-decade career, Dr. Gazdar served 23 years with the National Cancer Institute (NCI) a senior scientist and section head. His NCI experience included initially leading its Viral Pathology Section; the Human Tumor Cell Biology Laboratory for the NCI's VA Medical Oncology Branch from 1975 to 1981; and then the Human Tumor Cell Biology Section for the NCI-Navy Oncology Branch from 1981 to 1991. His team collected, cataloged, and analyzed thousands of human cancer specimens with an emphasis on lung cancer and lymphomas. In 1991, he joined his long-time colleague Dr. John D. Minna at the University of Texas Southwestern Medical Center, Dallas, Texas, where he had a distinguished 27-year career as professor of pathology as the W. Ray Wallace Distinguished Chair in Molecular Oncology Research, and deputy director of the Nancy B. and Jake L. Hamon Center for Therapeutic Oncology Research. Dr. Gazdar's efforts in the laboratory yielded the first large panel lung and breast cancer cell lines, used by investigators around the world, and he developed molecular methods for detecting early lung tumors. Dr. Gazdar also identified several genes involved in the pathogenesis of different cancers. In lung cancer, he uncovered mutated genes dysregulated by mutation and DNA methylation, provided some of the first work characterizing neuroendocrine cancers such as small cell lung cancer, and played a major role in the discovery of the mutated epidermal growth factor

receptor (*EGFR*) gene as a therapeutic target in lung cancer arising in never-smokers. During his long career, Dr. Gazdar published about 800 articles, book chapters and commentaries, and has been cited over 110,000 times, ranking him among the top 1% of scientists in the biomedical field. His numerous honors and recognitions include a 2004 award from the prestigious Jacqueline Seroussi Memorial Foundation for Cancer Research in Israel and the 2003 Mary J. Matthews Pathology/Translational Research from the International Association for the Study of Lung Cancer (IASLC). Dr. Gazdar was an inspirational role model for many young scientists mentoring over 100 post-doctoral fellows from around the world. IASLC established the Adi Gazdar Translational Research Fellowship Award on 2017 to honor his legacy in lung cancer training.

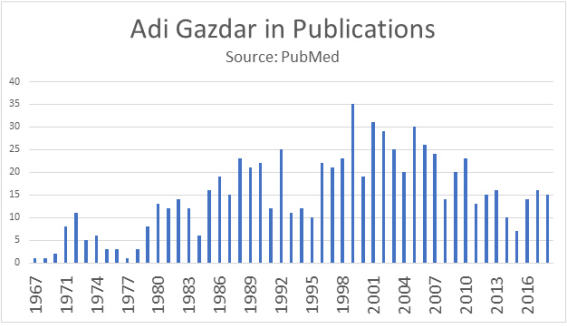
S02.02 ADI GAZDAR'S LEGACY

P. Ujhazy[1], M. Antman[1], C. Burgess[1], J. Mulshine[2]

[1]*National Cancer Institute, Rockville/United States of America,* [2]*Rush University, Chicago/United States of America*

Adi F. Gazdar (1937-2018) belongs to the 150 most successful scientists of all time. His impact in cancer research, virology, molecular pathology, cell biology, and many other disciplines was immense. A giant in lung cancer research, Dr. Gazdar pioneered numerous concepts and his work was seminal in the establishment of the current standard of care. He will be remembered as a prolific innovator, respected mentor, valued collaborator, and an altruistic human being. Here we will quantify the scientific legacy of Dr. Gazdar using various bibliometric analyses. The impact of Dr. Gazdar's work was evaluated with the use of a panel of bibliometric tools including PubMed, iSearch, iGrants, iCite, Google Scholar, Web of Science, Clarivate Analytics, and Dimensions. Adi Gazdar has published more than 700 scientific publications that were cited more than 120,000 times, his H index is 171, and his most cited paper has more than 4000 citations (see Figure 1).



His Weighted Relative Citation Ration (RCR) since 1994 is 1,283 with a mean RCR of 2.78 and median 1.33 per publication. By disciplines, most of his publications are in oncology, followed by studies on the respiratory system, cell biology, pathology, biochemistry and molecular biology, experimental medicine research, genetics, internal medicine, and biology. By scientific topics Dr. Gazdar published on lung cancer (small cell and non-small cell), tumor suppressor genes, viruses, breast cancer, allele loss, DNA methylation, risk factors, T cells, colorectal carcinoma, model systems, and growth factors and others. Many of his papers are related to drug development and testing and he published more than 10 papers on each of the following agents: decitabine, cisplatin, gefitinib, azacytidine, etoposide, insulin, doxorubicin, erlotinib, levodopa, tretinoin, and cyclophosphamide. Perhaps the most impact of Dr. Gazdar's work had the creation and distribution of cell lines and models that allowed to characterize the retroviral particles in patients with T-cell lymphoma, test virtually all current chemo and targeted therapy agents used in the treatment of lung cancer, and define molecular subtypes of small cell and non-small cell lung cancers that are currently used in diagnosis. The National Cancer Institute US in collaboration with a team at the University of Texas Southwestern are currently assessing the tremendous impact that these cell lines had on all aspects of lung cancer research and standard of care. This Stewardship Project is led by Dr. James Mulshine from Rush University.

The preliminary data generated by this project indicate that Dr. Gazdar's 278 lung cancer cell lines led to 33,207 publications, which were cited 2,968,974 times, referred by 4,700 patents, linked to 422 clinical trials, and produced 14,057 supporting grants by 1,019 funders world wide. An example for the most cited cell line H460 is in Figure 2. This cell line itself had 11,124 publications cited 347,117 times, was mentioned in 1,564 patents, was linked to 118 clinical trials and 4,890 grants funded by 717 organizations. Doctor Adi F. Gazdar left behind an immense wealth of work that has changed cancer research and standard of care.

S02.03 THE IMPACT OF CELL LINE DEVELOPMENT IN LUNG CANCER RESEARCH

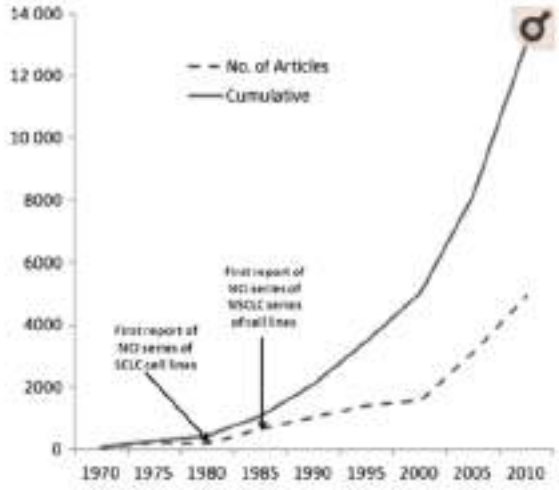
P. Bunn, Jr

Univ. of Colorado Cancer Center, Aurora/United States of America

Advances in Lung Cancer Research using patient derived cell lines and xenografts In the 1970s there were few lung cancer preclinical models and therapy selection was generally empiric. When the NCI established a branch to specifically study lung cancer (the NCI-VA Medical Oncology Branch) a systematic effort to establish permanent lung cancer cell lines with orthotopic implantation into athymic mice was implemented. The branch was led by Dr. John Minna and the cell line efforts were led by Dr. Adi Gazdar. The cell lines were given sequential numbers starting from NCI-H1 indicating the NCI origin and that they were human cell lines. Figure 1 shows how often these lines have been use in publications on lung cancer. These lines were initially used to study various chemotherapy agents and combinations such as the etoposide/cisplatin in small cell lung cancer (SCLC) xenografts. The expression of multiple proteins such as CD56 and many neuropeptides distinguished these SCLC cell lines from NSCLC cell lines. Originally it was recognized that most SCLC cell lines grew as floating aggregates but that s minority grew attached to the plastic. These later cell lines were termed "variant" lines were as the floaters were called "classic". Essentially all of the lines had p53 mutations and loss of Rb. More recent studies indicated that the classic lines highly expressed neuroendocrine features. The variant lines more often had amplified myc. a new model of SCLC subtypes defined by differential expression of four key transcription regulators: achaete-scute homologue 1 (ASCL1); neurogenic differentiation factor 1 (NeuroD1), yes-associated protein 1 (YAP1) and POU class 2 homeobox 3 (POU2F3). These high NE SCLC cell lines and tumors also expressed *NKX2-1*, the entire range of NE markers, and lacked expression of the neuronal and NE repressor REST. The low NE subtype had undergone epithelial mesenchymal transition (EMT) and had activated the Notch, Hippo and TGFβ pathways and MYC oncogene. Recent studies found that 16% of human SCLC tumors and 10% of SCLC cell lines were of the low NE subtype, as well as cell lines from the GEM model. Synaptophysin was a more commonly expressed marker for variant SCLC cell lines, which rarely showed Dopa decarboxylase activity. These cell lines and patient samples were also used to describe the expression of N-Myc and L-Myc in small cell lung cancers. Reports demonstrated that 6 of 31 independently derived human small-cell lung cancer (SCLC) cell

lines had 5- to 170-fold amplified N-myc gene sequences. A third myc-related gene (L-myc) cloned from SCLC DNA with homology to a small region of both the c-myc and N-myc genes. SCLC cell lines may prove useful in defining patients most likely to benefit from immunotherapy. For example, human SCLC cells, in contrast to other lung cancer types, are characterized by greatly reduced transcription of HLA-A,B,C and beta 2m genes, which suggests the existence of a mechanism for evading the host immune response to the tumor and of an E1a-like product in this type of tumor cell. Cell lines with myc amplification were shown to be especially sensitive to aurora kinase inhibitors. The human lung cancer cell lines were also used to define many of the genetic, proteomic and transcription features of lung adenocarcinomas, squamous carcinomas and large cell carcinomas. Early studies demonstrated a significant correlation between EGFR gene copy number, EGFR gene mutations, and gefitinib sensitivity. EGFR protein was necessary but not sufficient for predicting sensitivity. Gefitinib-sensitive lines showed a G(1) cell cycle arrest and inactivation of downstream signaling proteins; resistant cell lines had no changes. The in vivo effects mirrored the *in vitro* effects. Cell lines have also been used to study EGFR exon 20 mutations and HER2 mutations. HER2(YVMA) mutations were shown to activate cellular substrates more potently than HER2(WT); and that lung cancer cells expressing this mutation remain sensitive to HER2-targeted therapies but insensitive to EGFR TKIs. HER2 mutations were in-frame insertions in exon 20 and target the identical corresponding region as did EGFR exon 20 insertions.HER2 exon 20 insertions were shown to be sensitive to the irreversible pan-HER receptor tyrosine kinase inhibitor pyrotinib. EGFR-mediated bypass signaling has been reported after ALK and ROS1 blockade as well as RET and NTRK1 blockade. EGFR signaling provided a critical adaptive survival mechanism that allows cancer cells to evade oncogene-specific inhibitors, providing a rationale to co-target The RAS-MAPK dependence was shown to be a hallmark of EML4-ALK lung adenocarcinoma and provided a rationale for the upfront inhibition of both ALK and MEK to forestall resistance and improve patient outcomes. Dr. Gazdar and colleagues also developed a method to reproducibly generate continuously replicating human bronchial epithelial cell (HBEC) lines that provide a novel resource to study the molecular pathogenesis of lung cancer and the differentiation of bronchial epithelial cells. In summary, human lung cancer cell lines have contributed greatly to the development of novel biomarkers and therapies for lung cancer and much of the work stemmed from early development by Dr. Gazdar and his team at the NCI.

Figure 4



Number of citations for human lung cancer cell lines. Data were obtained from a search of the PubMed database from within the EndNote program by use of the medical search heading terms "lung neoplasms", "cell line, tumor", and "humans." The cumulative number of citations and the number of citations per 5 years are shown. The results are from a search performed in June 2010. NCI = National Cancer Institute; NSCLC = non–small cell lung cancer; SCLC = small cell lung cancer.

S02.04 DR. GAZDAR AS A MENTOR

T. Mitsudomi

Kindai University Faculty of Medicine, Osaka-Sayama/Japan

It was September in 1989 when I joined the NCI-Navy Medical Oncology Branch as a postdoctoral fellow. At that time, I was in my 10th year as a surgeon. The reason why I wanted to join the NCI-Navy was that I was greatly fascinated by the book entitled "The Biology of Lung Cancer" published by Marcel Dekker authored by many of the NCI-Navy MOB investigators. Especially, I was attracted by experimental works that used many lung cancer cell lines established by Adi's group. When I first met Adi, my impression was that he was a calm and quiet person. My first project was to characterize peripheral airway cell phenotype in the adenocarcinoma cell lines by examining the expression of surfactant proteins as well as class II MHC. But I did not like this project and after 2 months or so, he agreed to change my theme to KRAS or TP53 mutations in lung cancer cell lines. He never pushed me to do or not to do something and never became emotional. I was deeply immersed in the research to look for the clinical and pathologic significance of those genetic abnormalities in lung cancer. This was what is called "translational research" today. I thought I could find what I should pursue throughout my life as a lung cancer doctor. It is obvious that without this experience and Adi, my life would have been so different. In addition, human network owing to Adi has been a precious treasure for me. One day in 1990, he gave me a paraffin block of bronchial biopsy sample and told me to search for TP53 mutation. It is currently a routine diagnostic workup to examine genetic alterations in the biopsy samples when you see lung cancer patients. It was as if he had known what would be the future diagnostic workup before 30 years. During this fruitful time of my life, I am so proud that I was able to co-authored 18 papers with Adi. After coming back to Japan, I saw Adi occasionally but periodically at various meetings such as the AACR, ASCO, ELCC and especially WCLC. Every time, he encouraged me to pursue my goal and gave some suggestions on my experiments. When Adi was to edit a special issue on Lung Cancer in Never Smokers in Translational

Lung Cancer Research in 2018, he invited me to write about GGO lesions in never smokers. It was the last homework that he assigned to me. I am going to organize the Annual meeting of the Japanese Lung Cancer Society in December 2019. When I talked to him and his wife Celia at the Toronto WCLC meeting in 2018, Adi promised me to come to Japan to give a lecture. That was our last conversation. The promise has been broken and I really miss him. Adi. Please rest in peace. There are many of your children all over the world who have inherited your spirit as a lung cancer researcher.

S02.05 THE IMPORTANCE OF ELUCIDATING GENOMIC EVENTS IS LUNG PREMALIGNANCY

K. Fong

The Prince Charles Hospital, Chermside/Australia

In contrast to the dramatic explosion of knowledge for cancer genomics such as trunk/branch; driver/passenger; intrinsic/acquired mutations from rapid technological developments, much work is still needed in the study of preneoplasia. Very sadly, lung cancer research around the world in 2018 lost a legend in preneoplasia research, Dr Adi Gazdar, who has either trained or worked with many of the scientists contributing to recent lung preneoplasia research. This is in addition to his enduring contributions establishing globally used lung cancer cell line resources and making lung cancer pathology discoveries. This research area owes much to pioneering work started over 20 years ago when Dr Gazdar, Dr John Minna and colleagues started thinking about preneoplastic molecular changes and field cancerisation (Smith, Hung et al. 1996, Yashima, Litzky et al. 1997). Subsequently, he and his former-post-doctoral Fellow Igancio Wistuba, another world renowned pathologist, summarised the main morphologic forms of preneoplastic lung lesions recognize then; squamous dysplasias, atypical adenomatous hyperplasia, and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, and highlighted different molecular pathways for adenocarcinoma: smoking-associated activation of RAS signaling, and nonsmoking-associated activation of EGFR signaling; the latter is detected in histologically normal respiratory epithelium (Wistuba and Gazdar 2006). It is clear that there has been steady progress in lung preneoplasia research, with the hope of translation to human benefit through prevention and/or early diagnosis. Many scientists in the field of lung preneoplasia have been influenced by the foundational work from Dr Adi Gazdar, scientist, pathologist, teacher and friend to many of us. The ability to diagnose pre- neoplasia at its earliest stages will help enable the development of novel diagnostic, prevention strategies and therapeutics during the process of carcinogenesis when clinical intervention could be curative; a laudable goal in lung cancer where most cancers are now clinically diagnosed in advanced stages.

S02.06 NEW DEVELOPMENTS IN SCLC AND NEUROENDOCRINE TUMORS

L. Byers

The University of Texas MD Anderson Cancer Center, Houston/United States of America

In an IASLC memorial earlier this year, Dr. Gazdar was very appropriately described as "a true giant in the field of lung cancer." Dr. Gazdar's profound impact on our field continues to be felt both in the clinic and at the bench. As a world-renowned molecular and clinical pathologist, he played a key role in setting the standards for classifying human lung cancers. As a scientist, he established ~400 human cancer cell lines. These included a large number of molecularly-annotated non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC) cell lines that have led to countless, practice-changing biological discoveries. As a founding-father of lung cancer research, he had a remarkable depth of knowledge in lung cancer biology and pathology. He shared his expertise through hundreds of publications. However, he also gave generously of himself (and his knowledge) to collaborators and mentees – serving as an advisor and teacher to almost everyone in the field who had the opportunity to be around him. Having contributed to key discoveries over five decades, Dr. Gazdar intuitively understood which new developments were likely to make the biggest impact and what questions we should be asking next. This was especially true for small cell lung cancer (SCLC) and other neuroendocrine tumors, where despite years of research there had been relatively few advances in the clinic. In a review published a year before his death, Dr. Gazdar and his co-authors shared their excitement for the recent worldwide resurgence of SCLC research – which they describe as "The Second Golden Age" of SCLC research.1 Several new developments in SCLC and neuroendocrine tumors have contributed to a better understanding of the disease and have shown promise for translational application. These include the discovery of (1) significant heterogeneity between patients with SCLC, (2) the plasticity of SCLC over time, (3) the role of intra-tumoral heterogeneity in metastasis and resistance, and (4) the identification of new therapeutic targets, immunotherapy approaches, and candidate biomarkers for SCLC. Going forward, opportunities and unmet needs in SCLC include enrolling patients onto clinical trials that can identify therapeutic vulnerabilities among specific SCLC subtypes; deeply profiling relapsed SCLC (through new models and patient specimen profiling); and extending our understanding of the immune microenvironment in SCLC. Given the pace and impact of recent discoveries in SCLC, it is no surprise that Dr. Gazdar and his co-authors concluded that "...while the past has been bleak, the future offers great promise." 1. Gazdar AF, Bunn PA, Minna JD. Small-cell lung cancer: what we know, what we need to know and the path forward. Nat Rev Cancer 2017;17:725-37.

YI01.01 PLANNING AN ACADEMIC CAREER IN LUNG CANCER

D. Gandara

UC Davis Comprehensive Cancer Center, Sacramento/United States of America

For those graduating from training in oncologist specialties worldwide in 2019, never have there been so many and such diverse opportunities, including Industry-related and Governmental positions. While the term "private practice" has specific connotations for oncologists in the USA that may no be applicable elsewhere in the world, the requisites for a career in academic medicine are uniform on a global basis. For example, it is often stated that that for clinical investigators a career in academic medicine is like a 3 legged stool, supported equally by clinical care, research and teaching. Some would add that administration is the fourth leg of an academic career, since it is often a significant component of time-spent. For those in a purely laboratory-based academic career, clinical care may be replaced by other activities. Assuming that you choose to be an academic physician with clinical care responsibilities, there are 3 broad categories of effort: clinical educator/administrator, clinical investigator and clinician-scientist. Making the decision on which career pathway to follow is often not easy, and may be influenced by your country of origin and associated opportunities and challenges for different specialties in oncology where you intend to work. In fact, changing the decision between academic and non-academic career pathways have never been easier. There are many examples today of oncologists moving back and forth between academics and industry, with equal success in both venues. This presentation will give a "personalized" approach to career planning taken from my own and other shared experiences. Since the ratio of pros/cons for academic medicine are largely applicable on an individual basis, this presentation mode will hopefully provide young investigators attending WCLC 2019 with personal insight and position them well for making this career-defining decision.

YI01.02 WHY TO BECOME A MEMBER OF THE IASLC

G. Scagliotti

University of Turin; San Luigi Gonzaga Hospital, Orbassano/Italy

Since the 1970s, the International Association for the Study of Lung Cancer (IASLC) has promoted research and education into all aspects of lung cancer and other thoracic malignancies, as well as encouraged worldwide cancer prevention efforts. According to its mission statement the International Association for the Study of Lung Cancer (IASLC) must embrace the study of the etiology, epidemiology, prevention, diagnosis, treatment and all other aspects of lung cancer and other thoracic malignancies; provide education and information about lung cancer and other thoracic malignancies to IASLC members, to the medical community at large, and to the public; use all available means to eliminate lung cancer and other thoracic malignancies as a health threat for the individual patient and throughout the world. In the last ten years those goals have been embraced by a growing number of members worldwide and now the association counts on approximately 7.000 members with a large portfolio of scientific and educational activities, being now IASLC the premiere society in the field of thoracic oncology. Beyond this bold statement the really question here is why me? While IASLC in the context of many other offers coming from other scientific organizations? The answer comes from one of our members "Being a member helped me in many, many ways. First coming to the IASLC World Conference on Lung Cancer. I was a resident and presenting in front of 100 people [....] that helped me secure my fellowship position. The IASLC helped me with great networking opportunities to interact with many members of the lung cancer community". That is really the key message. Inclusivity and multidisciplinary. The composition of our Board and committees reflect this sense of inclusivity. We want all the players in the thoracic oncology arena to have the appropriate voice, and the younger generation at the foremost. IASLC mentors and support younger people in the context of several activities within the organization. IASLC has a wide range of fellowships that support people to travel and present at meetings, to get involved in research, and more importantly to get a research grant to make your ideas a reality, and to meet people who can help you further in boosting your career. Our annual meeting is a reference meeting and every year the most relevant scientific research results have been constantly presented. The targeted therapy meeting held every year at the end of February in Santa Monica remains a unique forum of scientific exchange between researchers and pharma not paired by any other type of meeting throughout the world. Equally relevant are the regional meetings that are mainly educational but are also offering the opportunity to report about your own research. One of the main duties of a membership association is to provide value to its members, through high quality and relevant offerings and deeper, more efficient mechanisms for engagement. Creating a robust experience for IASLC members and honoring our commitment to geographic and discipline diversity is our goal The most challenging part for any scientific society is to understand the differences in generational needs. We need to identify the best new talents, the rising stars in our field, who will not only disrupt conventional thinking; they will lead the IASLC in the future. Specific actions will be considered and others are already in place to convince younger generations to see themselves in the IASLC mission. We want you joining us in the fight against tobacco, we want you to be the ambassadors of our organization for the present and, more importantly, the future of our patients with the ultimate goal to be part of a dream:the eradication of thoracic malignancies

Keywords: thoracic malignancies, fellowship, membership

YI01.03 MAKING THE MOST OF WCLC: A GUIDE FOR FIRST TIME ATTENDEES

H. Wakelee[1], B. Bunn[2]

[1]*Stanford University, Stanford/United States of America,* [2]*IASLC, Denver/United States of America*

Congratulations on making the decision to attend the International Association for the Study of Lung Cancer (IASLC) World Conference on Lung Cancer (WCLC)! This is the largest meeting in the world focused entirely on thoracic malignancies and is truly an international and multidisciplinary event. However, it is possible to get lost with so many concurrent sessions and in the sea of thousands of delegates. So having a game plan is critical. You will want to have a roadmap and plan for each day but also allow time for networking and to have some fun. With the virtual meeting available afterwards do not worry too much if you want to be in two places at once. You can be... "virtually." Check out the "First Time WCLC Attendees" tab on the IASLC WCLC2019 conference website for great guidance from Dr. Anne-Marie Baird. To paraphrase her: #1 Prepare #2 Attend the Young Investigators Symposium #3 Check out the Posters #4 Network #5 Engage with Social Media. These are all outstanding suggestions! To help you prepare be sure to look at the program in advance and get a sense of the conference center layout. Each morning there is a Plenary session highlighting key topics with talks given by world leaders. These can be amazing! The top abstracts of the meeting will be presented in the Presidential symposium on Monday morning Sept 9. The conference app (available a week or so before the start of WCLC2019) is a great way to keep track of everything. With so many concurrent sessions it will be important to have the info at your fingertips. There is a daily press conference that you can attend or review in the press and media section of the WCLC website. Highlights of the day (HOD) will be presented Mon Sept 9 and Tues Sept 10 from 10:30-12 of the conference and also included in emails and on the website. Checkout the daily newspaper (WCLC Daily News) for more highlights. Also you may want to follow everything that is happening on social media! IASLC

is active on: Twitter, Facebook, LinkedIn, YouTube, Instagram Important Hashtags for lung cancer #LungCancer, #CureMESO, #NSCLC, #SCLC, #CancerResearch, #Oncology, #clinicaltrials IASLC 2019 World Conference on Lung Cancer – Social Details: • Official Conference Hashtag: #WCLC19 • Official Hashtag of Lung Cancer Social Media Community: #LCSM The IASLC operates a social media booth at each WCLC for new users to learn about social media, get a tip-sheet and take photos with special branded backdrop (which is really fun)! As you look at the program you will see there is a great mix of education sessions, workshops and new data presentations. You will likely want to attend a mix of all of these. The education sessions may be a focus since those will include global experts summarizing particular topics and future predictions. It can be a bit tricky to understand the significance of some of the new data without knowing the background and the education sessions will help with that knowledge. It is also great to go to some of the mini-orals (MA) and oral (O) sessions to hear the latest research, particularly in your areas of interest. The mini-orals can be tricky as each one goes by fast so be ready! Again, plan in advance. As Dr. Baird points out, the poster/networking sessions are really wonderful. A lot of critical data that might not be as "flashy" is buried in the posters and you are likely to learn a lot. Even more importantly you will have a chance to network and find out who around the world is focusing in the same areas where you have interests. There are 2 poster sessions each day. The poster sessions are particularly great because you actually get to interact with people. If you see someone you want to talk to at the poster session do not be intimidated if they happen to be a "name" you have read multiple times in key papers. Everyone is excited to meet eager people working to help fight lung cancer! The importance of networking cannot be over-emphasized. Getting to know the field and others who share your passion for fighting lung cancer and other thoracic malignancies can make a tremendous impact on your future academic career. Branch out and meet people in other disciplines and from other parts of the world. Having a common interest in fighting lung cancer can lead to some strong connections and it is incredibly fun to attend future conferences knowing that you will get to connect with friends you met at your first IASLC WCLC. Important collaborations can also be started including international efforts. If you are still in training this networking time is also critical to your future job hunting! Remember to have FUN! Sign up and attend the IASLC social events. These involve good food, great music and sometimes dancing and most importantly a real opportunity to network. Saturday – Opening Ceremony and Welcome Reception Monday - IASLC Foundation Road to Hope gala Tuesday - Closing Ceremony After running around at the conference there will be times you just want to sit and relax. Fortunately there is an IASLC membership lounge in the exhibit hall open during exhibit hours. All members are invited to use the space for meetings, to sit for a few minutes, and to learn more about the IASLC and its committees. More details can be found here: https://wclc2019.iaslc.org/networking_opportunities/ Also, make some time before or after the conference to be a tourist in the local region. Most convention centers are fairly similar, but thinking about the last 3 IASLC WCLC conferences you can imagine how Yokohama, Toronto and Barcelona are all very different and fabulous places to explore. Enjoy your first IASLC WCLC and hopefully you will plan to make it an annual event!

YI01 FIRST TIME ATTENDEE SESSION
SATURDAY, SEPTEMBER 7, 2019 07:00–08:30

YI01.04 CONGRATULATIONS, YOUR ABSTRACT HAS BEEN ACCEPTED, AND NOW? - TIPS AND TRICKS TO PREPARE A PRESENTATION FOR WCLC

B. Solomon

Peter MacCallum Cancer Center, Melbourne/Australia

This presentation will provide a practical guide about how to prepare and deliver an effective and engaging presentation at WCLC. Tips and suggestions will be provided for oral presentations, miniorals, posters and E-posters.

YI02 CLINICAL TRIALS
SATURDAY, SEPTEMBER 7, 2019 09:00–10:30

YI02.02 BASKET AND UMBRELLA TRIAL DESIGNS IN ONCOLOGY

J. Menis

University of Padova, Istituto Oncologico Veneto (IOV), Padova/Italy

Cancer treatment has made gigantic improvements in patients' prognosis in multiple cancer types, by virtue of major steps forward in the concept of personalized medicine. This involves scientific progress in tumour biology, genomics technology, computational analysis and drug discovery that has propelled advances in both translational and clinical cancer research. In particular, rapid development, decreased cost, and increased availability of next-generation genomic sequencing and other methods for both molecular and, more recently, immunological tumor classification have changed the paradigm for understanding and treating cancer. Until recently, drug development has been conducted separately for different histological tumor types since the histological type was the primary known determinant of drug efficacy. However, this histology focus has been integrated by new knowledge on genomic alterations and immunological profile. Therefore, clinical trials have been evolving in parallel, from the traditional two-arm comparison of an experimental treatment vs. a control, to accelerate identification of promising therapies, to increase throughput and to allow for the increasing use of molecular and immunological classification of patients into smaller sub-groups. Also cost-efficiency need to be considered: classical phase I, II and III models for drug development require large resources, limiting the number of experimental agents that can be tested and making the evaluation of targeted agents inefficient. On the other hand, methodology and quality assurance need to be preserved since the validation of biomarkers is generally affected by several challenges, such as the multitude of assessment methods (i.e. immunohistochemistry, fluorescence in situ hybridisation, next-generation sequencing, etc.), reliability in terms of sensitivity and specificity, reproducibility of the test, feasibility of obtaining an adequate and representative tumour sample and, finally, the overall related costs. All these considerations, added to the strong collaboration with the regulatory agencies, approving novel agents based on data obtained from phase 1/2 trials, have led to an evolution in the design of early-stage clinical trials. The enrichment design can require many fewer patients, i.e. only those patients hypothesized to benefit, to be randomized relative to the "all comers" randomized design. The choice between an unselected versus enriched design should always be made also based on the existing level of evidence for the predictive biomarker. Two main enrichment strategies can be used to avoid over-treatment and save valuable resources, by matching the right drug to the right subgroup of patients. They can be defined as: basket trials and umbrella trials. Basket trials allow patients with multiple diseases and one or more target to be enrolled in cohorts or groups in one trial (the basket). They are often viewed as parallel phase II trials within the same entity, designed on the basis of a common denominator. Researchers are therefore allowed to separately analyse the patients' responses as each tumour type can be put in one cohort, and assess the impact of the drug on all of the patients as one group. If one group shows a good response, this group will be expanded to immediately assess whether others could benefit from the new therapy. If another group does not show evidence of effectiveness, this group may be closed and the other cohort can continue the recruitment. Basket trials can be further sub-classified in three groups: basket trials on one drug in several tumour types (1), basket trials on one drug for one molecular alteration in several tumour types (2), and basket trials on one drug in several molecular alterations in several tumour types. Umbrella trials are built on a centrally performed molecular portrait and molecularly selected cohorts with matched drugs, and can include patients' randomisation and strategy validation. In the umbrella design, a separate enrichment trial is conducted for each bio- marker stratum. The enrichment design for a given stratum uses as the test regimen a drug expected to be active for the alteration defining that stratum. Beyond new designs, new end-points and new evaluation techniques are also warranted to finally achieve methodology and clinical improvements, in particular within immunotherapy trials. As clinicians continuously learn from their patients, applying knowledge gained from one set of patients to their forthcoming patients, in adaptive designs, modifications of some aspects of the trial can be prospectively planned so that changes (''adaptations'') may take place while the study is ongoing (for example: a treatment arm or a subgroup of patients could be dropped; the trial size could be

increased, etc). Planning for such types of studies would allow to overcome the challenge related to the limited available information in the literature describing the targeted sub-populations. Alongside the growing complexity of these clinical trials, new frameworks for stronger and faster collaboration between all stakeholders in drug development, including academic institutions and frameworks, clinicians, pharma companies and regulatory agencies, has to be further encouraged. In the current era, the main goal should be to identify large and meaningful differences in small, molecularly and immunologically selected groups of patients and to develop rapidly new compounds. Basket and umbrella trials respond to the need of ''trials designed to learn'', that can evolve into ''trials designed to conclude''. Menis J, Hasan B, Besse B. YI02.03 STATISTICAL PITFALLS IN CLINICAL TRIAL DESIGN

U. Dafni

University of Lausanne, Athens/Greece

This topic will be discussed in the context of the following principles that clinical trials should adhere to. A *clinical trial* is an experiment testing medical treatments on human subjects. The process of evaluating medical treatment in humans starts with a Phase I clinical trial, followed by a Phase II and a Phase III trial towards regulatory approval. *Phase III* Phase III clinical trials are the gold standard for the evaluation of therapeutic interventions' efficacy. The goals of a Phase III clinical trial include minimization of random error, elimination of systematic error (bias) and ensuring the generalizability of study results. The clinical trial design is the methodology for achieving these goals. Randomization, always present in phase III trials, provides a treatment assignment that is independent of outcome and patient/disease features, thus balancing treatment groups on known and unknown factors associated with outcome. Further, the intention-to-treat (ITT) analysis approach is the gold standard for all phase III randomized, controlled clinical trials. It analyzes all patients in the treatment groups as randomized without regard to treatment actually received. The systematic error (Bias), which is any effect rendering the observed results not representative of the treatment effect, is addressed through randomization and corresponding ITT analysis. Minimization of random error is addressed through the use of adequately large sample size. *Phase II* Phase II clinical trials can be either randomized (screening, selection, randomized discontinuation designs) or non-randomized. The latter may be seriously misleading since the impact of prognostic factors is usually far larger than that of treatment, while known prognostic factors may explain little variance. Randomized phase II trials allow control of selection bias and simultaneous testing of several new treatments, combinations, doses etc. They are preferable than non-randomized trials (some degree of control is better than none!) but they could be misleading due to the small sample sizes. They cannot replace phase III trials. In Phase II trials, the objective is to select active drugs for further testing and document toxicity, but not to provide definite estimate of new drugs' efficacy, wh8ch is achieved only though a well-powered Phase III clinical trial. *Hypothesis Testing* In any experiment, two hypotheses covering all possible outcomes are pitted against each other. Only one of them can be true. The *alternative hypoth*esis is the statement we would like to prove, and the *null hypothesis,* the statement we would like to reject. The only possible conclusions in hypothesis testing are: 1. *Reject the Null Hypothesis*, and thus prove the desired alternative hypothesis (positive trial), or 2. *Not able to reject the null hypothesis* (negative trial). Any trial needs to be designed in such a way that it is known a-priori what the errors relative with each of the two possible conclusions will be. Rejecting the null wrongly (false positive result), is subject to *Type-I error (alpha)*, or *significance level*, while not rejecting the null hypothesis wrongly (false negative result), is subject to *Type-II error (beta)*. The *sample size* of the trial is decided at the design stage to guarantee that these two errors remain below pre-defined bounds. These bounds are usually 5% for Type-I error, and 20% for type II error. One more important design characteristic is *power*, which is equal to (1-beta) and it is the probability of correctly rejecting the null hypothesis (values usually set above 80%). *Superiority vs Equivalence/Non-inferiority* Clear distinction should be made between superiority and equivalence/non-inferiority Phase III trials, with each testing a different type of null hypothesis. In a superiority trial we aim to reject a null hypothesis of "*no effect*" or "*no difference*", while in an *equivalence* trial we aim to reject a null hypothesis of "*different effect*". More particularly, in a superiority trial we aim to demonstrate the superiority of a new therapy compared to an established therapy or placebo. In this case, the determination of the sample size takes into account the *clinical significance* (by how much the new therapy should be better than the established one), the *power* and the *significance level* of the test, as well as the magnitude of the variation of the corresponding measure of interest. In equivalence trials, the objective is to demonstrate that a new treatment is equivalent to a standard therapy with regards to a specific clinical end point, while it has an intrinsic benefit for other clinical end points, while in non-inferiority trials, to evaluate whether the new treatment is not inferior to or as effective as the standard therapy for a particular end point. In this case, a *tolerance and a non-inferiority margin* must be predefined, along with the *power* and the *significance level* of the test. Failure to reject the Null hypothesis should not be confused with acceptance of the Null hypothesis. *Subgroup Analysis* Another issue that should be taken into account in the design of a trial is subgroup analysis, involving multiplicity issues. It is common practice to perform multiple subgroup analyses, but the probability of a false positive finding (type-I error) increases as the number of subgroup analyses increases (*curse of multiplicity*). *Prognostic vs Predictive Marker* The correlation between a biomarker and a true clinical endpoint corresponds to a prognostic marker, but not to a predictive one. It is the statistically significant difference in treatment effect between the levels of the biomarker (treatment by group interaction), that characterizes a predictive biomarker.

Keywords: interpretation of negative results, non-randomized evidence, multiplicity issues

YI02 CLINICAL TRIALS
SATURDAY, SEPTEMBER 7, 2019 09:00–10:30

YI02.04 BIOINFORMATICS: THE BASICS

Y. Shyr

Vanderbilt University Medical Center, Nashville/United States of America

For physicians, advanced data science methods such as artificial intelligence (AI), machine learning and novel statistical methods are no longer just a headline in the news. Use of advanced data science methods are gaining acceptance in the field of medicine, as researchers push the limits of rapidly progressing technologies to assist in delivering excellence in health care. With the growth in use of advanced data science methods, however, we must bear in mind the limitations of these technologies. AI—specifically, machine learning (ML) of the deep-learning type—is only as good as the training dataset from which the algorithm learns. Deep learning in the clinical setting is most highly developed for image recognition; a training dataset for this purpose consists of a large number of case and control images. The algorithm then uses these images to teach itself how to differentiate, for example, malignant lesions from benign tumors or normal tissue. If the training dataset consists only of unambiguous cases and controls—rather than representing real-world variation and ambiguity—the algorithm will fail to function as desired with real-world patients. Thus, well-considered experimental design remains essential to realize the promise of deep learning. This talk will provide an overview of the state of the art in AI, machine learning, novel statistical methods, and deep learning algorithm for clinical application, including examples from the research literature as well as FDA-approved devices that use advanced data science

methods. We will then address the pitfalls of deep learning, including the need for clear and rigorous standards for regulatory approval of devices and software. We close with thoughts on the future of advanced data science methods in medicine.

YI02.05 PRINCIPLES TO GET YOUR PAPER PUBLISHED

A. Adjei

Mayo Clinic, Rochester/United States of America

How to get your Manuscript Published Alex A. Adjei, MD;PhD Mayo Clinic, Rochester, MN, USA Scientific publication is the backbone of academic research. Findings by investigators need to be disseminated to the community so that results can influence human health and well-being as well lay groundwork for future research. In spite of the central role of publishing in academic life described above, there are very few formal courses or seminars teaching academics, particularly physician scientists on how to publish their work. The table below outlines reasons for rejection of manuscripts, coming out of a survey of a number of journal editors Using information from this survey as a starting point, we will discuss the "fatal flaws" that lead to outright rejection of manuscripts, and outline strategies on how to write a manuscript of high impact, which is likely to be accepted for publication.

YI03 SCIENTIFIC MENTORING
SUNDAY, SEPTEMBER 8 10:30–12:00

YI03.01 WHY TO APPLY FOR INTERNATIONAL FELLOWSHIP?

C. Mascaux

Strasbourg University Hospital, Strasbourg/France

First of all, if you aim for an academic career, the international fellowship is a requirement in most countries. If you are not choosing an academic career, the international fellowship will be very useful anyway. This fellowship can be clinical, scientific or both, depending on your wish. Be aware of choosing an appropriate destination and team based on what you are looking for. Depending on the country where you trained and the country that you are choosing for your fellowship, you may or may not be fulfill the requirement for clinical practice. You must make sure that your salary will be funded and that your income is sufficient for leaving in the city of your fellowship. A fellowship needs to be planned several months in advance for the administrative preparation. Overall, international fellowship will be a uniquely rich experience. It will open new perspectives in your career. You will learn from the new team and modulate your clinical/scientific interpretations and your decisions. It will diversify your clinical/scientific interests, increase and diversify your knowledge and you expertise. The international fellowship will also allow you to built an international network and collaborations, and increase your visibility. In addition of being a very valuable professional experience, it will be a very rich personal challenge, from which you will enjoy and learn as well, by discovering and experiencing a different context of life, different culture and also perhaps a different language. Both for the professional and the personal side of your life, the international fellowship will open your mind and will be an unforgettable experience

Keywords: international fellowship, experience, requirement

YI03 SCIENTIFIC MENTORING
SUNDAY, SEPTEMBER 8 10:30–12:00

YI03.02 HOW TO APPLY FOR INTERNATIONAL FELLOWSHIP?

M. Tsao

Princess Margaret Cancer Centre, Toronto/Canada

International fellowship to pursue further training is an important part of career development for junior clinicians and investigators. International fellowship will not only increase the clinical and/or research skill of the fellow, it also offers an important opportunity to establish interaction network with senior investigators and peer young investigators across the world. When applying for international fellowship, several aspects should be considered: (1) choosing the field for further training, (2) application procedure, and (3) funding availability. The choice of field for further training will largely determine the future career of the candidate and should be in line with one's scientific or career passion and clinical/research interest. Prior experience with a role model and mentorship during earlier formative years usually has great influence on one's decision to pursue career choice. Fellowship training can be limited to clinical only, research only or combined clinical and research training; the latter for a candidate who wishes to pursue clinician-scientist career. Once a decision to pursue further training is made, the candidate should look for fellowship opportunities. This is often through discussion with local mentors or colleagues with prior international fellowship experience, or via familiarity with potential mentors who have published extensively in the area of candidate's interest or have lectured at international meetings. On-line searches for institutions with established fellowship program may also be useful, but many training programs may not be openly advertised, thus personal approaches and recommendations are often more fruitful. Writing an application letter that demonstrates strong background, qualification, prior track record, commitment and clear post-fellowship career pathway are key elements to win an opportunity for further interview. Availability of secured partial/full funding from local Institution or independent funding agency is a great asset for an application. While one year fellowship that involves only clinical training may be sufficient, training that involves laboratory research will usually require a minimum of 2 years tenure, as the latter usually requires more time to accomplish specific research projects. In such case, preliminary data obtained during first fellowship year may greatly contribute to applications for fellowship offered by international societies (e.g., IASLC, ASCO, AACR) or funding agencies.

Keywords: Training, career development, fellowship fund

SUNDAY, SEPTEMBER 8 10:30–12:00

YI03.03 SCIENTIFIC MENTORSHIP: WHAT SHOULD YOU EXPECT?

R. Rosell

Germans Trias i Pujol Science Institute, Badalona, Barcelona/Spain

Scientific Mentorship: What Should You Expect? I am honored to speak to young investigators on mentorship. Over several decades I have had the opportunity to serve as mentor of many clinical investigators, both local and worldwide. Throughout the years, most of my mentors have been involved in translational research and laboratory work, which, on many occasions, has resulted in fruitful research, culminating in theses and publications in relevant journals. One of the key points in assuming the responsibility of training is to work very closely, as friends, standing side by side, studying the relevant research project and its progress. There are several emotions among the mentor and young investigators. The mentor feels joy and delights in seeing the young investigators progress, converting in an overall happiness at the project accomplishment. The mentors joy comes once every young investigator achieves the main objective of his/her work in process. Transparency is the fuel of friendship between the mentor and young investigator. The mentor should be fully involved and open, in order to build a strong mentor/investigator relationship. The mentor must show emotional honesty, even if there is the possibility of someone taking advantage of his/her vulnerabilities. Unmasking oneself is the only means to building

successful scientific relationships. The mentor should apply an open policy of collaboration, assuming the young investigators could have an even greater capacity for research, than the mentor himself. Most of the time, this behavior will be a benefit for the investigators. There have been many examples of investigators contributing to important findings in a plethora of different research areas. Cancer biology was recognized as an important cancer field in the late 90's, and many investigators have made exciting contributions in tumors, such as, non-Hodgkin's lymphomas (Calvo et al JNCI 1998), gastric cancer (Wei et al JNCI 2011) and many others, culminating in salient publications in the field of lung cancer (Karachaliou et al JAMA Oncol 2015). The principal contributions will be included in the presentation.

Keywords: young investigators, mentorship

YI03 SCIENTIFIC MENTORING
SUNDAY, SEPTEMBER 8 10:30–12:00

YI03.04 ONCOLOGY FELLOWS' CAREER PLANS AND EXPECTATIONS

M. Ito

Institute for Health Science Research Germans Trias i Pujol (IGTP), Badalona/Spain

I will discuss how I planned my fellow career and tips for achieving based on my own experience. My own career is short, at around 10 years, but I would be glad if my presentation could be of some service to fellows in the same position. If you want to achieve something different than your current situation for your own career, then you gain qualifications, earn achievements such as publishing papers, participate in the academic community, or organize projects, but it is difficult to decide on the ultimate goal at an early stage. For young fellows to build a career, the process is more crucial than setting the outcome, therefore it is essential to know oneself, in addition to learning the latest information on thoracic oncology. Read articles, participate in academic conferences and train at other facilities as a means of understanding your own knowledge and competencies, rather than simply as a means of learning about thoracic oncology. Although training at special facility will provide the smallest amount of information about thoracic oncology at one time, I believe it is the most efficient means of learning about oneself. This type of learning enables you to directly and simultaneously understand your disadvantages, advantages and characteristics. I have worked and researched at several hospitals and research institutes both in Japan and overseas. I made use of the scholarship system in the past to conduct clinical training in Spain, which enabled me to gain a wealth of clinical experience that I would not have been able to experience in Japan. I am currently affiliated with a research institute in Barcelona and have been involved in research there since 2017 under world-renowned supervisors. I contribute to joint research between Japan and Spain, and Spain and the US, and this, among other opportunities, has enabled me to learn a great deal at my current facility. This experience has not only strengthened my resolve about the new goals I want to achieve, it has also made me fully aware of areas where I am lacking. For the training at a special facility, getting the grant is crucial. I have received some grant support from several academic associations including IASLC. The financial supports allowed me to gain and achieve ambitious aims. Through the project, I have been inspired and it brought me new ambitions. Although there are more and more opportunities of the grant in these days, winning is getting more competitive. Fortunately, I could receive grant support several times. However, I failed many times to get the support. To get the grant, I will show tips based on my own experience at my presentation. If training at a special facility or getting the grant is difficult, I recommend continuing to participate at international conferences. This is also particularly important for learning the latest information about thoracic oncology. I have participated 13 times in international conferences to date, and have participated in the World Conference on Lung Cancer (WCLC) since the 13th congress held in 2009. I strongly recommend checking all the abstracts before attending the conference, preparing questions and discussing matters with as many people as possible during the conference. WCLC has research in all fields related to thoracic oncology, so it is relatively easy to make new acquaintances and partnership in your own field of research or interest. In this instance also, it is important to make presentations and receive as much input as possible, to clarify areas where you may be lacking and you have advantage, thus using this opportunity as efficiently as you can. Attending congress also gives you chances to get informed the grant opportunity and which facility is attractive for you to make training. In summary, it is not easy to make decisions about your career, and often we are unaware when we are at a turning point. No one knows the correct answer. Building a career involves not only your own intentions, but also your situation and funds. The important thing is to focus on the quality of the process to ensure that you do not waste time, and to always be aware of your own strengths and weaknesses, and using or supplementing these characteristics to discover what you want to achieve and what you can achieve in your career. Training at a special facility and keeping to join academic congress clearly enhance our academic career. It will give you new confidence to find or continue on your mission for thoracic oncology.

YI04 BASICS OF IMMUNOLOGY
SUNDAY, SEPTEMBER 8 13:30–15:00

YI04.02 IMMUNO-ONCOLOGY TRIALS: OTHER ENDPOINTS NEEDED?

M. Reck

Lung Clinic Grosshansdorf, Grosshansdorf/Germany

The implementation of immunotherapies has completely changed and improved management of patients with non-small-cell lung cancer (NSCLC). In contrast to cytotoxic agents and targeted therapies immunotherapies do not directly affect the tumor but lead to an indirect reactivation of T-cell mediated immune reaction. Therefore different endpoints may be required for an appropriate assessment of efficacy of these novel compounds. In various trials it could be demonstrated that in contrast to conventional anti tumor therapies, which show an impact on early overall survival (OS), immunotherapies seem to impact the long term survival rates, leading to a phenomenon, which is characterized as „plateau of long term survival". In contrast other conventional markers of efficacy like response rate (RR) or progression free survival (PFS) do not appear as the best endpoints to reflect the complete efficacy of immunotherapies at least not in biomarker unselected populations. In a number of randomized phase 3 trials in untreated as well as pretreated patients no significant differences in PFS were shown despite the fact that these trials demonstrated a clear survival benefit in favour of the immunotherapies or immunotherapy combinations. In addition exploratory analyses revealed a survival benefit even in patients, who received immunotherapies beyond progression suggesting that indeed response and PFS may be suboptimal endpoints. Reflecting these experiences clearly new statistical approaches are needed to focus on OS as probably the most relevant endpoint and to provide the opportunity to capture the late impact of immunotherapies on OS with the prolongation of long-term survival in an adequate way. Currently the first modifications of conventional statistical models are in development evaluating for example the model of disproportional hazard ratios and others in upcoming trials. Another significant problem is the appearance of „crossing" Kaplan Meier curves, which has frequently been observed in trials with immunotherapy combinations. These curves suggest, that there are different subpopulations with different sensitivities toward the novel treatments represented. Reflecting the lack of valid predictive biomarkers, which are able to separate the different subgroups, innovative statistical models are needed to define and to describe the benefitting populations. Lastly the „explosion" of numerous clinical trials investigating novel immunotherapy combinations will require a modification of our traditional endpoints. Given the number of novel agents and the speed of development it won´t be feasible to conduct individual signal generating phase II trials for each of these agents. New models of platform trials with a new model of statistical assessment are required to provide the opportunity to investigate multiple combinations in one trial and to provide the flexibility to add novel combinations, which just may have been developed to ongoing protocols. In summary immunotherapies have substantially contributed to therapeutic improvements in NSCLC, but they are requesting a change of our conventional consideration of efficacy. Besides all endpoints of objective efficacy it will be of paramount importance that future endpoints also cover patient relevant endpoints like tolerability, improvement of quality of life or duration of symptom control.

YI04 BASICS OF IMMUNOLOGY
SUNDAY, SEPTEMBER 8 13:30–15:00

YI04.03 THE PLACE OF IMMUNOTHERAPY IN NSCLC THERAPEUTIC ALGORYTHM

R. Stahel

University Hospital Zurich, Zurich/Switzerland

Place of immunotherapy in the NSCLC treatment algorithm Therapy with immune checkpoint inhibitors has entered standard of care for patients with metastatic NSCLC. Data from extended phase I studies are available on the long-term effect of single agent immune checkpoint inhibition in later line. These studies demonstrate a 16% 5-year survival for nivolumab and pembrolizumab in pretreated patients (1), the impact of PD-L1 expression on long term outcome (2) and the importance of obtaining an objective response (3). Nivolumab and pembrolizumab, both PD-1 directed antibodies and atezolizumab, a PD-L1 directed antibody all have been approved for second or later line therapy based on comparative studies with docetaxel monotherapy demonstrating superior survival and an improved toxicity profile. However, results of recent studies in first line treatment have led to a rapid adoption of immune checkpoint inhibition upfront. This started with the results of the KEYNOTE-024 study demonstrating survival benefit of single agent pembrolizumab over platin-based combination therapy for patients with advanced NSCLC with a tumor proportion score of 50% or higher (4). With these results, PD-L1 testing has entered clinical routine. A series of clinical trials examined the survival impact of adding immune checkpoint inhibition to standard platin-based chemotherapy. Based on these results pembrolizumab added to platin-based chemotherapy, carboplatin and pemetrexed in non-squamous NSCLC (KEYNOTE,-189), carboplatin-paclitaxel or nab-paclitaxel in squamous NSCLC (KEYNOTE-407) (5,6), or alternatively atezolizumab combined with bevacizumab, carboplatin and paclitaxel (IMpower150) or with carboplatin and nab-paclitaxel (Impower130) for non-squamous NSCLC (7,8) have become standard of care, independent of the expression of PD-L1 in tumor tissues. The results of these t and additional trials in first line metastatic NSCLC have been summarized recently (9). Obviously, important questions remain to be answered. One open question regards the upfront treatment of patients with tumors having a strong PD-L1 expression. Lacking randomized data the debate remains open whether pembrolizumab alone or its combination with platin-based chemotherapy would ultimately be the best option. The KEYNOTE-042 trial compared pembrolizumab with platin-based chemotherapy in patients with tumors with at least 1% PD-L1 expression. The trial was positive for pembrolizumab, however the analysis of patient subgroups according to PD-L1 expression suggests the benefit to be mostly derived from patients with strongly expressing tumors and thus these results might only marginally impact clinical practice. A second open question regards the optimal selection of patients which could be spared from upfront treatment with chemotherapy and could benefit from single agent immune checkpoint or combined PD-+/PD-L1 and CTLA4 inhibition. Two trials examining the role of nivolumab in first line treatment (CHECKMATE-026 and CHECKMATE-227) demonstrated that a high tumor mutation burden is predictive for a better response to immune checkpoint inhibition. The later trial (10) and the analysis subgroups of the MYSTIC trial are in support of the hypothesis of potential superior effects of combining PD-1/PD-L1 inhibition with CTLA4 inhibition for patients with a high tumor mutation burden, measured directly in tumor tissue or indirectly on circulating tumor DNA, however, formal prove from prospective trials is pending. It is important to note that with the exception of IMpower150 and Impower130, all other trials excluded patients with known EGFR and ALK mutations, the main reason being the relative lack of efficacy of second line immune checkpoint inhibition in these patients. The benefit in progression-free survival and overall survival seen in patients with EGFR mutated tumors when treated with the atezolizumab bevacizumab quadruplicate, but not with the atezolizumab triplicate lends support for the use of the quadruplicate regimen for patients with EGFR mutated tumors failing tyrosine kinases. YI04 BASICS OF IMMUNOLOGY
SUNDAY, SEPTEMBER 8 13:30–15:00

YI04.04 HOW TO SELECT PATIENTS FOR IMMUNOTHERAPY

N. Rizvi

Columbia University Medical Center, New York/United States of America

With the wide application of immune checkpoint blockade in the treatment of cancer, biomarkers may determine the line of therapy immunotherapy may be administered or when to combine with other agents. Patient selection on clinical characteristics and co-morbidities also need to be incorporated into treatment decision making. An overview of patient characteristics and external influencing factors will be provided in this review including more complicated scenarios such as patients with co-existing autoimmune disease or solid tumor transplant populations.

Workshops

WS02 MESOTHELIOMA WORKSHOP (TICKETED SESSION)
SATURDAY, SEPTEMBER 7, 2019 08:00–11:30

WS02.02 PATHOLOGY SECTION I: SYNOPSIS EURACAN/IASLC

A. Nicholson

Royal Brompton and Harefield NHS Foundation Trust, London/United Kingdom

Whilst molecular and immunologic breakthroughs have transformed the management of lung cancers, changes have not been as marked for malignant pleural mesothelioma. Therefore, in 2018, a multidisciplinary group (pathologists, molecular biologists, surgeons, radiologists and oncologists), sponsored by EURACAN/IASLC, met in order to critically review the current classification, in which pathologic diagnosis has hitherto been essentially limited to three histologic subtypes.1 Subsequent recommendations in relation to pathology classification were firstly to include architectural patterns, and stromal and cytologic features that refine prognostication. Second, subject to data accrual, malignant mesothelioma in situ could be an additional category. Third, grading of epithelioid MPMs should be routinely undertaken, 2 Fourth, other prognostically relevant histologic characteristics should be routinely reported. Clinically relevant molecular data such as PD-L1, BAP1, *CDKN2A*) should be incorporated into reports, if undertaken and other molecular data accrued as part of future trials. Resection specimens (i.e. extended pleurectomy/decortication and extrapleural pneumonectomy) should be pathologically staged with smaller specimens being clinically staged. When surgical biopsies are taken, at least 3 separate areas should be sampled from the pleural cavity, if feasible. Image-acquisition protocols/imaging terminology should be standardized to aid research/refine clinical staging. Multidisciplinary tumor boards should include pathologists to ensure appropriate treatment options are considered and all histologic subtypes should be considered potential candidates for chemotherapy and first line clinical trials unless there is a compelling reason. WS02 MESOTHELIOMA WORKSHOP (TICKETED SESSION)
SATURDAY, SEPTEMBER 7, 2019 08:00–11:30

WS02.04 MOLECULAR SECTION

L. Fernandez-Cuesta

International Agency for Research on Cancer (IARC-WHO), Lyon/France

Molecular and immunologic breakthroughs are transforming the management of thoracic cancer, although advances have not been as marked for malignant pleural mesothelioma (MPM) where pathologic diagnosis has been essentially limited to three histologic subtypes. A multidisciplinary group (pathologists, molecular biologists, surgeons, radiologists and oncologists), sponsored by EURACAN/IASLC met in 2018, to critically review the current classification. Multidisciplinary recommendations for pathology classification and application were made, which will allow more informative pathologic reporting and potential risk stratification, to support clinical practice, research investigation and clinical trials. I will present the main points of the discussion around the use of molecular characteristics to inform and improve the current histopathological classification.

WS03 ITONF WORKSHOP: BRIDGING THE GAPS IN THORACIC ONCOLOGY NURSING - A GLOBAL PERSPECTIVE
(SIGN UP REQUIRED)

WS03.08 PANEL - EMERGING THERAPIES - IMMUNOTHERAPY

R. Thomas

Guy's and St Thomas' NHS Trust, London/United Kingdom

This panel session will focus on emerging immunotherapies, the aim is to bring the UK perspective to the panel particularly focusing on the role of the Lung Cancer Clinical Nurse Specialist (CNS) and how to support and counsel patients who are about to commence one of the new therapy combinations. The presentation from the UK will look at the current therapies in immunotherapy and then also look at two case studies which will bring the clinical trial data into real time perspective. In the UK there have been no new immunotherapies launched, however, what the landscape of immunotherapies is changing in the UK for non-small cell lung cancer patients in the form of multi-drug combinations. Most recently we have seen the introduction of Durvalumab as a treatment for locally advanced unresectable non-small cell lung cancer post platinum based chemoradiation (1). This combination is still awaiting formal NICE approval but NHS patients can access this via a Cancer Drugs Fund. The PACIFIC Trial demonstrated that patients who received Durvalumab after platinum based chemoradiation had a significant improvement in their progression free survival when compared to chemoradiation plus a placebo. The median duration of progression free survival was 17.2 months in the Durvalumab arm compared to 5.6 months in the placebo arm. The median time to death or distant metastases was 28.3 months in the Durvalumab arm compared to 16.2 months in the placebo arm (2). In the advanced metastatic setting there has recently been the introduction of the KEYNOTE-189 data which is looking at pembrolizamab + platinum/pemetrexed in patients who did not have any molecular mutations. This trial demonstrated an overall survival with a 51% reduction in the risk of death and superior progression free with a 48% reduction in the risk of progression or death. In March 2019 The IMpower150 trial showed significant improvements in progression-free and overall survival with atezolizumab plus bevacizumab plus carboplatin plus paclitaxel (ABCP) versus the standard-of-care bevacizumab plus carboplatin plus paclitaxel (BCP) in chemotherapy-naive patients with non-squamous metastatic non-small-cell lung cancer who have an ALK rearrangement or who have an EGFR mutation. This combination has now been approved by NICE and will provide patients who progress on a tyrosine kinase inhibitor a multi-drug treatment combination which has been demonstrated in the Impower 150 trial to deliver overall survival of around 19.2 months when compared to bevacizumab/carboplatin and paclitaxel. The UK has demonstrated the importance of the input of the Lung Cancer CNS in supporting patients who are about to commence treatment and also in proactively monitoring patients for potential adverse events (3). However, with the emergence of multidrug treatments how do we as Lung Cancer CNS's assess which adverse events are related to the immunotherapy and which are related to the chemotherapy. Looking at the current clinical trial data from the studies above and then focusing on two real life patient case studies will provide some clear guidance on how to support patients whilst monitoring for any potential adverse events and dealing with these in a timely and accurate manner. The table below sets out just some of the main challenges faced in identifying immunotherapy related adverse events.

We as nurse specialists are now experienced at caring for patients on single agent immunotherapy treatments but one of the many challenges is that many lung cancer patients will have co-morbidities which can cloud the identification of immunotherapy adverse events. For example 40-70% of lung cancer patients will also have a diagnosis of COPD. Pneumonitis can present in a very similar pattern to organising pneumonia and chest infections meaning that accurate and detailed assessments are needed to ensure adverse events are identified and treated accordingly. However, when you also add into the treatment plan platinum doublet chemotherapy with or without radiotherapy the potential for adverse events increases, the panel will look at the PACIFIC data to assess the reporting of adverse events in this patient group. The panel will also then assess the trial data for platimum doublet chemotherapy and immunotherapy in the treatment of metastatic non-small cell lung cancer and whether this patient group with a potentially higher symptom burden reported an increase in the number of adverse events when compared to either single agent immunotherapy or platinum doublet chemotherapy alone. One other important focus of the panel discussion will be to look at what the future treatment landscape for patients may be and how this will impact on progression free survival and living with lung cancer. This will mainly cover recent updates from ASCO and will aim to provide a flavour of what we may see coming into clinical practice in the coming months. WS04 STAGING WORKSHOP PART 1: IASLC DATABASE CHALLENGES AND APPLICATION
MONDAY, SEPTEMBER 9 14:00–15:30

WS04.01 CHALLENGES OF DATA ENTRY IN IASLC DATABASE

B. Fournier

IUCPQ-Laval University, Quebec/Canada

Session Staging Workshop Part 1: IASLC Database Challenges and Application. Our experience with the registry of the patients at IUCPQ- University Laval Quebec From 2015, IASLC submitted to the Union for International Cancer Control (UICC) & to the American Joint Committee on Cancer (AJCC) recommendations for the 8th Edition for the Staging of Lung Cancer. Those recommendations issued from a retrospective data collection of patients (94,708) diagnosed with lung cancer around the world between 1999 and 2010 were accepted by UICC and AJCC in 2017.1-2-3 Since the Staging and Prognostic Factors Committee of IASLC has entered in the next phase of the project designed to inform the 9th forthcoming TNM edition. Volunteer site participants were invited to submit data on patients diagnosed with lung cancer between January 1, 2011, and December 31, 2019.4 IUCPQ has officially started the collaboration to the Lung Cancer Staging Project in June 2018. So far, we have entered over 1 000 patients in the database. Accesses to Patients' Medical Chart and to the Electronic Data Base (EDB) are the main tools used to participate to this project. Our growing experience at IUCPQ with IASLC database demonstrates that a strategy to access medical charts, a multidisciplinary team work and constant review of the data are key points to ensure the quality of the data collection. This presentation will describe our experience with the registry of the patients in the Electronic Data Capture system. 1 Rami-Porta, R., Bolejack, V., Crowley, J., Ball, D., Kim, J., Lyons, G. et al. WS04 STAGING WORKSHOP PART 1: IASLC DATABASE CHALLENGES AND APPLICATION
MONDAY, SEPTEMBER 9 14:00–15:30

WS04.02 CHALLENGES IN IMAGING EVALUATION TO ENTER DATA IN THE IASLC DATABASE

H. Prosch

Medical University of Vienna, Vienna/Austria

Soon after the publication of the proposals for the 8thedition of the TNM staging system, the International Association for the Study of Lung Cancer (IASLC) opened a new database for data collection for the next iteration of the lung cancer staging system (1). The database contains more than 450 fields, which address data on patient characteristics, baseline laboratory values, as well as the results of pulmonary function, imaging, and pathological tests. As the database collects the data about lung cancer newly diagnosed between January 1, 2011, and December 31, 2019, the data entered might be predominantly retrospectively collected in some centers. From an imaging perspective, this might lead to a number of problems. First, at least some of the elements required by the database might not be mentioned in the radiological reports. This may necessitate a re-evaluation of the imaging studies by an experienced radiologist, which might not be possible in all centers. Furthermore, the levels of training of the radiologists and reporting across different countries may be variable and thus introduce some degree of imprecision into the quality of the data. As an example, in T staging, particular attention has to be paid to thorough measurements to ensure that the largest diameter in the axial, coronal, or sagittal plane is measured (2). Caution should also be taken not to overdiagnose additional pulmonary nodules as metastases. In N staging, particular attention has to be paid to the lymph node atlas-mining, particularly the well-known pitfall in the correct assignment of lymph nodes at levels 4 and 10 (3-5). Furthermore, the quality of imaging and the availability of more advanced/expensive imaging techniques may also vary from country to country. As an example, the availabilities of PET/CT and/or MRI are not homogenous all over the globe. However, if PET/CT is not performed routinely in operable patients, as many as 20% of unexpected distant metastases might be missed (6). Future staging projects should specifically address these issues in order to further improve the the quality of data necessary to improve the next iteration of the staging system. 1. WS04 STAGING WORKSHOP PART 1: IASLC DATABASE CHALLENGES AND APPLICATION
MONDAY, SEPTEMBER 9 14:00–15:30

WS04.03 HOW TO ADJUST PATHOLOGY EVALUATION ACCORDING TO IASLC DATABASE

P. Joubert

Quebec Heart and Lung Institute, Quebec/Canada

In 2016 the 8th edition of the TNM by the International Association for the Study of Lung Cancer (IASLC) refined the definition of early-stage lung cancer by further subdividing the T1 and T2 descriptors according to 1 cm size cut-offs. In addition, in nonmucinous adenocarcinoma (AC) with a lepidic component only the size of the invasive component defines the T descriptor rather than the total size of the lesion. These modifications not only led to a better prognostication of surgical adenocarcinoma patients, but they also emphasize the importance to accurately assess (grossly and microscopically) and report the histological patterns of adenocarcinoma. In addition, although the number of metastatic lymph nodes was not integrated in the N descriptor, its relevance has been demonstrated and will be addressed in the upcoming edition. The purpose of this presentation is to review the key elements of a pathology report when evaluating a pulmonary carcinoma, and to discuss the challenges encountered in pathology for the development of the upcoming edition of the TNM.

WS04 STAGING WORKSHOP PART 1: IASLC DATABASE CHALLENGES AND APPLICATION
MONDAY, SEPTEMBER 9 14:00–15:30

WS04.04 INSTITUTIONAL BENEFITS OF ADHERENCE TO IASLC DATABASE

C. Labbe

IUCPQ, Quebec/Canada

The International Association for the Study of Lung Cancer (IASLC) Lung Cancer Staging Project, through an electronic data capture system, is a global effort to study and improve the current and future lung cancer staging system. In 2016, the 8thedition of the TNM was developed with the participation of 35 centres from 16 countries. In 2018, the Heart and Lung Institute in Quebec City, Canada, started to collect and send data for the upcoming 9thedition of the TNM classification. The purpose of this presentation is to review and discuss the potential institutional benefits of adherence to the IASLC electronic database, namely the comprehension by all participating centers of the role and the importance of the database, the organization of an interdisciplinary group to ensure that the entire clinical pathway of lung cancer patients is evidence-based, the standardisation of radiology and pathology reports, and the improvement in rates of lobe-specific systematic nodal dissection for all lung resections.

WS04 STAGING WORKSHOP PART 1: IASLC DATABASE CHALLENGES AND APPLICATION
MONDAY, SEPTEMBER 9 14:00–15:30

WS04.05 DEVELOPING THE IASLC LUNG CANCER STAGING DATABASE AND RECOMMENDATIONS FOR THE 9TH EDITION

D. Giroux[1], H. Asamura[2], P. Ugalde[3]

[1]*Cancer Research And Biostatistics (CRAB), Seattle/United States of America,* [2]*Keio University School of Medicine, Tokyo/Japan,* [3]*Institut Universitaire de Cardiologie et Pneumologie de Quebec, Quebec/Canada*

Background Since the turn of the century, the international database of the IASLC Staging Project has served as the foundation for evidence-based recommendations for revisions to the TNM classification system for lung cancer. These recommendations were adopted by the Union for International Cancer Control (UICC) and the American Joint Committee on Cancer (AJCC), establishing the IASLC Staging Project as a global resource for lung cancer staging research. The project is currently midway through its third iteration of data collection, which was begun in 2017 and includes lung cancer cases diagnosed from 2011 through 2019, with follow-up for survival through 2021. The preferred mechanism for data collection is direct, online entry into a central database administered by Cancer Research and Biostatistics (CRAB) in Seattle, Washington. Discussion The data fields in the lung cancer database are extensive, having been revised in 20171 by the IASLC Staging and Prognostic Factors Committee (SPFC) to address specific research questions framed by each of its 15 subcommittees, such as the impact of direct extension into specific anatomic sites on survival, the relative effects of location vs size of involved nodes, or the importance of the size of distant metastases relative to the number of lesions and distant sites. The committee will consider the prognostic value of these anatomic parameters independently and in the context of non-anatomic factors such as sex, comorbidity, laboratory values that correlate with survival, or molecular markers. Existing institutional databases and large registries have traditionally been used to supplement the data contributed using the online system; however, these external sources rarely contain sufficient detail to address all of the committee's stated objectives.2 The SPFC is chaired by Hisao Asamura, MD, and has separate subcommittees for T, N, M, ground glass opacities and adenocarcinoma in situ, neuroendocrine tumors, stage groupings, lymph node chart, validation and methodology, prognostic factors, R factor (completeness of resection), radiology and imaging, multiple pulmonary nodules, molecular markers, and data quality, as well as a steering committee that provides oversight. SPFC members are expected to demonstrate leadership and promote participation in the project, as well as develop and evaluate proposals for change. The current SPFC membership reflects the diverse geographic representation in the database used to support the most recent (8th edition) recommendations. As of 5 June 2019, over 3,000 patients from 14 countries have been enrolled directly in the online system. Larger databases designed to be compatible with the project have also been transferred from Japan and the United States. In the newly redesigned IASLC web site (www.iaslc.org), new participants can sign up online to contribute data by choosing the IASLC Staging Project page under the Research & Education heading. Following the publication of the core recommendations for the 9th edition of TNM, the web site may also be used to submit research proposals for secondary use of the data. Secondary use may be restricted according to agreements with individual sites in some cases. All proposals will be reviewed by the steering committee according to published guidelines.3 Conclusion In the context of shifting paradigms and rapid advancements in treatments, diagnostics, and molecular technologies, the SPFC is tasked with evaluating and improving TNM staging on a global scale. To this end, we aim to engage a wide variety of research partners and to increase participation in previously underrepresented regions such as Egypt and India, where the first sites from each of these countries have recently been recruited. The collection of a large and comprehensive database will be pivotal to the SPFC's ability to provide data-informed, universally applicable, and balanced recommendations that will be used world-wide by physicians, researchers, and patients. As we continue to prepare for upcoming analysis of the 9th edition database, the IASLC membership is encouraged to participate through the contribution of data and engagement with the SPFC and its mission. This global effort to improve the TNM staging criteria presents a unique opportunity to collaborate in international public health research. References Giroux DJ, Schil PV, Asamura H, et al. WS04.06 CASE DISCUSSION

P. Ugalde[1,2]

[1]*Institut Universitaire de Cardiologie et Pneumologie de Québec, Québec/ Canada,* [2]*Institut Universitaire de Cardiologie et Pneumologie de Quebec, Quebec/Canada*

In this presentation we will present how we access a Patient Medical Record to include a case in the IASLC database. Through a precise strategy we collect patient's data and include in the Electronic Data Base.

WS05 STAGING WORKSHOP PART 2: THE IMPORTANCE OF INVASIVE NODAL STAGING IN THORACIC MALIGNANCIES
MONDAY, SEPTEMBER 9 15:45–17:15

WS05.01 INVASIVE PRE-OPERATIVE STAGING OF LUNG CANCER

S. Call

Hospital Universitari MútuaTerrassa, Terrassa/Spain

Although reliable mediastinal staging is essential for the management of NSCLC, the optimal approach to invasive mediastinal staging remains controversial. According on the current guidelines, preoperative invasive mediastinal staging can be omitted if all the following criteria apply: a) primary tumour located in the outer third of the lung; b) largest diameter of the tumour is ≤3 cm; c) absence of intrathoracic lymph node(s) on CT and PET (1,2). The rationale is that, in this situation, the rate of unsuspected pathologic mediastinal nodal disease is < 10% (3,4). When tumours are classified as clinical (c) N2-3 on PET-CT, the risk of mediastinal nodal involvement is at least 60% (1). In this situation, it is mandatory to pathologically confirm all abnormalities detected by CT or PET starting with an endosonography method (EBUS-FNA, EUS-FNA or their combination) and to reserve mediastinoscopy to validate their negative results (1,2). Regarding those tumours with an intermediate risk of N2-3 disease (and normal mediastinum by CT and PET) the rate of unsuspected N2 disease is: 20%-42%, for tumours classified as cN1, and 6%- 22.2% for tumours classified as cN0 and tumour size greater than 3cm (5-8). For these clinical scenarios, there is a little disagreement between American and European guidelines about the best staging procedure to start with. The American College of Chest Physicians (ACCP) guidelines suggest endosonography methods over surgical procedures (1), and the European Society of Thoracic Surgeons (ESTS) guidelines describe that the choice between mediastinoscopy with biopsies, or with pre-surgical lymphadenectomies or endoscopic staging by EBUS/EUS with FNA depends on local expertise (1,2). Regarding the accuracy of invasive mediastinal staging methods in this type of patients (clinical N0 disease by PET-CT), minimally invasive endoscopic techniques have a poor sensitivity (0.17-0.41) (5,9). On the other hand, due to the fact that performance of mediastinoscopy is investigator dependent, there is an important heterogeneity in the reported sensitivity and negative predictive values:0.32 to 0.97 and 0.8 to 0.99, respectively (2). Transcervical lymphadenectomies (video-assisted mediastinoscopic lymphadenectomy[VAMLA] and transcervical extended mediastinal lymphadenectomy[TEMLA]) are the only pre-surgical staging procedures with the highest sensitivity and negative predictive value reported to date for those patients with normal mediastinum by PET and CT: 0.88-0.96 and 0.94-0.99, respectively (8-10). Focusing oncN1 tumors, endosonography methods have a reported sensitivity ranging from 0.38 to 0.43. (5,6). This sensitivity increased to 0.73 by adding a confirmatory mediastinoscopy to validate negative endosonographies (6). Based on the results from the first prospective multicentre study (ASTER III) to evaluate the performance of surgical mediastinal staging (by mediastinoscopy or by VAMLA) in patients with cN1, the superiority of surgical method was confirmed obtaining a global sensitivity of 0.73 and a negative predictive value of 0.92 (7). Regarding those tumours with high SUVmax, cN0 but size greater than 3cm and specially in adenocarcinomas the rate of unsuspected N2 is: 6%-14.8% (3,4). A recent prospective study to validate the feasibility and accuracy of VAMLA reported a rate of 22.2% of unsuspected N2 disease for cN0 tumour >3cm (19% N2 tumours and 3,2% N3 tumours) (8). Therefore, based on this results, it is recommendable to validate negative results of endosonographies with a surgical procedure in the same line of those patients with tumours classified as cN1. *Conclusions* Currently, surgical methods are mainly indicated to validate negative results of minimally invasive endoscopic techniques for those tumours with high suspicion of mediastinal involvement by PET-CT. Based on the latest evidence, mediastinoscopy and, especially, transcervical lymphadenectomies are the most reliable staging methods for the subgroup of patients with intermediate risk of N2 disease and normal mediastinum by PET and CT. Consequently, future staging algorithms should recommend surgical methods as the preferred technique for this subset of patients. *References* 1. De Leyn P, Dooms C, Kuzdzal J, et al. WS05.03 HOW TO PERFORM A PROPER SYSTEMATIC NODAL DISSECTION IN LUNG CANCER SURGERY

K. Masai[1], K. Kaseda[1], K. Asakura[1], T. Hishida[1], H. Asamura[2]

[1]*Keio University School of Medicine, Tokyo/Japan,* [2]*Division of Thoracic Surgery, Department of Surgery, Keio University School of Medicine, Tokyo/ Japan*

In 1960, Cahan first reported lobectomy with regional lymph node dissection, which was called "radical lobectomy."1 Since then, this procedure has been widely accepted, and systematic nodal dissection (SND) is an internationally accepted standard procedure for lymph node dissection in cases of non-small cell lung cancer (NSCLC). The purpose of SND is aimed at removal of all mediastinal lymph node stations regardless of the anatomical location of the primary tumor in the lobe. The significance of SND can be discussed from the clinical aspects of accurate staging and survival benefit. Metastatic lymph nodes obtained via SND can undergo careful and accurate accurate histopathological evaluation, which offers several clinical advantages. However, the therapeutic effect of SND remains unclear.2-5 Technically, SND involves complete excision of all tissues in a particular anatomical compartment along with a few components of surrounding anatomical structures. An ideal technique involves en bloc removal of all tissue that may contain cancer cells, including lymph nodes and surrounding fatty tissue within pre-defined anatomical landmarks. All of lobectomies for NSCLC are performed via posterolateral incision using minimally invasive open surgery (MIOS) approach in our institution. Common to both sides, the fourth or fifth intercostal space provides better access in SND. During the SND, special care is warranted to prevent interruption of

the lymphatic vessels and/or injury to the lymph nodes themselves. Additionally, connective tissue ligation is necessary in a few cases to prevent postoperative chylothorax. Identification of the bilateral recurrent nerves is important because recurrent nerve paralysis can cause serious postoperative complications. Based on AOSOG Z0030 trial, complications of SND include postoperative chylothorax (1.7%), intraoperative bleeding (1.1%), and recurrent laryngeal nerve injury (0.9%).5 Although SND is a standard procedure of lymph node dissection for NSCLC, previous studies have analyzed in detail the lymphatic pathway and the pattern of lymph node involvement based on the primary location by lobe. Asamura et al. 6 reported that right upper lobe tumors and left upper segment tumors tend to metastasize to the superior mediastinum and that these lesions rarely metastasize to the subcarinal nodes without concomitant metastasis to the hilar or superior mediastinal nodes.6 The lobe-specific patterns of nodal metastases are being recognized owing to increasing analyses of the lymph node metastatic pathway.6-9 Based on these results, lobe-specific lymph node dissection is being increasingly performed under certain conditions, for example, based on tumor location, tumor size, cell type, and the percentage of the area of ground glass opacity visualized in the tumor on computed tomography. WS05.04 PARTICULARITIES OF LYMPHADENECTOMY IN MALIGNANT PLEURAL MESOTHELIOMA

A. Bille

Guy's Hospital NHS Foundation Trust, London/United Kingdom

Malignant Pleural Mesothelioma (MPM) is an aggressive disease with a poor prognosis. Patients treated with multimodality approach have a survival of 20 to 30 months. Survival is worse in patients with nodal disease1. Lymph node involvement is reported in 35 to 50% of patients undergone surgery. The lymph node staging system and the nodal categories (N0–N3) in the mesothelioma TNM staging are based on the lung cancer TNM. There are significant anatomic differences between the lymphatic drainage pathways of the pleura and the lung parenchyma2. The parietal and visceral pleura have two distinct and separate lymphatic drainage probably. The MPM arises from the parietal pleura and the intrapulmonary lymph node may not be the first lymph nodes to be involved, but they may be involved in a later phase. The lymph drainage of the parietal pleura flows initially through intercostal lymphatic channels, anteriorly to the internal thoracic artery nodes or posteriorly to the internal intercostal lymph nodes (Figure 1). Drainage can also be directly into axillary or cervical lymph nodes. Diaphragmatic lymphatic drainage can flow into mediastinal, internal thoracic, or abdominal nodes3. The MPM may involve also the endothoracic fascia, the chest wall, the mediastinal adipose tissue, the pericardium and the diaphragm, making the lymphatic drainage more complex. The intercostal space lymph nodes, the paraspinal lymph nodes, the peri diaphragmatic lymph nodes and the internal mammary chain lymph nodes may be the first lymphatic stations to be involved rather than the intrapulmonary lymph nodes. It was reported that extrapleural and the mediastinal nodes (N2) may in fact be the initial site of nodal metastases in patients with mesothelioma, with N1 nodes becoming secondarily involved only when invasion of lung parenchyma occur4. Data from several single-institutional retrospective series have yielded conflicting evidence as to whether there is indeed a prognostic difference between patients with pathologic N1 (pN1) and pN2 pleural mesothelioma. Those data are based on the lymph node mapped derived from lung cancer staging system. The IALSC TNM collected data from 29 institution and specifically analysed the impact of pathological nodal status on survival5,6. 851 cases were eligible for the pathological N status analysis. According to the analysis for the revision of the N descriptor the survival of pN1 and pN2 was 16.9 and 17.4 months (p=0.28)5. Interestingly 54% had skip metastases based on the lung cancer staging map. Based on this evidence in the 8th TNN edition N1 and N2 were grouped together3 and N3 disease was re classified as N2 disease. Like for other tumours, such as breast or melanoma, few papers tried to identified a sentinel lymph node in MPM with no success7. In the paper of Edwards et al8 there is no mention of the intercostal lymph nodes sampling, reflecting how limited the data on lymph node mapping are and how variable is the sampling technique between surgeons. During the operation an extensive nodal sampling should be performed. The intercostal lymph node at different levels, the mediastinal and intrapulmonary stations, the peri diaphragmatic and the internal mammary lymph nodes should be sampled. Specifically, the peri diaphragmatic lymph node should be categorized in above and below the diaphragm if the diaphragm is removed. All these lymph node stations should be sampled to collect more data on the lymph node drainage and spread of the disease according to the parietal and visceral pleura involvement. In conclusion, there is variability in the lymphatic drainage in mesothelioma. The lymph node map we used for mesothelioma is inadequate and a different lymph node map specific for mesothelioma should be created based on the different lymphatic drainage of the parietal and visceral pleura compared to the lung. There are no guidelines in how to perform lymph node sampling in mesothelioma. A routine lymphadenectomy should be performed at the time of surgery considering extrapleural, mediastinal and intrapulmonary lymph node stations according to the different lymphatic drainage of the parietal and visceral pleura. WS05.05 LYMPHNODE DISSECTION IN THYMIC MALIGNANCIES: IMPLICATIONS OF THE ITMIG/IASLC LYMPH NODE MAP OF THE TNM CLASSIFICATION AND STAGING

Y.T. Kim, I.K. Park

Seoul National University Hospital, Seoul/Korea, Republic of

The significance of lymph node metastases and lymph node dissection (LND) remains unclear and underestimated in thymic malignancies. Given the fact that LND is an important surgical procedure for most of the solid organ malignancies, the role of LND in thymic malignancies should be established. The ITMIG and the IASLC proposed a new lymph node map and separated N stage in the eighth edition of TNM stage classification system for thymic malignancies. They recommended that any suspicious nodes should be routinely removed. For stage I or II thymoma, adjacent nodes as well as anterior mediastinal nodes should be removed, and for stage III thymoma, systematic anterior mediastinal node dissection and systematic sampling of appropriate intrathoracic nodes were recommended. For the thymic carcinoma, a systematic sampling of anterior mediastinal, intrathoracic, supraclavicular, and lower cervical nodes were recommended. However, there is no prospective study to validate such recommendations as these recommendations are based on the old map and old staging system. As a consequence, a revised recommendation based on a new map and a new staging system is necessary. Four aspects should be considered with regards to the appropriate LND during thymectomy. The first aspect is an indication. In what circumstances, the LND should be performed?. The second one is the lymph node stations to be dissected. Proper understanding of lymphatic pathway in thymus would be helpful to select lymph node to dissect. The third aspect is the adequate number of the lymph node to dissect. Often time, the quality of LND is evaluated by the number of the dissected lymph node. The last aspect is the surgical approach. It is sometimes challenging to dissect every nodal station by means of minimally invasive surgery. What are the surrogate markers to predict lymph node metastasis in thymic malignancies? In many studies, histologic type and T stage have been reported as predictors of lymph node metastasis. Lymph node metastasis is more frequent in thymic carcinoma and carcinoid compared with that in thymoma. Also, it is frequent in tumors invading adjacent structures (T2 or T3). Which lymph nodes stations are essential to dissect? Murakami et al. reported that the main lymphatic flow is a cranial direction to the cervical area, and they nicely described that the right paratracheal node group is the largest collecting area. In our group, we found that the right paratracheal lymph node station is the most common area of lymph node metastasis among deep regional node groups. Can we score adequacy of LND in thymic malignancies? Our group previously showed that lymph node dissection more than 10 nodes predict prognosis better. When we divided patients into N0a when LND less than 10 were performed, N0b when LND was performed more than 10, and Nx when no LND was performed, the prognosis of N0a group was inferior to N0b and was similar to Nx group. In our recent paper, we reviewed 131 thymic malignancy patients who underwent LND using 8th TNM staging and ITMIG Lymph node map. Lymph node metastasis was detected in 13 patients (N1 in six and N2 in seven). Six N2 patients (86%) had right paratracheal node metastases. The rates of node metastasis were 1% in T1 as compared to 37.5% in T2 or T3 ($p < 0.001$). The rates of node metastasis were 8% in the M0 as compared to 43% in the M1 ($p = 0.03$). The rate was higher in thymic carcinoma (25%) than in thymoma (5.1%, $p = 0.01$), and the rates also differed between the subtypes of thymoma. There was no node metastasis of the A, AB, or B1 histologic subtypes. Tumor size was also a significant factor which can predict node metastasis. The optimal cutoff value for the node metastasis was 6 cm, and the specificity was 62%. Only 16% of the patients had received a preoperative histologic diagnosis. All patients with node metastasis had cTNM stage II or higher thymic malignancy. The freedom from recurrence rate of the pN1 or pN2 was significantly worse than that of the pN0 (5-year rate 38.5% versus 87.9%, $p < 0.001$). Based on the previously mentioned information, we proposed a revised recommendation for LND in thymic malignancies. For N1, peri-thymic, prevascular, and supradiaphragmatic lymph nodes should be included as a routine en-bloc dissection. Lower cervical lymph nodes and paraaortic nodes should be either sampled or dissected, especially in c-stage II or higher. For right paratracheal N2 nodes, sampling for c-stage I, dissection for c-stage II or higher is recommended. For other N2 nodes, sampling is recommended in c-stage II or higher, or in thymic carcinoma. Almost all of the anterior regional nodes can be dissected during total thymectomy. During MIS, the paratracheal node can be dissected via right side approach. The paraaortic and subaortic nodes can be dissected via left side approach. The cervical lymph node can be dissected by adding cervical approach if it is necessary. However, the routine dissection of the cervical node is not recommended. A bilateral approach may be recommended, especially if the left side is chosen for the resection of the primary tumor. In summary, LND is recommended in locally advanced thymoma and thymic carcinoma. As the frequent metastatic stations are peri-thymic and right paratracheal lymph nodes, LND of these stations are necessary. LND may be possible during minimally invasive surgery, and the bilateral approach may be recommended in tumors with higher than T2, especially in left-sided tumors.

Lymph node group	Recommendations
Anterior regional nodes (N1)	
Peri-thymic nodes	
Prevascular nodes	Routine en-bloc dissection
Supradiaphragmatic nodes	
Low anterior cervical nodes	Sampling in stage I, Dissection in stage ≥ II
Paraaortic nodes	
Deep regional node (N2)	
Right paratracheal nodes	Sampling in stage I, Dissection in stage ≥ II
Other nodes	Sampling in stage ≥ II, thymic carcinoma

***All suspicious nodes should be dissected**

WS05.06 RELEVANCE OF LYMPHADENECTOMY IN CARCINOMA OF THE ESOPHAGUS AND OF THE ESOPHAGOGASTRIC JUNCTION

G. Darling

University of Toronto, Toronto/Canada

Historically surgeons thought that removal of lymph nodes was unimportant as esophagectomy was viewed as a palliative operation. As more patients survive their surgery, overall survival has become an important goal. Does lymphadenectomy contributes to improved survival? The optimum lymphadenectomy has two components: required nodal resection for accurate staging and required nodal resection for optimizing survival. Number of resected nodes required for accurate staging In patients who have 8 metastatic nodes, removing more nodes doesn't change prognosis or improve survival. However in early stage disease, resection of a high number of nodes is required to be certain that the patient is truly N0. Using the WECC database, Rice reported that for short (<2.5cm), well differentiated and superficial cancers, >60 resected nodes are required to be certain that the patient is truly N0 [1]. A minimum of >12 resected nodes is required to achieve >90% sensitivity in staging accuracy [2] and Rizk identified that if > 18 nodes are resected the T stage is no longer prognostic [3]. The International Society for Diseases of the Esophagus consensus conference recommended that the minimum number of nodes required for accurate staging is 15 and this remains the current recommendation of the NCCN [4]. Patients with < 15 nodes resected are less likely to have nodal metastases identified and there is a survival benefit when > 15 nodes are resected, suggesting that with < 15 resected nodes, patients are understaged [5,6,7]. Further, with less than 15 nodes examined, N0 vs. N1 becomes the deciding factor in prognosis [8]. Patients who had a transhiatal esophagectomy, or had < 16 nodes resected or were pN1 had similar median survival (13, 14, 12 months respectively) compared to those who have a transthoracic resection (24 months), or were pN0 (38 months) or had> 16 nodes resected (25 months) [9]. Number of resected nodes required to optimize survival Rizk reported that the optimal number of resected nodes varies based on pT stage. For pT1 tumors only 10 nodes are required whereas for pT2 20 nodes but ≥ 30 nodes are required for pT3/4 tumors [10].

However Greenstein reported that survival was improved if > 10 nodes were removed for cT2-3N0 patients but > 18 nodes for cT1N0 [11]. Altorki reported that the number of nodes required to impact survival depended on N status. Survival increases with number of nodes removed but for N1 patients removal of > 17 nodes was required but for N0 patients resection of > 40 nodes was required to improve survival [12]. Using the SEER database, > 30 resected nodes are required to optimize survival [13, 14]. Samson, using the NCDB, compared mortality between patients who met the NCCN guideline of removing ≥ 15 nodes vs those who had < 15 nodes removed. Removal of >15 nodes was associated with lower mortality and the optimum threshold identified was 25 nodes [15]. Peyre also identified that removal of 23 nodes was the optimum threshold for surviva [16]. However, studies by Lagergren report no benefit to increased lymph node removal[17,18]. The minimum number of resected nodes required is 15 however, but the number required to optimize survival is 23-30. Required Nodal stations for resection and the relevance of tumor location and histology The lymphatics of the esophagus run longitudinally in the submucosa as well as draining horizontally into regional lymph nodes or directly into the thoracic duct. Akiyama reported that tumors of the upper third of the esophagus could have lymph node metastases from the upper mediastinum to the upper abdomen. Tumors of the lower third of the esophagus most commonly had lymph node metastases near the celiac and left gastric artery but also in the infracarinal mediastinum. The 8th edition of the AJCC staging manual identified all nodes as regional nodes. Thus all regional lymph nodes should be resected including the upper abdominal nodes and mediastinal nodes. This applies to tumors of all histogies. The effect of induction therapy on lymph node harvest suggests that preoperative chemoradiation may reduce the number of lymph nodes harvested [20,21], however in the CROSS trial there was no difference in lymph node harvest [22]. Summary Lymphadenectomy is important in esophagectomy for cancer with regard to staging accuracy but also contributes to survival. The more nodes examined, the higher the accuracy of N staging. The number needed to ensure accurate N stage for early cancers ranges from 40 to 60 nodes for T1 cancers, while the minimum number for all cancers is 15 nodes. Resection of < 15 nodes understages patients and compromises survival. The more nodes removed, the better the survival. However the optimum threshold appears to be 23-30 nodes. An important consideration is that all nodes are considered regional nodes and should be resected as a key component of esophagectomy for cancer. References 1. Rice. Ann Surg. 2017; 265: 122–129. 2. Background: Systematic assessment of lymph nodal involvement by EBUS-TBNA is indicated for suspected and proven lung cancers. Nodal size and PET characteristics help guide which lymph nodes to sample. Especially smaller lymph nodes remain challenging, since PET is of limited value due to low resolution. Additional ultrasound B-mode features such as lymph node size, margin or node heterogeneity have shown variable predictive outcomes. Ultrasound strain elastography (EBUS-SE) is a promising technique. By monitoring tissue deformation over time using ultrasound imaging, a relative tissue strain can be computed. Lower tissue strain is shown to correlate to malignancy. Using a standardized measurement procedure (RespirationDOI: 10.1159/000494143), we aimed to assess the value of strain elastography for predicting lymph node malignancy in addition to size information. **Method:** This multicenter prospective international trial [NCT02488928] included patient with suspected or proven lung cancer in five hospitals. Measurements were obtained following to a standardized operating procedure using Pentax-Hitachi EBUS systems. Nodal cytopathology combined with follow up imaging (>6 months) or surgery were used as reference standard. If uncertainty in outcome remained, nodes were excluded in final analysis. **Result:** EBUS-SE was performed in 416 patients and 525 lymph nodes (June 2016 – July 2018). Final diagnoses showed 272 benign and 253 malignant nodes. Mean lymph node size was 12.3 mm. B-mode size and mean strain correlated to risk of malignancy with AUC of 78% and 76.8% (95% CI 0.73-0.81). Using a clinical work-up setting with 10mm and 8mm size cut-offs for aspiration, short axis size higher than 8 or 10mm resulted in respective sensitivity of 85% and 72%, specificity of 52% and 71%, PPV of 62% and 70% and NPV of 79% and 73%. Addition of strain elastography (mean<90) to EBUS-short-axis size (<10mm) increased overall sensitivity from 72% to 90% and NPV from 73% to 81%. More nodes were found false positive, specificity decreased from 71% to 42% and PPV went from 70% to 59%. Addition of strain (mean<78) to EBUS-size (<8mm) increased sensitivity from 85% to 94% and NPV from 79% to 85%. Specificity decreased from 52% to 32% and PPV from 63% to 55%. **Conclusion:** EBUS strain elastography is of added value in guiding nodal sampling. Strain and size combined can help identify more malignant nodes, although it will ultimately also lead to more false positive sampling. Strain information may especially be of potential value in nodes of small size, where PET resolution is limited.

[1]*McMaster University, Hamilton/Canada,* [2]*University of Manitoba, Winnipeg/Canada,* [3]*McGill University, Montreal/Canada,* [4]*Division of Thoracic Surgery, University of Alberta, Edmonton/Canada,* [5]*Dalhousie University, Halifax/Canada,* [6]*University of British Columbia, Vancouver/Canada,* [7]*Laurentian University, Sudbury/Canada,* [8]*University of Ottawa, Ottawa/Canada,* [9]*University Health Network, Toronto/Canada*

Background: Current staging guidelines with endobronchial ultrasound (EBUS) still recommend systematic biopsy of at least 3 mediastinal stations prior to surgical resection. Recently, a 4-point ultrasonographic score (Canada Lymph Node Score- CLNS) was developed to determine the probability of nodal metastasis in any given lymph node. A LN with CLNS<2 is considered very low probability for malignancy. We hypothesized that, during EBUS assessment of patients with cN0 non-small cell lung cancer, individual nodal stations that have CLNS<2 do not require routine biopsy because they are likely to represent true pN0 disease.

Method: The CLNS is a prospectively validated score that uses four ultrasonographic features to accurately predict LN malignancy. LNs were evaluated for ultrasonographic features at the time of EBUS and the CLNS was applied. "Triple Negative" LNs were defined as cN0 on CT (LN≤1cm), PET (no hypermetabolic activity) and EBUS (CLNS<2). Specificity, NPV, and false-negative rates were calculated against the gold-standard pathological diagnosis from surgically excised specimens. **Result:** In total, 122 LNs in 58 cN0 patients were assessed. Triple Negative LNs were associated with the following T-stage distribution (T1a=12.07%, T1b=24.14%, T2a=34.38%, T2b=10.34%, T3=17.24%, T4=1.72%). Triple Negative LNs had a specificity, NPV, and false-negative rate of 86.10% (95%CI: 78.40-91.80%), 93.40% (95%CI: 86.90-97.30%), and 6.60%, respectively when using <2 as the CLNS malignancy cut-off. In total, only 5.74%(n=7) Triple Negative nodes were actually proven to be malignant, 6/7 (85.71%) on EBUS-TBNA, and 1/7 (14.29%) only after surgical resection. **Conclusion:** Triple Negative LNs have a high NPV for malignancy. At the time of EBUS in cN0 patients, it may be possible that Triple Negative LNs do not require tissue sampling, thereby saving procedural time, cost, and discomfort. Findings also suggest that Triple Negative LNs with inconclusive biopsy results may not require repeat sampling. A prospective comparative trial is required to confirm these findings.

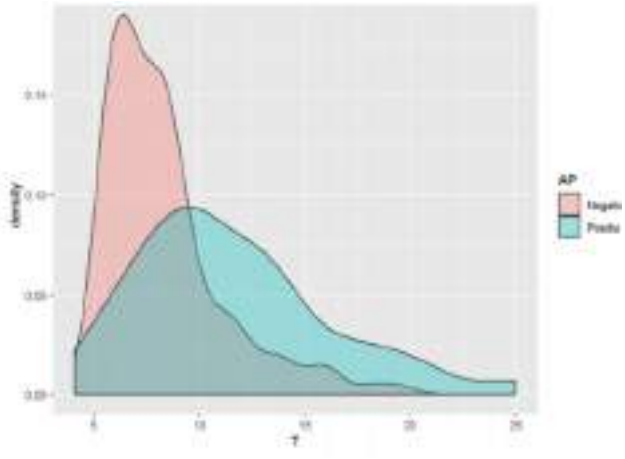
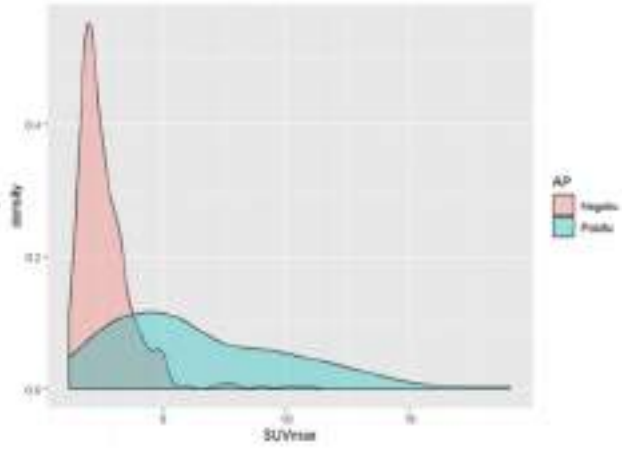
Pathological Anatomy, Hospital Universitari de Bellvitge, University of Barcelona, IDIBELL, CIBERES, Barcelona/Spain,* [5]*Thorax Institute, Germans Trias i Pujol University Hospital, IGTP, CIBERES, Barcelona/Spain*

Background: The mediastinal lymph nodes (LN) staging is routinely performed by PET-CT and EBUS- TBNA. Nevertheless, there are no studies that explore the diagnostic capacity of both techniques together. This study aims is to find an algorithm based on combined PET-CT and EBUS image variables together with clinical criteria that provides the most accurate probability of malignancy for each LN explored. **Method:** Retrospective study of mediastinal staging of non-small cell lung cancer, based on PET-CT and EBUS-TBNA. The LN were identified by level (N1, N2 and N3) and by anatomical region (AR) (subcarinal, not subcarinal, and hilar). Standardized Uptake Value (SUV) was determined for each sampled LN (maximum, medium and peak) as well as for pulmonary mass, liver, and blood pool. The ultrasound features collected were: diameter in the short axis (DSA), morphology, border, ecogeneicity and presence of the vascular hilium. For the construction of the predictive algorithm a mixed model of logistic regression of Firth was used. **Result:** 116 consecutive patients were included and a total of 358 LN were evaluated. The set of variables that presented the best discrimination were: age, DSA, SUVmax and AR. The model determines the probability for malignancy for each LN, using the following formula = (-9.26) constant + (-0.21) Age + (4.29) SUVmax + (0.52) DSA + AR. The discrimination power of the model measured by the Area Under the Roc curve was = 0.95.

Distribution density of diameter (mm) and SUVmax of positive and negative lymph nodes





Conclusion: The model including age, DSA, SUVmax and AR provide the probability of malignancy for each LN with the highest accuracy. All other variables can be discarded when combining PET-CT and EBUS image features.

OA01.05 CRYOBIOPSY COMPARED WITH FORCEPS BIOPSY IN PATHOLOGICAL DIAGNOSIS AND BIOMARKER RESEARCH IN LUNG CANCER: A PROSPECTIVE, SINGLE-ARM STUDY

T. Naito[1], H. Udagawa[1], K. Kirita[1], T. Ikeda[1], Y. Zenke[1], S. Matsumoto[1], K. Yoh[1], S. Niho[1], G. Ishii[2], K. Goto[1]

[1]*National Cancer Center Hospital East, Kashiwa/Japan,* [2]*National Cancer Center, Kashiwa/Japan*

Background: Cryobiopsy is a novel transbronchial biopsy tool that enables the collection of larger samples than forceps biopsy. We evaluated the usefulness of cryobiopsy compared with forceps biopsy in pathological diagnosis and biomarker research in lung cancer. **Method:** In this prospective single-arm study, 121 patients with or suspected of having lung cancer underwent concurrent transbronchial biopsy using a cryoprobe (ERBECRYO2) and forceps from the same lesion. Sample size and morphological classification were determined for patients whose cryobiopsy and forceps biopsy samples both contained tumor cells (n = 81). Patients diagnosed with non-small-cell lung carcinoma (NSCLC) with adequate samples from the two procedures (n = 65) were analyzed for programmed death ligand 1 (PD-L1) expression score (22C3). Genomic DNA and RNA were extracted from cryobiopsy and forceps biopsy formalin-fixed paraffin-embedded samples (20 NSCLC patients, 20 sections, 10 μm thick each) for whole-exome sequencing and RNA sequencing. **Result:** Cryobiopsy samples were significantly larger than forceps biopsy samples (median 11.1 mm^2[range: 3.3–135.0] vs. 2.0 mm^2[0.7–6.6], $p < 0.01$). The confirmation rate of morphological classification of cryobiopsy samples was significantly higher than that of forceps biopsy samples (86% vs. 79%, $p < 0.01$, adenocarcinoma/squamous-cell carcinoma/small-cell carcinoma/other = 35/19/12/4 and 30/15/11/4, respectively). The success rate for evaluating PD-L1 score using cryobiopsy and forceps biopsy samples was 94% and 95%, respectively. A greater proportion of cryobiopsy samples tended to have PD-L1 > 1% than forceps biopsy samples (51% vs. 42%, $p = 0.06$). Significantly larger amounts of DNA (median 1.60μg vs. 0.58μg, $p = 0.02$) and RNA (median 0.62μg vs. 0.17μg, $p < 0.01$) were extracted from cryobiopsy samples than forceps biopsy samples. The success rate for whole-exome sequencing (90% vs. 15%, $p < 0.01$) and RNA sequencing (75% vs. 10%, $p < 0.01$) was higher for cryobiopsy samples than forceps biopsy samples. The median tumor-mutation burden in cryobiopsy samples was 84 (range 3–2396). **Conclusion:** Cryobiopsy provided larger sample sizes compared with forceps biopsy, and were more useful for morphological classification, PD-L1 evaluation and genetic analysis.

OA01 ADVANCED DIAGNOSTIC APPROACHES FOR INTRATHORACIC LYMPH NODES AND PERIPHERAL LUNG TUMORS
SUNDAY, SEPTEMBER 8 10:30–12:00

OA01.06 CONE BEAM CT IMAGING FOR TRANSBRONCHIAL NAVIGATION IN SMALL PERIPHERAL PULMONARY LESIONS

R. Verhoeven, J. Fütterer, W. Hoefsloot, E. Van Der Heijden

Radboud University Medical Center, Nijmegen/Netherlands

Background: Small peripheral lung lesions have historically been identified and followed according to risk of malignancy. Ideally an accurate minimally invasive diagnostic procedure would become the more common first approach. The bronchoscopic approach herein remains of limited widespread use, and reported pooled diagnostic yields remain at approximately 70% even with the help of additional advanced guiding technology. We evaluated if inter-procedural cone beam CT (CBCT) improves yield in two prospective trials: CBCT assisted navigation bronchoscopy with electromagnetic navigation (EMN) guidance (CONTROL-E, NCT03355586) and without EMN using augmented CBCT fluoroscopy alone (CONTROL-A, NCT03274609). **Method:** All patients with an indication for a minimal invasive diagnostic procedure of their peripheral pulmonary lesion as found by our multi-disciplinary tumor board between Dec 2017 and Jan 2019 were included. A total of 84 patients (100 nodules) were included and had a navigation bronchoscopy in the hybrid operating room under general anesthesia. Procedural workflow was as follows: CONTROL-A started off with a CBCT scan. The lesion and pathway were then segmented on a separate workstation. Afterwards, both pathway and nodule were projected 2D on live fluoroscopy for navigation and biopsy guidance. CONTROL-E workflow started with electromagnetic navigation (EMN). Upon reaching the planned target or concluding upon unsuccessful navigation, CBCT imaging was performed for verification (or if applicable; consecutive repositioning guidance). In both workflows, r-EBUS mini probe imaging and ROSE were available for additional guidance and verification. **Result:** The mean lesion size in CONTROL-A (46 patients) was 16.7mm (range 5-43 mm), and 11.5mm (range 4-33 mm) in CONTROL-E (38 patients). A bronchus sign was seen in 62% and 71% of cases, respectively. The CONTROL-E study showed that EMN with r-EBUS had an approximate navigation success rate of 58%. Addition of live 3D-CBCT guidance was performed in all cases, increasing navigation success to 88%. The CONTROL-A study had navigation success of 80% by utilizing only r-EBUS and augmented CBCT-fluoroscopy. However, additional EMN (cross-over) was needed in several cases for navigation guidance, increasing navigation success to 88%. In follow up, both studies showed a diagnostic yield lower than the navigation success: in CONTROL-E 71% and in CONTROL-A, 72% had a biopsy outcome correlating to golden standard follow up. **Conclusion:** Cone beam CT is of significant added value for transbronchial navigation to small peripheral lung lesions, with or without trans-parenchymal access. Diagnostic yield however remains approximately 71%. Additional refining of navigation and biopsy tools is necessary to further increase intuitiveness and accuracy.

OA01.07 ULTRATHIN BRONCHOSCOPY COMBINED WITH VBN AND EBUS FOR THE DIAGNOSIS OF PPLS WITH OR WITHOUT FLUOROSCOPY: A RANDOMIZED TRIAL

X. Zheng[1], F. Xie[2], J. Sun[1]

[1]*Shanghai Chest Hospital, Shanghai Jiao Tong University, Shanghai/China,* [2]*Shanghai Chest Hospital, Shanghai/China*

Background: Since the utility of lowdose computed tomography screening for lung cancer, the detection rate of groundglass nodules (GGNs) has increased.Transbronchial biopsy for peripheral pulmonary lesions is generally performed using ultrathin bronchoscopy combined with virtual bronchoscopic navigation (VBN) and endobronchial ultrasound (EBUS). The use of fluoroscopy with this method has not yet been explored. The study was designed as a randomized trial to determine the role of fluoroscopy in this method. **Method:** Patients with peripheral pulmonary lesions suspicious for malignant were enrolled in the study and randomized to two groups, fluoroscopy group and non-fluoroscopy group. Fluoroscopy group was performed with a 3.0 mm external diameter and 1.7 mm internal diameter ultrathin bronchoscope, EBUS, VBN guidance and fluoroscopy. Non-fluoroscopy group was performed with the same ultrathin bronchoscopy combined with EBUS and VBN guidance, but without fluoroscopy. Biopsies Cytological and histological examinations were performed in both groups. **Result:** A total of 126 patients were enrolled and randomized, of whom 120 patients (60, non-fluoroscopy group; 60, fluoroscopy group) were analyzed. The diagnostic yield was 75% (14 benign and 46 malignant lesions) in the non-fluoroscopy group and 83.3% (6 benign and 54 malignant lesions) in the fluoroscopy group (P=0.37). There were no obvious complications including pneumothorax, bleeding, chest pain and pneumonia in both groups. **Conclusion:** There was no difference in the diagnostic yield of the non-fluoroscopy group method compared to the FG method using ultrathin bronchoscopy, navigational technology and EBUS for transbronchial biopsy to diagnose peripheral pulmonary lesions.

OA02.01 ALECTINIB IN PREVIOUSLY TREATED RET-REARRANGED ADVANCED NON-SMALL-CELL LUNG CANCER: A PHASE 1/2 TRIAL (ALL-RET)

N. Yanagitani[1], S. Takeuchi[2,3], T. Murayama[3], K. Yoshimura[3], Y. Imai[3], S. Takahara[3], T. Kawakami[3], T. Seto[4], Y. Hattori[5], K. Ohashi[6], M. Morise[7], S. Matsumoto[8], K. Yoh[8], K. Goto[8], M. Nishio[1], S. Yano[2,3]

[1]*The Cancer Institute Hospital of Japanese Foundation for Cancer Research, Tokyo/Japan,* [2]*Cancer Research Institute, Kanazawa University, Kanazawa/Japan,* [3]*Kanazawa University Hospital, Kanazawa/Japan,* [4]*National Organization Hospital Kyushu Cancer Center, Fukuoka/Japan,* [5]*Hyogo Cancer Center, Akashi/Japan,* [6]*Okayama University Hospital, Okayama/Japan,* [7]*Nagoya University Graduate School of Medicine, Nagoya/Japan,* [8]*National Cancer Center Hospital East, Kashiwa/Japan*

Background: *RET* rearrangements occur in 1–2% of non-small cell lung cancers (NSCLCs). Alectinib (300 mg twice daily) has been approved for the treatment of *ALK*-rearranged NSCLC in Japan; it also has a high activity against RET *in vitro*. A global trial (ALEX study) showed the efficacy and safety of alectinib (600 mg twice daily) in *ALK*-rearranged NSCLC patients. We conducted a phase 1/2 study of alectinib to establish the recommended dose (RD) and examined its activity in *RET*-rearranged Japanese NSCLC patients. **Method:** This study was a single-arm, open-label, multi-institutional phase 1/2 trial. *RET*-rearranged NSCLC patients treated with at least one regimen of chemotherapy were recruited. *RET* rearrangements were screened using LC-SCRUM-Japan, a nationwide genomic screening network. In phase 1, alectinib (600 or 450 mg twice daily) was administered, following a 3 + 3 design. The primary endpoint was safety. During phase 2, alectinib at the RD defined in phase 1 was administered. The primary endpoint was the objective response rate in RET inhibitor-naïve patients. **Result:** Between March 8, 2016 and January 29, 2018, 35 patients were enrolled, and 34 patients were administered alectinib. *KIF5B-RET* was the most common fusion gene (22 cases [63%]), and the *CCDC6-RET* fusion was identified in 8 cases. The remaining 5 cases were not distinguishable. In cohort 1 (600 mg twice daily), we observed 5 DLTs (grade 3 rash, increased aspartate aminotransferase, erythema multiforme, thromboembolic event, and increased CPK) in 3 of 6 patients. In accordance with the protocol, we moved to cohort 2 (450 mg twice daily) and observed no DLTs in 3 patients. Additionally, pharmacokinetic analysis indicated that the mean exposure (AUC0–10) of 600 mg twice daily was higher than that previously reported in AF-002JG trial (global phase 1 study). Therefore, we determined 450 mg twice daily as the RD for phase 2. Twenty-five RET inhibitor-naïve patients were treated with the RD, of whom 1 achieved an objective response (4%) and 13 achieved disease control at 8 weeks (52%) as determined by central review. The median progression-free survival was 3.4 months (95% CI 2.0-5.4), and the median overall survival was 19.0 months (5.4-NE). We observed grade 3 neutropenia, pneumonitis, diarrhea, hyponatremia, increased CPK and blood bilirubin (4%) in patients treated with 450 mg alectinib twice daily; no grade 4 adverse events

were observed. **Conclusion:** Alectinib had limited activity in patients with *RET*-rearranged NSCLC. Further investigation of new targeted therapeutics is required to improve outcomes for these patients.

Background: HS-10296 is an oral, potent, high selective third generation EGFR tyrosine-kinase inhibitor (EGFR-TKI) for sensitizing mutations, and the EGFR Thr790Met (T790M) resistance mutation which has been demonstrated by phase I study. This phase II, open-label, multicenter single-arm study was designed to confirm the efficacy and safety of HS-10296 in a large population of non-small-cell lung cancer (NSCLC) patients with EGFR T790M mutation, who had progressed after first generation EGFR-TKI treatment. **Method:** Patients aged at least 18 years with centrally confirmed EGFR T790M-positive mutations, locally advanced or metastatic (stage IIIB/IV) NSCLC after first generation EGFR-TKI treatment received HS-10296 110 mg orally once daily until disease progression, or intolerable toxicity, or patient withdrawal. Patients with asymptomatic, stable brain metastases not requiring steroids were allowed to enroll. The primary endpoint was the objective response rate (ORR) by independent central review using Response Evaluation Criteria in Solid Tumors, version 1.1 every 6 weeks. Response endpoints (ORR and disease control rate [DCR]) were assessed in response analysis set. Secondary end points including progression-free survival (PFS), duration of response (DoR), depth of response (DepOR), overall survival (OS) and safety were evaluated in full analysis set. The final data cutoff was on Jan 5, 2019. The study is still ongoing. **Result:** Totally, 244 patients (median age 60.8) entered study in 36 sites in mainland China (189 patients) and Taiwan (55 patients) between May 16, 2018 to Oct 23, 2018. 2 patients were excluded from the evaluable for response analysis set (n=242) due to absence of measurable disease at baseline by independent central review. At data cutoff, 182 (74.6%) patients remained on treatment. The median duration of follow-up was 4.7 months. 160 of 242 patients achieved confirmed partial responses by independent central review. The ORR was 66.1% (95% CI: 59.8-72.1). The DCR was 93.4% (95% CI: 89.5-96.2). The most common adverse reactions ($\geq$ 10%) were blood creatine phosphokinase increased (43 [17.6%]), aspartate aminotransferase increased (29 [11.9%]), pruritus (28 [11.5%]), rash (28 [11.5%]) and alanine aminotransferase increased (26 [10.7%]). The most common all-causality grade 3 and 4 adverse events were blood creatine phosphokinase increased (14 [5.7%]) and hyponatraemia (4 [1.6%]). Serious adverse events were reported in 30 (12.3%) patients, of which 19 (7.8%) were investigator assessed as possibly treatment-related to HS-10296. Three deaths were due to adverse events; one was related to cardiopulmonary failure, other two events occurred after disease progression. There was no interstitial lung disease during study treatment. **Conclusion:** HS-10296 has demonstrated good clinical benefit with minimal toxicity in patients with EGFR T790M-positive NSCLC patients who have progressed after first generation EGFR-TKI treatment. The Phase III study has already launched comparing HS-10296 with gefinitib in advanced NSCLC patients with EGFR sensitizing mutations. (The study was sponsored by Jiangsu Hansoh Pharmaceutical Co., Ltd.; ClinicalTrials.gov number, NCT02981108)

Background: AXL, a transmembrane receptor tyrosine kinase, is aberrantly expressed in various cancers, and associated with poor prognosis and treatment resistance. AXL overexpression is associated with resistance to PD-1 immune checkpoint inhibitors (Hugo *et al*. 2016). EnaV, a novel ADC of anti-AXL human IgG1 and monomethyl auristatin E, demonstrated potent anti-tumor activity in preclinical models, including NSCLC (Boshuizen *et al*. 2018). In a phase 1, dose escalation, multi-cohort trial (NCT02988817) in heavily pretreated patients with relapsed or refractory solid tumors, EnaV 2.2 mg/kg once every 3 weeks (1Q3W; recommended phase

2 dose) showed preliminary anti-tumor activity. Here we present initial results from patients with NSCLC in the phase 2a, expansion phase of this trial. **Method:** We analyzed data from EnaV 2.2 mg/kg 1Q3W, in the cohort of pretreated patients with stage III/IV NSCLC without sensitizing EGFR mutations (EGFR WT) or ALK rearrangements (ALK$^-$) who had failed ≤4 prior lines of therapy, including platinum-based chemotherapy and PD-1/PD-L1 inhibitor (either in combination or sequentially). Endpoints include safety, objective response rate (ORR; RECIST 1.1), and AXL expression in fresh tumor biopsies (immunohistochemistry). **Result:** In the EGFR WT/ALK$^-$ cohort, 26 patients (median age 65.5 years, range 38–74; 57.7% male) with ECOG PS of 0 (11.5%) or 1 (88.5%) have been enrolled. Most patients (23/26) were treated with a checkpoint inhibitor. At a median follow-up of 18 weeks (range: 2–54), the most common (≥20%; any grade) treatment-emergent adverse events (TEAEs) were fatigue, constipation, nausea, decreased appetite, decreased weight, diarrhea, and vomiting. Two patients had a TEAE leading to dose reduction. Grade ≥3 TEAEs occurred in 12 patients, with the most common being gastrointestinal disorders in eight patients (constipation [n=1]; colitis, diarrhea, nausea, vomiting [n=2 each]; abdominal distension [n=1]. The confirmed ORR is 19% (95% CI: 8.5%, 37.9%). The disease control rate (CR+PR+SD) is 50% (13/26). Nine of 12 (75%) evaluable fresh biopsies were positive for AXL tumor cell staining. **Conclusion:** In this high unmet need patient population, with advanced EGFR WT and ALK$^-$ NSCLC who are pretreated with PD-1/PD-L1 inhibitors and platimum-based therapies, EnaV monotherapy demonstrated a manageable safety profile and encouraging preliminary clinical activity. This cohort has expanded to allow up to 60 patients to gain further knowledge of AXL as a potential biomarker for responsiveness to EnaV and to gather additional data on safety and efficacy. Background: Previous clinical trials demonstrated that alectinib (ALEC) had a longer time-to-progression than crizotinib (CRZ) in 1st-line settings. Information on long-term overall survival (OS), however, is still limited with a few studies having reported that the sequential strategy of "CRZ followed by other ALK-inhibitor" can provide extended OS. In Japan, ALEC was approved for a 1st-line setting earlier than in other countries. **Method:** We reviewed the clinical data of ALK-rearranged NSCLC patients who received CRZ or ALEC between May 2012 and Dec 2016. Patients were divided into two groups according to the first-administered ALK inhibitor, the CRZ or ALEC group. In order to evaluate the efficacy of the sequential strategy of "CRZ followed by ALEC", the combined time to treatment failure (TTF) was calculated in the CRZ group as defined by the sum of the "TTF of CRZ" plus the "TTF of ALEC" if patients were treated with ALEC followed by CRZ. In the ALEC group, the "TTF of ALEC" was calculated. The primary endpoint is the comparison between the combined TTF in the CRZ group with the TTF in the ALEC group. **Result:** Of 864 patients enrolled from 61 institutions, 840 patients were analyzed. Median age was 61 (range, 20-94); 56% were female; and 95% had adenocarcinoma. There were 535/305 patients in the CRZ/ALEC group. In the CRZ group, 282 patients received ALEC after CRZ failure. The combined TTF in the CRZ group was significantly longer than TTF in the ALEC group; median, 34.4 vs 27.2 months (mo); hazard ratio (HR), 0.709 [95%CI;0.559- 0.899]; *P*=0.0044. However, there was no significant difference in OS between the patients who received ALEC after CRZ in the CRZ group and the patients in the ALEC group; median, 88.4 months vs. not reached; HR 1.048 [95%CI;0.758-1.451]; *P*=0.7770. In the whole population, the CRZ group had a significantly shorter OS than the ALEC group; median, 53.6 mo vs not reached HR, 1.821 [95%CI;1.372-2.415]; *P*<0.0001. **Conclusion:** The combined TTF in the CRZ group was significantly longer than TTF in the ALEC group, however, OS benefit of sequential therapy of CRZ followed by ALEC was not shown.

Hoffmann-La Roche Ltd., Basel/Switzerland,* [10]*Department of Oncology, University of Turin, Turin/Italy*

Background: The ALUR (NCT02604342) primary analysis (cut-off January 2017) demonstrated improved efficacy and safety with alectinib versus chemotherapy in patients with *ALK*+ NSCLC previously treated with chemotherapy and crizotinib. These patients can develop crizotinib resistance through *ALK* secondary mutations, but limited data exist regarding alectinib's efficacy in patients with different post-crizotinib genetic profiles. We report final data from ALUR including treatment outcomes according to genetic profile. **Method:** Overall, 119 patients with locally determined *ALK*+ NSCLC were randomised 2:1 to receive alectinib 600mg bid or chemotherapy (pemetrexed 500mg/m^2 or docetaxel 75mg/m^2 q3w). The primary endpoint was PFS by investigator. Targeted genomic sequencing (FoundationONE® [tissue; 315 genes] and FoundationACT® [plasma; 62 genes]) was performed retrospectively using tumour tissue (n=33) and baseline plasma (n=59). **Result:** Final efficacy data confirmed those of the primary analysis (table). Grade ≥3 treatment-emergent adverse events were lower with alectinib (37.7%) than with chemotherapy (43.2%); adverse events causing treatment discontinuation were lower with alectinib (5.2% versus 10.8% chemotherapy), despite alectinib's longer treatment duration. *ALK* fusions were confirmed retrospectively in 26/33 (78.8%) tissue and 41/59 (69.5%) plasma (post-crizotinib) samples. ORR in alectinib-treated patients with *ALK* fusions was 72.2% (13/18, tissue) and 63.0% (17/27, plasma) versus 0% for chemotherapy (tissue [0/8], plasma [0/14]). *ALK* secondary mutations were detected in 16/59 (27.1%) patients (plasma, both arms). ORR in the alectinib arm (plasma) was similar in patients with *ALK* fusions with (60.0%, 6/10) or without (64.7%, 11/17) *ALK* secondary mutations, but lower in patients with gene mutations other than *ALK* (23.1%, 3/13). **Conclusion:** Final data from ALUR confirm the primary analysis, demonstrating improved efficacy and safety with alectinib versus chemotherapy in post-crizotinib *ALK*+ NSCLC. The role of reconfirming *ALK* status upon sequential ALK inhibitor treatment requires further investigation, due to the limited data and known technical challenges of plasma testing. Funding: F. Hoffmann-La Roche Ltd.

Background: Small-cell lung cancer (SCLC) accounts for approximately 10–15% of the total number of lung cancer cases. In extensive-stage (ES) SCLC, the 5-year survival rate is less than 5%, which was mainly caused by rapid recurrence and resistance to second-line chemotherapy despite the high response to first-line chemotherapy. This study evaluated the efficacy and safety of apatinib, an orally administered small-molecule targeted drug, in second-line and later-line therapy for patients with ES-SCLC (ChiCTR-OPC-17013964. **Method:** From July 28, 2017 to March 24, 2019, 52 patients who failed in first-line and above chemotherapy treatment were enrolled and received apatinib 500 mg per day. The efficacy was evaluated after 4-weeks treatment (1 cycle), and then evaluated once every 2 cycles. The primary endpoint was progression-free survival (PFS), and secondary endpoints were overall survival (OS), overall response rate (ORR) and disease control rate (DCR). The adverse events were also recorded. **Result:** Of 52 enrolled patients, 36 patients were available for efficacy analysis. The median PFS was 6.18 months (95%CI: 3.26-7.99) and the median OS did not achieve. The mPFS of patients received apatinib as second-line treatment was 6.48 months. Patients who received first-line chemotherapy more than 6 months had longer PFS and OS than patients received less than 6months. 31 patients were available for tumor response evaluation. The ORR and DCR were 19.35% and 83.87%, respectively. During the treatment, 96

adverse events were detected. Among them, 3-4 grade adverse reactions were hypertension (8.33%), hand-foot syndrome (5.56%), hypodynamia (5.56%) and proteinuria (2.78%), which all alleviated by reducing dose and symptomatic treatment.

Table 1 Patient baseline characteristics

Baseline characteristics	N = 36	Percentage
Age (< 60 / ≥ 60)	13/ 23	36.11%/ 63.89%
Gender (male/ Female)	30/ 6	83.33%/ 16.67%
ECOG (0/ 1/ 2)	3/ 18/ 15	8.33% / 50.00%/ 41.67%
Primary lesion (Right lung/ Left lung)	25/ 11	69.44%/ 30.56%
Radiotherapy (Yes /No)	30/ 6	83.33%/ 16.67%
First line-PFS (< 6 m / ≥ 6 m)	19/ 17	52.78%/ 47.22%
The number of treatment lines for apatinib		
Second line treatment	18	50.00%
Three-line treatment	15	41.67%
Four-line treatment	3	8.33%

Conclusion: Apatinib was effective for SCLC patients who failed in first-line and above chemotherapy and the adverse events were tolerable.

Background: The ALTER 1202 trial showed significant improvement in progress-free survival and well tolerant with anlotinib in advanced small cell lung cancer (SCLC) patients received at least two lines chemotherapy. Here, we reported the effect of anlotinib in patients previously received chemoradiotherapy. **Method:** The ALTER 1202 was a randomized, double-blind phase 2 trial conducted at 11 centers in China. Patients with advanced SCLC that received at least two previous lines of chemotherapy were enrolled and randomized in a 2:1 ratio to receive either anlotinib or placebo until tumor progression or unacceptable toxicity. The subgroup analysis assessed the effect of anlotinib in patients with previous concurrent, sequential and alternate chemoradiotherapy. The primary outcome was progressive-free survival (PFS). The secondary outcomes were overall survival (OS), objective response rate, disease control rate and safety. Data are reported as per the 30 June 2018, data cutoff date. This trial is registered with ClinicalTrials.gov, number NCT03059797. **Result:** Between March 30, 2017 and June 8, 2018, a total of 120 patients who met all eligibility criteria were randomly assigned to the anlotinib group (82 patients) or placebo group (38 patients). And 46 patients in anlotinib group and 22 patients in placebo group previously received chemoradiotherapy. Among them, the median PFS was 5.49 months (95% confidence interval [CI], 2.83 to 6.47) with anlotinib versus 0.69 months (95% CI, 0.66 to 0.76) with placebo (hazard ratio [HR], 0.14; 95% CI, 0.07 to 0.28; P<0.0001). Meanwhile, anlotinib significantly prolonged OS compared with placebo (9.49 months [95% CI, 7.29 to 12.68] versus 2.56 months [95% CI, 0.49 to 5.22]; HR, 0.46 [95% CI, 0.22 to 0.98]; P=0.0388) in patients previously received chemoradiotherapy. The most common adverse events were hypertension (39.13%), weight loss (39.13%), hypertriglyceridemia (36.96%) and leukopenia (30.43%). While, the most common grade 3 or worse adverse events were hypertension (15.22%), hypertriglyceridemia (10.87%), γ-glutamyl-transferase increased (8.70%). **Conclusion:** Anlotinib improved PFS and OS in advanced SCLC patients previously received chemoradiotherapy and was well tolerated.

Background: SCLC accounts for ~15% of lung cancers, with 5-year survival <10%. 50-90% of patients with extensive disease respond to initial treatment; many rapidly relapse due to acquired resistance to front-line platinum-based chemotherapy. Limited treatment options are available for second-line patients. nal-IRI is a liposomal formulation of irinotecan (topoisomerase-1 inhibitor), utilizing intraliposomal stabilization technology to enable high drug load and in-vivo stability. **Method:** RESILIENT (NCT03088813) is a two-part Phase 2/3 study assessing the safety, tolerability, and efficacy of monotherapy nal-IRI in SCLC patients who progressed on/after a

front-line platinum regimen: Part 1 includes dose-finding then dose-expansion. Key eligibility criteria included ECOG PS 0-1 and adequate organ function, with prior exposure to immunotherapy allowed. Eligible patients received nal-IRI 70mg/m2 or 85mg/m2 (free-base equivalent) q2w. Primary endpoints were safety and tolerability. Efficacy assessments included objective response rate (ORR), best overall response (BOR), progression-free survival (PFS), and overall survival (OS). **Result:** 30 patients were treated for >12 weeks in Part 1 (male, 43%; median age, 60.4y; platinum-resistant, 40%) with tumor assessments q6w. During dose-finding, 5 patients received nal-IRI 85mg/m2 (deemed not tolerable: dose-limiting toxicity) and 12 patients received nal-IRI 70mg/m2 (deemed tolerable: selected for dose expansion). At data cut-off** (median follow-up, 4.4mo), 25 patients had received nal-IRI 70mg/m2. Diarrhea was the most common gastrointestinal adverse events (AEs) (Gr3, 20%). Hematologic AEs included neutropenia (Gr3, 8%; Gr4, 8%), anemia (Gr3, 8%), febrile neutropenia (Gr3, 4%), thrombocytopenia (Gr3, 4%; Gr4, 4%). Preliminary efficacy identified 11 patients with partial responses (ORR 44%), BOR (PR+SD) of 72%, and 12-week disease control rate (DCR12wks PR+SD) of 48%. PFS and OS are not yet mature. **Conclusion:** Part 1 demonstrated encouraging anti-tumor activity for nal-IRI 70mg/m2 in patients with SCLC (ORR: 44%, BOR: 72%). nal-IRI 70mg/m2 was generally well tolerated. Future research is warranted to assess nal-IRI in second-line SCLC.

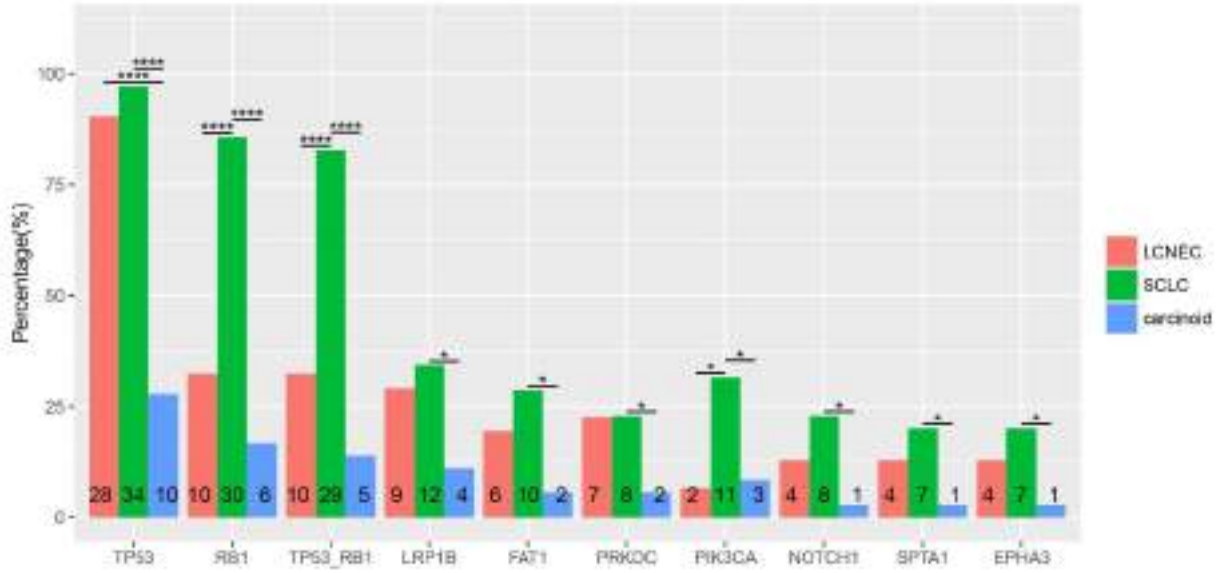
Background: LCNEC and SCLC are aggressive neuroendocrine carcinomas with overlap in clinical, histopathologic, morphologic and genomic features. Differential molecular features between the two subtypes have not been well elucidated, contributing the uncertainty for optimal clinical strategy for each subtype. Here we interrogated the genomic characteristics in LCNEC as compared to SCLC along with their histologically related subtypes: carcinoids and atypical carcinoids via comprehensive genomic profiling. **Method:** FFPE samples from 31 LCNECs, 35 SCLCs, 14 carcinoids and 22 atypical carcinoids were sequenced in a CLIA-certified sequencing laboratory using 520-cancer-related gene panel, with an average sequencing depth of 1385X. **Result:** Comparative mutational analysis revealed that both LCNEC and SCLC sub-cohorts displayed higher rate of TP53 alterations than that of carcinoid (p<0.001, p<0.001). SCLC patients harbored more RB1 and PIK3CA mutations than LCNECs (p<0.001, p=0.014) and carcinoids (p<0.001, p=0.018). In addition, mutation frequencies of *LRP1B*, *FAT1*, *PRKDC*, *PIK3CA*, *NOTCH1*, *SPTA1* and *EPHA3* in SCLC were significantly higher than that in carcinoid. Mutations in *TP53* and *RB1* occurred concurrently in 83% (29/35) SCLC patients, whereas in only 32.3% (10/31) LCNECs. (Fig.1) We further investigated the distribution of mutations across KEGG pathways and found that mutation frequencies in both HIF-1 and Notch signaling pathways were lower in LCNEC than SCLC (p=0.032, p=0.025). Copy number variation (CNV) analysis revealed that LCNEC and SCLC had comparable CNVs which were significantly higher than carcinoid (p<0.001, p<0.001) and atypical carcinoid (p=0.010, p=0.028). TMB analysis also revealed a comparable TMB status of LCNEC (12.7/Mb) and SCLC (11.9/Mb), and relatively lower TMB in both carcinoid (2.4/Mb, p<0.001, p<0.001) and atypical carcinoid (5.6/Mb, p=0.003, p=0.009) than LCNEC and SCLC.



Conclusion: We demonstrated the differential genomic characteristics in the four subtypes of neuroendocrine carcinomas. Compared with SCLC, LCNEC has lower mutation frequencies in *RB1*, *PIK3CA*, as well as HIF-1 and Notch signaling pathways. In addition, LCNEC and SCLC had comparable CNV and TMB status, which significantly higher than that of carcinoids and atypical carcinoid.

Background: Background: Accounting for 15% of all lung cancer diagnoses, small cell lung cancer (SCLC) is an aggressive malignancy with dismal clinical outcomes, due in part to failure to define clinical biomarkers predictive of unique, targetable vulnerabilities. Recent data has begun to delineate molecular subsets of SCLC by uncovering inter-tumoral heterogeneity in features such as DNA damage response, EMT, and neuroendocrine (NE) status. However, it remains unclear whether the subsets defined by these features are predictive of response to cancer therapies and could be employed as patient selection criteria. **Method:** Methods: Using RNAseq data from 81 resected SCLC tumor samples and 62 SCLC cell lines, we applied non-negative matrix factorization (NMF) to optimize delineation of transcriptionally defined clusters. Reverse phase protein array (RPPA) and drug response data for cell lines were analyzed post-clustering to compare features between clusters. Clustering analyses were validated *in vivo* using CTC-derived patient xenograft (CDX) models, while single-cell RNAseq (scRNAseq) from these same models was used to assess intratumoral heterogeneity among clusters. **Result:** Results: NMF identifies four biologically distinct clusters among SCLC tumor samples and cell lines, each defined almost solely by differential expression of the transcription factors *ASCL1* (SCLC-A, 36%), *NEUROD1* (SCLC-N, 31%), and

POU2F3 (SCLC-P, 16%), including a cluster defined by the absence of all three (SCLC-Inflamed/Mesenchymal, or SCLC-IM, 17%). SCLC-A are neuroendocrine, epithelial tumors with susceptibility to drug classes including BCL-2 inhibitors. SCLC-N are neuroendocrine, cMYC-high tumors with susceptibilities including Aurora kinase inhibitors that are neither epithelial nor mesenchymal. SCLC-P are non-neuroendocrine, epithelial tumors vulnerable to PARP inhibitors and nucleoside analogs. Lastly, SCLC-IM consists of mesenchymal, non-neuroendocrine tumors with high-expression of immune checkpoints, STING-related genes, and inflammatory markers that may represent those SCLC which are sensitive to immune checkpoint blockade. scRNAseq reveals intratumoral heterogeneity among cluster assignment within tumors that fluctuates coincident with the onset of therapeutic resistance. **Conclusion:** Conclusions: SCLC tumors can be assigned to one of four molecular subtypes on the basis of differential expression of three transcription factors. These subtype assignments reflect profound distinctions in underlying biology and susceptibility to a range of candidate drug classes. While subtype assignment on a single-cell basis within a tumor is largely homogeneous, rare cells from distinct subtypes (or representing multiple subtypes), as well as shifting assignments following treatment indicate the possibility of subtype-switching, or subtype-selection, as mechanisms of therapeutic resistance.

Background: Immune-checkpoint inhibitors (ICIs) have shown promising activity in only a fraction of patients with small cell lung cancer (SCLC), and factors associated with clinical benefit are not well characterized. The development of immune-related adverse events (irAEs) may correlate with benefit from immune checkpoint inhibitors (ICIs) among patients with cancer. Whether an association exists between irAE development and improved clinical outcomes to ICIs in small cell lung cancer (SCLC) is unknown. **Method:** We retrospectively analyzed data from five participating academic centers: the Dana-Farber Cancer Institute, East Carolina University, Columbia University, Beth Israel Deaconess Medical Center, and Johns Hopkins University. Patients with SCLC who received at least one dose of a programmed death (ligand) PD-(L)1 inhibitor alone or in combination with a cytotoxic T-lymphocyte associated protein 4 (CTLA-4) inhibitor were included in this study. To account for the time-dependent nature of irAE onset and clinical benefit from immunotherapy, we identified patients with early irAEs (defined as those occurring within 6 weeks of ICI treatment initiation) and performed a landmark analysis at this time point. **Result:** Among 157 patients treated with ICIs, 65 (41.4%) experienced at least one irAE. Median time to the first irAE onset was 28 days (IQR:15-56). Baseline clinicopathologic characteristics were well balanced between patients who developed irAEs and those who did not. Median tumor mutational burden (TMB) was significantly higher among patients with irAEs compared to those without (14.4 vs 8.4 mutations/megabase [mut/Mb], P <0.01). Patients who developed at least one irAE had a significantly higher objective response rate (26.3% versus 3.3%, P <0.001), and significantly longer median progression-free survival (mPFS, 4.1 vs 1.3 months, HR: 0.30 [0.20-0.43, P <0.001]) and median overall survival (mOS, 14.1 vs 2.9 months, HR: 0.32 [0.21-0.48], P <0.001). The proportion of patients who were progression-free at 6, 9, and 12 weeks was significantly higher in patients who developed early irAEs compared to those who did not develop early irAEs (6 weeks: 89.5% vs 69.5%, P =0.01; 9 weeks: 71.1% vs 40%, P =0.001; 12 weeks: 65.8% vs. 31.6%, P <0.001). The median TMB was also significantly higher in patients who developed early irAEs (14.5 vs 8.7 mut/Mb, P <0.01). **Conclusion:** Patients with SCLC treated with ICIs who developed early irAEs had a higher TMB and enhanced antitumor responses compared to those who did not develop irAEs. Whether a higher TMB is associated with the development of irAEs remains to be determined mechanistically.

Background: Lung-MAP is a master protocol for patients (pts) with stage IV previously treated SqNSCLC. S1400I enrolled pts who were not eligible for a biomarker-matched sub-study. (Lung-MAP Sub-Study S1400I, NCT02785952) **Method:** S1400I is phase III randomized trial for immunotherapy-naïve patients with ECOG 0-1 not selected by PD-L1 expression. Pts were assigned 1:1 to nivolumab and ipilimumab (N+I) vs nivolumab (N). N was given at 3 mg/kg q 2w, I was given at 1 mg/kg q 6w. The primary endpoint was overall survival (OS). Secondary endpoints: investigator-assessed progression-free survival (IA-PFS), response by RECIST 1.1, and toxicity. **Result:** From December 18, 2015 to April 23, 2018, 275 pts enrolled and 252 determined eligible (125 N+I and 127 N). Median follow up for patients still alive was 17.4 months. The study was closed for futility at an interim analysis. Baseline characteristics were similar across arms. mOS was 10.0 m (8.0-12.8) and 11.0 m (8.2-13.5) for N+I and N. HR 0.97 (0.71-1.31), p 0.82. mPFS was 3.8 m (2.3-4.2) and 2.9 m (1.8-3.9) for N+I and N. HR 0.84 (0.64-1.09), p 0.19. The response rate was 18% (12-25) in N+I and 17 % (11, 24) in N. Outcomes were similar across TMB subgroups and PD-L1 expression levels. Most AE were low grade. There were 5 grade 5 AE in N+I arm and 1 in N arm. Grade ≥3 treatment-related AEs occurred in 48(39%) of pts on N+I vs 38(31%) on N. irAE reported in 39% of pts on N+I and 34% of patients on N. Drug-related AEs led to discontinuation in 25% of pts on N+I and 16% of pts on N.

OS and PFS based on TMB and PD-L1				
	N+I Median in months	N Median in months	HR	p
OS PD-L1 ≥5	14.1 (5.8-17.5)	12.0 (8.2-19.8)	1.06 (0.58-1.92)	0.86
OS PD-L1 <5	8.3 (6.0-10.7)	10.3 (6.3-13.5)	1.01 (0.62-1.65)	0.97
OS TMB ≥10	13.1 (9.3-17.0)	11.4 (8.2-16.1)	0.86 (0.56-1.32)	0.48
OS TMB <10	7.6 (5.7-10.2)	10.0 (6.3-15.2)	1.08 (0.68-1.71)	0.74
PFS PD-L1 ≥ 5	3.9 (1.7-7.1)	2.9 (1.8-4.7)	0.65 (0.38-1.08)	0.10
PFS PD-L1 <5	4.4 (2.1-6.0)	1.6 (1.5-3.0)	0.64 (0.41-1.01)	0.06
PFS TMB ≥ 10	4.2 (3.4-5.9)	3.4 (1.8-5.3)	0.75 (0.52-1.10)	0.15
PFS TMB < 10	1.9 (1.5-4.1)	2.7 (1.6-3.3)	0.92 (0.62-1.39)	0.70

Conclusion: S1400I failed to show improvement in outcomes with N+I. Study was closed for futility at interim analysis. Toxicities were not different between two arms. Molecular correlates will be presented at the meeting.

Background: Platinum-based chemotherapy remains 1st line therapy for advanced non-small cell lung cancer (NSCLC) without oncogenic drivers in China. Camrelizumab (SHR-1210, a potent anti-PD-1 monoclonal antibody) has shown promising activity in multiple malignancies. Here, we report interim analysis results on efficacy and safety of camrelizumab plus carboplatin/pemetrexed as 1st line treatment in Chinese advanced/metastatic non-squamous NSCLC patients with negative oncogenic drivers. **Method:** In this open-label, randomized, multicenter phase 3 study (SHR-1210-303), patients with advanced/metastatic, non-squamous NSCLC with negative EGFR or ALK were stratified by sex and smoking history (≥ 400/year versus < 400/year) and were randomly assigned (1:1) to receive 4 to 6 cycles of carboplatin (AUC=5) plus pemetrexed (500 mg/m2) with or without camrelizumab (200 mg), followed by pemetrexed with or without camrelizumab as maintenance therapy up to disease progression or intolerable toxicity. Treatment was given every 3 weeks. Crossover to camrelizumab monotherapy was permitted for patients in the chemotherapy arm who had confirmed disease progression. The primary endpoint was PFS per blinded independent central review according to RECIST v1.1. Secondary endpoints

included ORR, DCR, DoR and OS. Data of subgroup analysis will be reported. Clinical Trials.gov number: NCT03134872. **Result:** Between May 12, 2017 and Jun 6, 2018, 419 patients were randomized, among whom 205 received camrelizumab plus chemotherapy and 207 received chemotherapy treatment. After a median follow-up of 11.9 months, median PFS was 11.3 months (95% CI 9.5-not reached) in camrelizumab plus chemotherapy arm and 8.3 months (95% CI 6.0-9.7) in chemotherapy arm (HR 0.61 [95% CI 0.46-0.80], p=0.0002). ORR, DCR, DoR and OS with camrelizumab plus chemotherapy were superior to chemotherapy (Table 1). Grade 3/4 adverse events occurred in 66.8% of patients in camrelizumab plus chemotherapy arm and 51.2% of patients in chemotherapy arm. There were 5 treatment-related deaths in camrelizumab plus chemotherapy arm and 4 in chemotherapy arm.

Table 1. Responses per blinded independent central review and overall survival in the total study population

	Camrelizumab plus chemotherapy (n=205)	Chemotherapy alone (n=207)	p-value
Objective response rate	60.0% (53.0-66.8)	39.1% (32.4-46.1)	p<0.0001
Disease control rate	87.3% (82.0-91.6)	74.4% (67.9-80.2)	p=0.0009
Duration of response (months)	17.6 (11.6-NR)	9.9 (8.5-13.8)	p=0.0356
Overall survival (months)	NR (17.1-NR)	20.9 (14.2-NR)	p=0.0272

Data are shown in % (95% CI) or median (95% CI). NR: not reached.

Conclusion: First-line camrelizumab plus chemotherapy shows substantial clinical benefit in patients with advanced/metastatic non-squamous NSCLC with negative EGFR or ALK in terms of PFS, ORR, and OS and acceptable safety profiles. The combination should become novel standard 1st line therapy for this population.

Background: Dysphagia (difficulty swallowing) and dysphonia (impaired voice) have been identified in patients with lung cancer as being a significant problem. However, research to date has been limited in its measurement and it remains unknown which patients experience dysphagia or dysphonia, and what the impact of these problems are to the patient. The purpose of this study was to identify the prevalence and nature of dysphagia and dysphonia in patients with limited stage SCLC. **Method:** A prospective cohort pilot study was conducted on 12 patients receiving chemoradiotherapy for limited-stage SCLC. Data collection included: videofluoroscopy swallowing studies (VFSS) to investigate swallowing physiology, aspiration risk and oesophageal motility disorders; limitations to oral intake; patient-reported swallowing problems; and patient-reported

voice problems. Data were collected before treatment and again at one, three and six months post-treatment. **Result:** No patient was observed to aspirate, and the pharyngeal swallow was safe and functional in all cases. Three patients exhibited oesophageal motility disorders before treatment, while three more exhibited these disorders at the post-treatment assessments. Oral intake was most compromised one month post-treatment; at this time one patient was tube dependent, two required a single consistency diet and two had a diet requiring special preparation. At all other time-points patients were managing a normal or near-normal diet. Despite an absence of oropharyngeal dysphagia observed on VFSS, three patients reported moderate or severe swallowing difficulties one month post-treatment; these self-reported difficulties were no more than mild at follow-up assessments. Three additional patients reported the onset of moderate or severe swallowing difficulties at three and six months post-treatment. Patients who reported swallowing difficulties at one month post-treatment had all received a mean radiation dose to the oesophagus of ≥15.7Gy and a maximum dose to the oesophagus of ≥42Gy, however these relationships were no longer apparent at three and six months post-treatment. Patient-reported voice difficulties were variable, with the worst scores being reported at one month post-treatment for a subset of patients, who continued to report problems across voice-related physical, functional and emotional domains at three and six months post-treatment. **Conclusion:** This is the first time that detailed swallowing and voice outcomes have been reported in patients with SCLC. Although patient numbers are small, this study identified discordance between observed swallowing function and patient-reported problems, which may have significant clinical implications for the management of patients with SCLC, as well as identify important issues for future research.

OA05.02 PATIENT EXPERIENCE, EXPECTATIONS AND KNOWLEDGE: LUNG CANCER IN AUSTRALIA

C. Holliday

Centre for Community-Driven Research, Genéve/Switzerland

Background: Lung cancer is the fourth most diagnosed cancer in Australia. In 2015, it was the fourth most common cause of death and the most common cause of cancer death. There were over 11,000 new cases of lung cancer in 2013, with more men (approximately 6,600) than women (approximately 4,500) diagnosed. In 2014, more than 8000 people in Australia died from lung cancer, nearly 5000 of whom were men. Patient Experience, Expectations and Knowledge (PEEK) is a research study developed by the International Centre for Community-Driven Research (CCDR). PEEK studies conduct patient experience research using a protocol that will allow for comparisons over time (both quantitative and qualitative components). This study in NSCLC is the largest mixed methodology study in Australia in the past five years. **Method:** In this study, 80 people with NSCLC stages I to IV throughout Australia participated in a structured (qualitative) interview and an online (quantitative) questionnaire. The interview and questionnaire comprehensively covered all aspects of disease experience from symptoms, diagnosis, treatment, communication, information provision, care and support, quality of life, and future treatment and care expectations. Statistical analysis of quantitative data was conducted using R, and content analysis of qualitative data was conducted using conventional analysis to identify major themes. **Result:** The most common symptom experienced before diagnosis was back and/or shoulder pain (n=35, 43.75%), and the most common symptoms leading to diagnosis was breathing difficulties (n=26, 32.50%). The majority (n=58; 72.50%) of participants knew nothing or very little about lung cancer at diagnosis, and the most commonly reported theme relating to discussion about treatment was that patients were presented with only one treatment plan, with little discussion about treatment options (n=36; 45.00%). There were 76.25% (n=61) of this study population that reported receiving support primarily from family and friends. Quality of life was negatively affected in 85.00% (n=68) of the study population, the most common reason being due to the emotional and physical impact on patients and family (n=44; 55.00%). There were 51.25% (n=41) of the study population that reported relationships being strengthened, despite 75.00% (n=60) of the study population reporting feeling burdensome to their family. In relation to future needs, 53.75% (n=43) of participants called for access to treatments to be more affordable and equitable; for information to address stigma and educate the public in relation to causes of lung cancer (n=16, 20.00%); for clinicians to display more compassion/empathy (n=20, 25.00%); and for support more groups and peer support (n=17, 21.25%). **Conclusion:** Based on patient experience and feedback, three recommendations are made to improve patient quality of life and/or ability to manage their own health: Public health campaigns developed to prevent lung cancer should be developed in a way that protects people currently diagnosed from the impact of negative stigma. Information and support services, including support for carers, should be more targeted to specific disease staging and sub-types of disease. Research funding should reflect the mortality and prevalence of lung cancer, and the number of clinical trials available should increase to aid timely decisions about new treatments.

OA05.03 DEVELOPMENT OF A FATIGUE AND BREATHLESSNESS GROUP FOR THORACIC ONCOLOGY PATIENTS

P. Labuc, F. Dickinson

Guys Hospital, London/United Kingdom

Background: Cancer related fatigue and breathlessness are well-established common symptoms of lung cancer, with 57%-100% of all lung cancer patients experiencing cancer related fatigue and 19%-51% experiencing dyspnoea. Both symptoms can be highly subjective and distressing for the individual, impacting on all domains of their life: physical, social and emotional. Due to this fatigue, dyspnoea and anxiety are a symptom cluster effecting up to 96% lung cancer patients, and is associated with poor performance status and reduced patient reported quality of life (QoL). In order to address this the symptoms of fatigue, breathlessness and anxiety need to be addressed concurrently in order to ensure the best results for the individual and improve QoL. **Method:** A literature review was completed using online journal libraries to determine the incidence and impact of fatigue and breathlessness on lung cancer patients, as well as the most effective symptoms management interventions. Following this, patients attending the thoracic oncology outpatient clinics at Guy's Cancer Centre completed a questionnaire to determine: 1. The incidence fatigue, breathlessness and mood changes 2, Their individual experience of the symptoms 3. If the symptoms are impacting on QoL 4. Would they want to attend a group to address these symptoms 5. The preferred location, time and frequency of the group Outcome measures to address the symptoms were reviewed to ensure that those with the highest validity were selected for use. **Result:** A six session group was developed, using the Breathing, Thinking Functioning model at its core, to ensure that the sessions address all domains of the patients life, as well as the mechanisms of dyspnoea. Sessions also addressed fatigue and sleep hygiene, once again addressing the issues holistically. Each session consists of both an educational element, to address the subject of the week, followed by a practical session to allow for practice of the techniques provided and assist the individuals to gain mastery of these. In order to gain both qualitative and quantitative data, patients complete the FACIT-Fatigue, EORTC QLQ-C30, Dyspnoea 12 and individual goal setting prior to commencing the programme. The individual goals are discussed with the clinician when attending the initial session to ensure that these are addressed during the group. On completion of the session these assessment are repeated in order to determine the impact that the group has had on all symptoms as well as the individuals QoL. **Conclusion:** Fatigue and breathlessness are debilitating side effects of a lung cancer diagnosis, which result in both physical and emotional changes for the patient. In order to address these symptoms holistically they need to be address concurrently, as well as addressing the impact they have on anxiety and depression. By providing a structured group programme to address these symptoms and the impact they have on the individual, it allows patients to master skills to reduce the impact of these symptoms, as well as promote self-management and improve QoL.

OA05.06 NURSING INTERVENTION ON IMMUNO-RELATED ADVERSE EVENTS IN LUNG CANCER PATIENTS

M. Arellano, I. Brao, M.P. Fernández

Institut Català d'Oncologia, L´Hospitalet de Llobregat/Spain

Background: New treatment of immunotherapy permits to stimulate the patient's immune responses against cancer. That it supposes a new strategy for melanoma, renal and lung cancers. Although, is different than Chemotherapy's toxicity, the effect on tissues and organs are systemic and can be dealing to unpredictable side-effects that should be detected and treated as soon as possible. Nurses are vital to manage toxicity related to immunotherapy & educate and to provide patient's with best education. Our objetive is to describe lung cancer clinical nurses specialists' role on the management of toxicities related to immunotherapy in lung cancer patients. How is the control and follow–up for those patients **Method:** In 2018, a cross-sectional study was conducted with lung cancer patients receiving immunotherapy at the Lung Functional Unit of Catalan Institute of Oncology, hospital Duran I Reynals in Barcelona-Spain. The variables included were socio-demographic profile, the clinical were; tumour histological, toxicities prevalence and severity and finally variables from the roles and references made by nurses. A descriptive analysis of prevalence was performed with type of toxicities and patient characteristics. **Result:** New patients receiving immunotherapy were 69 and the most common toxicities were; asthenia (82.5%), skin toxicity (35.5%), Pneumonitis (22.5%), colitis (20%), arthralgia (12.5%), endocrine toxicity (12.5%), emesis (10%), vascular (7.5%), gastritis (5%), hepatic (5%), renal (5%) & neurologic (5%). Attending grading severity, it was GI-GII, both were controlled by nurses, GIII and GIV required specialists, hospitalization and other professionals. Nurses visited 95% of the patients previously to initiate their treatments, attended 128 phone calls and in 111 patients they realised the follow-up and control. From total a 50% need emergency services and finally got hospitalization in 30% of them. **Conclusion:** Grades I and II are the most common toxicity. Nurses were in charge for patient education, providing careful information to patients, family members and caregivers, along the whole process. This role is vital to get better and earlier control on the side-effects, higher satisfaction and to facilitate the multidisciplinary team-working dynamic.

OA05.07 CO-OPERATION BETWEEN THE CITIES OF GLASGOW AND BETHLEHEM AND THE DEVELOPMENT OF A CANCER NURSING DIPLOMA AT BETHLEHEM UNIVERSITY PALESTINE

G. O Hare

Glasgow & Clyde Health Board, Alexandria/United Kingdom

Background: Cancer is a serious public health issue in Palestine. The impact of the conflict between Palestine and Israel has a negative impact on the diagnosis and treatment of cancer patients. In addition, the political situation has hindered the development of effective cancer nursing reflective practice and education for Palestinian nurses. A meeting between Gerry O Hare (oncology CNS Glasgow and Clyde Health Board) and Mariam Awad (Dean of Nursing Bethlehem University) in 2011 led to an exploration of opportunities for cancer nursing educational initiatives between Glasgow, Scotland and Bethlehem Palestine. Support for cancer nurses education was secured from Glasgow Health Board, the office of Lord Provost of Glasgow, Bethlehem University, Medical Aid for Palestine, European Oncology Nursing Society, Palestinian Dept of Health, and supportive UK and Bethlehem nurse academics. This multi-agency commitment and support resulted in the launch of the first Post-Graduate High Diploma in Cancer/Palliative nursing in Palestine by the Nursing Department at Bethlehem University Palestine in 2016. This is an example of motivated nurses from geographical distant countries positively influencing agencies to develop a pioneering cancer/palliative care nurse educational high diploma programme at Bethlehem University, Palestine. This initiative sends a message to cancer nurses globally to encourage them to cross cultural, political and geographical barriers to achieving positive outcomes for cancer nurse education. **Method:** Section not applicable **Result:** Section not applicable **Conclusion:** Section not applicable

OA06.01 COMPARISON BETWEEN RADIOMICS-BASED MACHINE LEARNING AND DEEP LEARNING IMAGE CLASSIFICATION FOR SUB-CM LUNG NODULES

I. Janzen[1], S. Seyyedi[1], R. Abraham[1], S. Atkar-Khattra[2], J. Mayo[3], R. Yuan[4], R. Myers[2], S. Lam[2], C. Macaulay[5]

[1]*Integrative Oncology, BC Cancer Research Center, Vancouver/Canada,* [2]*Department of Integrative Oncology, British Columbia Cancer Research Center, Vancouver/Canada,* [3]*Dept. Radiology, Vancouver General Hospital, Vancouver/Canada,* [4]*Diagnostic Imaging, BC Cancer Vancouver Center, Vancouver/Canada,* [5]*Integrative Oncology, BC Cancer Research Centre, Vancouver/Canada*

Background: New clinical challenges have arisen from the recent recognition for an improved mortality of cancers via lung cancer screening using LDCT. A particular challenge for physicians and CADx systems is the classification and prediction of behavior for sub-cm lung nodules that are frequently present in screening CT scans. By predicting and classifying the behavior of these small nodules, we can identify potential cancerous nodules into the earlier stages of malignancy making them more easily treatable. **Method:** We have evaluated a multitude of image processing techniques to assist in CADx systems for these small nodules such as Radiomic feature-based machine learning algorithms (linear discriminant analysis) as well as leveraging pretrained convolution neural networks such as VGG19 and InceptionV3 using deep learning/transfer learning techniques. The linear discriminate Radiomic analysis (LDA) classified a sample of CT imaged nodules (n=514) using quasi-volumetric nodule data (images of the nodules from CT slices above and below the central slice) into three discriminate categories: cancerous (clinically confirmed, n = 140) versus resolved (not present in follow up CT scans, n=107) versus stable (a negligible change in shape, texture, size in multi year follow up CT scans, n=267). Each nodule was segmented from the original CT scan using an inhouse lung CT image segmenation routine. This routine generated 2167 discrete CT nodule images upon which 133 Radiomic shape and texture features were calculated. **Result:** The LDA Radiomic analysis correctly

classified the individual nodual sections with an accuracy of 75.1% (jackknife - leave one out result) using only 18 features predefined traditional image analysis features (4 shape feature(s), 14 texture feature(s)) for cancer vs resolved + stable nodules. Requiring that more than or equal to 50% of sections from a nodule be classified as cancer for the nodule to be classified as cancer individual nodules could be correctly classified with an 80% accuracy. The leveraged pretrained networks (VGG19, and InceptionV3) trained using standard data augmentation and finetuning techniques, trained on this same quasi-volumetric image data as a binary classification task (malignant vs. benign nodules) achieved an average classification accuracy of 71% and 75% respectively through 10-crossfold validation. **Conclusion:** Machine learning using 18 Radiomics features was able to classify 75.1% of the 2167 CT nodule images (up to 5 images/CT slices per nodule) and 80% of the nodules correctly. The best of the Deep Learning networks achieved almost equivalent results. The image classification deep neural network results suggest the implementation of more advanced regularization and initialization deep learning techniques to further refine the decision boundaries for these pretrained networks might be benefitial. We believe the development of visualization neural network software to highlight the defining nodule features during classification would clinically assist in providing context clues for nodule diagnosis. This work has been supported by TFRI project ref:1068

OA06.03 AN OPEN SOURCE LUNG SCREENING MANAGEMENT SYSTEM

C. Henschke[1], A. Reeves[2], R. Avila[3], D. Moghanaki[4], A. Jirapatnakul[1], D. Yankelevitz[1]

[1]*Icahn School of Medicine at Mount Sinai, New York/United States of America,* [2]*Cornell University, Ithaca/United States of America,* [3]*Accumetra, Clifton Park/United States of America,* [4]*Atlanta Veterans Affairs Health Care System, Decatur/United States of America*

Background: Starting in 1992, the Early Lung Cancer Screening Project (ELCAP) investigators developed the ELCAP Management System (MS) to ensure high quality care and follow-up of the first 1,000 ELCAP participants. The resulting Lancet publication in 1999 created worldwide interest in screening and an updated web-based ELCAP MS was updated to be web-based and provided free of charge to participating institutions, together with the I-ELCAP protocol. **Method:** The ELCAP MS was designed to be comprehensive and rapidly capture information on each participant to be used by coordinators, navigators, nurses, radiologists, and other medical professionals to ensure appropriate follow-up and care. It provides rapid documentation of telephone or other inquiries, registering, scheduling screening appointments, reporting results, diagnosis of lung cancer, and treatment, and archives all CT images for integrated access of image and patient information. It has been iteratively updated through user feedback, and supports medical reimbursement requirements and continuous quality improvement to minimize harms of lung screening across International ELCAP (I-ELCAP) sites. **Result:** More than 81,000 participants in 80 institutions worldwide have contributed their LDCT findings and images. The MS has provided efficient data collection for rigorous assessment of screening outcomes which has resulted in some 300 publications and abstracts for protocol updating, comparisons, and continuous quality improvement. Having anticipated "open science", the ELCAP MS has been translated into an open source MS that offers a reference standard for data elements (1,500 data fields, 267 required) for robust and efficient management of lung screening programs. This first open source translation has been adopted by the United States Veterans Administration (VA) and integrated into its VistA Electronic Healthcare System for deployment at 10 VA medical centers through a grant for VA Partnership to increase Access to Lung Screening (VA-PALS). The software is being certified by the Open Source Electronic Health Record Alliance (OSEHRA); source code is available on GitHub. Automated quantitative tools have been developed for identification and characterization of nodules, emphysema, major airways, calcification scoring of coronary arteries, aortic valve, thoracic aorta, breast tissue, liver, bone, and image quality. These tools are integrated into the ELCAP MS, and in the future will provide automatically-generated quantitative LDCT reports. **Conclusion:** The ELCAP MS and I-ELCAP protocol have helped define current global standards for lung screening. Its developers have now made the ELCAP MS publicly available through OSEHRA for support of lung screening programs of any scale throughout the world.

OA06.05 EVALUATION OF A DEEP LEARNING-BASED AUTOMATIC CLASSIFIER FOR THE CLASSIFICATION OF PERIFISSURAL NODULES

D. Han[1], M. Heuvelmans[1,2], M. Rook[1,3], M. Dorrius[1], L. Van Houten[1], N. Waterfield Price[4], L. Pickup[4], P. Novotny[4], J. Declerck[4], M. Oudkerk[5], P.M.A. Van Ooijen[1], F. Gleeson[6], R. Vliegenthart[1]

[1]*University Medical Center Groningen, University of Groningen, Groningen/Netherlands,* [2]*Medisch Spectrum Twente, Enschede/Netherlands,* [3]*Martini Ziekenhuis, Groningen/Netherlands,* [4]*Optellum Ltd., Oxford/United Kingdom,* [5]*University of Groningen, Groningen/Netherlands,* [6]*Oxford University Hospitals NHS Foundation Trust, Oxford/United Kingdom*

Background: Perifissural nodules (PFNs) comprise approximately 20% of screening-detected nodules and are almost certainly benign. Automatic PFN classification could therefore reduce the number of follow-up procedures required for nodule work-up. Prior work has shown some success in AI classification with limited datasets. Here we evaluate the performance of a new deep convolutional neural network (CNN) for PFN classification, trained on a dataset of nodules retrospectively collected from multiple European centers, including validation on an independent reader-study dataset. **Method:** Data (1103 Patients, 1557 unique nodules and 3320 nodule images) were collected from three centers in the UK and the Netherlands. Each nodule was categorized into subtypes, including "PFN", by on-site radiologists. Labels were reviewed centrally, overseen by a single clinician to ensure consistency between sites. A CNN classifier was trained to produce a score that classifies nodules as (typical) PFN or not, using five-fold cross validation. The PFN classifier was developed by "transfer learning" from an existing benign-vs-malignant AI trained on the US National Lung Screening Trial. To compare the CNN with human performance, independent validation was performed on a separate dataset of 158 benign patients (196 nodules/nodule images) from two of the sites. Three readers (two radiologists and a radiology resident) were asked to label each nodule as typical PFN, atypical PFN, or non-PFN. To match the AI training procedure, only the typical-PFN labels were used in the reader study, and compared to atypical/non-PFN classified nodules. Model performance was evaluated by area under the ROC curve (AUC). For the independent validation, Cohen's kappa was used to measure both the model's agreement with reader consensus (at least 2 in agreement) and inter-reader agreement. For Cohen's kappa calculations the CNN score was binarized using a threshold determined from the internal validation data. **Result:** The mean cross-validated AUC on the internal dataset was 92% (95% CI = 90.6–92.9). For the independent dataset, the classifier labelled 61/196 (31%) as typical PFNs, and reader consensus gave 45/196 (23%). Versus reader consensus, the AUC of the CNN on the reader-study dataset was 96% (95% CI 93.3–98.4). Both the classifier–reader agreement [(k=0.74) 90%] and the inter-reader agreement [(k=0.64–0.79) 88%-92%] were substantial. **Conclusion:** The performance of the PFN classifier is similar to that of radiologists and is within the inter-reader variability of radiologists. This demonstrates the potential utility of CNN-based systems for automatic PFN classification.

Keywords: deep learning, Artificial Intelligence, perifissural nodules

OA06.06 INDEPENDENT VALIDATION OF A NOVEL HIGH-RESOLUTION COMPUTED TOMOGRAPHY-BASED RADIOMIC CLASSIFIER FOR INDETERMINATE LUNG NODULES

T. Peikert[1], F. Duan[2], S. Rajagopalan[1], R. Karwoski[1], A. Balar[3], D. Lakhani[3], S. Antic[3], B. Bartholmai[4], J. Tucker[4], P. Massion[3], F. Maldonado[3]

[1]*Mayo Clinic Rochester, Rochester/United States of America,* [2]*Brown University School of Public Health, Providence/United States of America,* [3]*Vanderbilt University Medical Center, Nashville/United States of America,* [4]*Mayo Clinic, Rochester/United States of America*

Background: Optimization of the clinical management of incidentally- and screen-identified lung nodules is urgently needed to limit the number of unnecessary invasive diagnostic interventions, and therefore morbidity, mortality and healthcare costs. We recently developed and internally validated a novel radiomics-based approach for the classification of screen-detected indeterminate nodules, and present herein validation of this algorithm in an independent cohort. **Method:** In a previous study, we developed a multivariate prediction model evaluating independent quantitative variables assessing various radiologic nodule features such as sphericity, flatness, elongation, spiculation, lobulation and curvature. Nodules between 7 and 30 mm of largest diameter were selected from the National Lung Screening Trial (n=726 indeterminate nodules, benign (n = 318) and malignant (n = 408)) were used to derive this model using least absolute shrinkage and selection operator (LASSO) method with bootstrapping method applied for the internal validation. Eight variables capturing vertical location, size, shape, density and surface characteristics were included with an optimism-correct area under the curve (AUC) of 0.94. For this study, an independent dataset of 203 incidentally-identified lung nodules obtained from the indeterminate pulmonary nodule registry at Vanderbilt University was identified. CT datasets were transferred to Mayo Clinic (Rochester, MN) for analysis. Nodules were segmented manually using the ANALYZE software (Biomedical Imaging Resource, Mayo Clinic, Rochester, MN), and radiomic analysis was performed using the 8-variable radiomic diagnostic algorithm derived from the NLST. The Brock model was also used to calculate probability of malignancy for all NLST and Vanderbilt nodules. **Result:** Brock scores were calculated for 685 NLST nodules (excluded: interval cancers, n=12; missing values needed for Brock score, n=29). The AUC for the Brock score (AUC_{Brock}) for NLST nodules was 0.83 which was inferior to the AUC for the radiomic model ($AUC_{Radiomic}$ =0.94, P<0.001). When the subset of intermediate pre-test probability of lung cancer was considered (Brock score > 10 but <= 60), the AUC_{Brock} was 0.61 (95% CI: 0.54-0.68) whereas the $AUC_{Radiomic}$ was 0.88 (95% CI: 0.84-0.93). A total of 203 incidentally found pulmonary nodules with available clinical information and biopsy or surgery-proven histology identified in the Vanderbilt indeterminate pulmonary nodule registry, and all histology data and corresponding CT images were reviewed. CT images were transferred to Mayo Clinic for analysis. After exclusion of duplicate CT datasets, unanalyzable CT images and not identifiable nodules (n=27 cases), 176 nodules were segmented and analyzed, including 84 benign and 92 malignant nodules. The AUC was 0.89 (95% CI: 0.85-0.94). For comparison, the AUC_{Brock} was 0.88 (95% CI: 0.83-0.94). When the subset of intermediate pre-test probability of lung cancer was considered (Brock score > 10 but <= 60), the AUC_{Brock} was 0.76 (95% CI: 0.63-0.89) whereas the $AUC_{Radiomic}$ was 0.85 (95% CI: 0.74-0.95). **Conclusion:** Our radiomic classifier demonstrates good performance characteristics on an independent retrospective validation dataset. If prospectively validated, integration into clinical decision making algorithm could significantly impact patient care.

OA06.07 DISCRIMINATION OF LUNG INVASIVE ADENOCARCINOMA WITH MICROPAPILLARY PATTERN BASED ON CT RADIOMICS

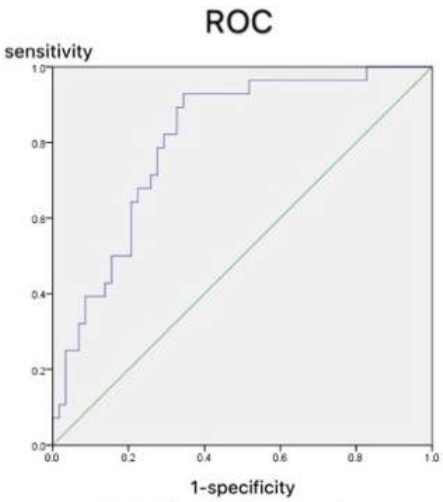
Y. Xu[1], W. Ji[1], L. Hou[2], C. Zhou[2], W. Wang[2], S. Zhou[3], F. Kong[2], H. Yang[2]

[1]*Radiology, Affiliated Taizhou Hospital of Wenzhou Medical University, Taizhou/China,* [2]*Radiation Oncology, Radiation Oncology Institute of Enze Medical Health Academy, Affiliated Taizhou Hospital of Wenzhou Medical University, Taizhou/China,* [3]*Department of Radiation Oncology, The Affiliated Taizhou Hospital, Wenzhou Medical University, Taizhou/China*

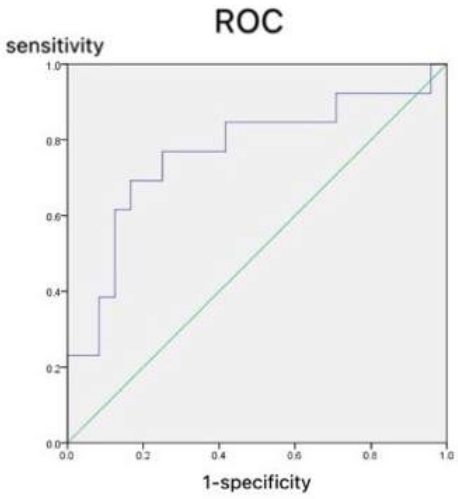
Background: To develop and validate the radiomics nomogram on the discrimination of lung invasive adenocarcinoma (IAC) with micropapillary pattern from non-micropapillary pattern lesion and improve the diagnostic accuracy rate of lung invasive adenocarcinoma with micropapillary pattern before operations and provide guidance for follow-up treatments. **Method:** Forty-one pathologically confirmed lung invasive adenocarcinomas with micropapillary pattern from January 2014 to December 2018 were included. Eighty-two pathologically confirmed lung invasive adenocarcinomas without micropapillary pattern from January 2018 to December 2018 were collected. Select 86 patients (70%) randomly from the 123 patients as the primary cohort, and the other 37 patients (30%) were set as an independent validation cohort. Least absolute shrinkage and selection operator (Lasso) was used for feature selection based on contrast enhancement CT images and then radiomics signature building. ROC analysis and AUC were used to value the ability to identify the lung invasive adenocarcinomas with micropapillary pattern. **Result:** According to GrayLevelCooccurenceMatrix3, Intensity Histogram and Shape, nine hundred and eighty-five radiomics features were extracted by IBEX. And after data pre-processing such as eliminating missing items, strong correlation variables and multicollinear variables, the features were reduced to 40 features. Based on Mann-Whitney U Test, 28 features were figured out from the 40 features. Then Lasso was used to reduce the features to 3 features (10-1clusterprominenc, -333-4clusterprominence, 8-1contrast) as the most meaningful discriminators to build the radiomics signatures (Table 1). According to SPSS21.0 binary logistic regression analysis, ROC analysis and AUC show that the radiomics signature have effective discrimination performance of lung invasive adenocarcinoma with micropapillary pattern from non- micropapillary pattern lesion (AUC=0.766) and it reflects better in the independent validation cohort (AUC=0.807) (Figure 1).

Table 1 Three characteristic prediction parameters in radiomics label

prediction parameter	P value	U value	W value	AUC
10-1clusterprominence	<0.005	765.000	4168.000	0.772
-333-4clusterpromise	<0.005	790.000	4193.000	0.765
8-1contrast	<0.005	919.000	4322.000	0.727



P1. ROC of primary cohort (AUC=0.766)



P2. ROC of validation cohort (AUC=0.807)

Conclusion: The radiomics signature established in this study have effective prediction of lung invasive adenocarcinoma with micropapillary pattern and non- micropapillary pattern lesion.

MONDAY, SEPTEMBER 9 11:00–12:30

OA07.01 OSIMERTINIB PLUS PLATINUM/PEMETREXED IN NEWLY-DIAGNOSED ADVANCED EGFRM-POSITIVE NSCLC; THE PHASE 3 FLAURA2 STUDY

P. Jänne[1], D. Planchard[2], P. Howarth[3], A. Todd[3], K. Kobayashi[4]

[1]*Lowe Center for Thoracic Oncology, Dana-Farber Cancer Institute, Boston/United States of America,* [2]*Medical Oncology, Thoracic Group, Institut Gustave Roussy, Villejuif/France,* [3]*Astrazeneca, Cambridge/United Kingdom,* [4]*Saitama Medical University, Hidaka-City/Japan*

Background: Osimertinib is a third-generation, CNS-active EGFR-TKI that potently and selectively inhibits both sensitizing EGFR and T790M mutations. Osimertinib is considered the standard of care for patients with newly-diagnosed advanced/metastatic NSCLC harbouring EGFR-activating mutations, based on results of the phase 3 FLAURA trial, which demonstrated a statistically and clinically significant progression-free survival (PFS) benefit for osimertinib over erlotinib or gefitinib. Evidence indicates that adding chemotherapy to gefitinib improves efficacy outcomes versus EGFR TKI monotherapy in newly-diagnosed patients with EGFRm NSCLC (Nakamura et al JCO 2018;36:9005). Adding platinum/pemetrexed to osimertinib could further improve outcomes for newly-diagnosed patients with EGFRm-positive NSCLC. **Method:** The phase 3, open-label, FLAURA2 study aims to assess the efficacy and safety of osimertinib plus cisplatin/carboplatin plus pemetrexed in adults with locally-advanced/metastatic EGFRm-positive (Ex19del and/or L858R) NSCLC who have not received prior therapy for advanced disease. Patients are required to have a WHO performance status (PS) 0-1, life expectancy >12 weeks and not be amenable to curative surgery or radiotherapy. An initial non-randomised run-in phase (n=30) will assess the safety and tolerability of osimertinib 80 mg once daily (QD) with either cisplatin or carboplatin, and pemetrexed, both administered every 3 weeks (Q3W) for 4 cycles, followed by osimertinib 80 mg QD plus pemetrexed maintenance Q3W until progression or discontinuation. Based on evaluation of safety data from the run-in after ≥12 patients from each group have received ≥3 cycles of study treatment or discontinued therapy, the second phase will randomise approximately 556 patients 1:1 to receive osimertinib 80 mg QD with pemetrexed and cisplatin/carboplatin for 4 cycles followed by osimertinib plus pemetrexed maintenance Q3W or osimertinib alone (80 mg QD), to be continued until progression or discontinuation. Randomisation will be stratified by race (Chinese/Asian vs. non-Chinese/Asian vs. non-Asian), WHO PS (0 vs. 1), and tissue EGFR mutation test at enrolment (cobas® EGFR Mutation Test vs local assessment). A futility analysis of the randomized phase is planned for when approximately 83 PFS events have occurred. The primary endpoint is PFS based on investigator assessment of response using RECIST 1.1 criteria (blinded central assessment is included as a sensitivity analysis). Secondary endpoints include overall survival, objective response rate, duration of response, PFS2, health-related quality of life and safety. Effects on CNS metastases in patients with lesions at baseline will be included as an exploratory endpoint. Enrolment is planned for Q3 2019 for the safety run-in and Q1 2020 for the randomized phase. **Result:** Section not applicable **Conclusion:** Section not applicable

OA07.02 LKB1 MUTATIONS IN METASTATIC NON-SMALL CELL LUNG CANCER (MNSCLC): PROGNOSTIC VALUE IN THE REAL WORLD

A. Golozar[1], J. Collins[2], K. Fraeman[2], B. Nordstrom[2], R. Mcewen[3], N. Shire[1], B. Higgs[1]

[1]*AstraZeneca, Gaithersburg/United States of America,* [2]*Evidera, Waltham/United States of America,* [3]*AstraZeneca, Cambridge/United Kingdom*

Background: Despite recent advances in treating mNSCLC, many patients fail to respond. Identifying genetic markers may help maximize clinical benefit and avoid unnecessary toxicity. *LKB1/STK11* alterations (*LKB1*m) and co-occurring *KRAS* mutations*/LKB1* loss (*KRAS/LKB1*) have been associated with poor outcomes in patients treated with immunotherapy (IO). Among chemotherapy-treated patients, however, the prognostic value is less understood. This retrospective study examined *LKB1*m, *KRAS/LKB1* and outcomes in patients with mNSCLC receiving IO (as monotherapy or in combination) or chemotherapy in the real-world setting. **Method:** Adult patients with mNSCLC who initiated first line (1L) treatment between Jan 2013 and Jun 2017 and had been profiled with the FoundationOne assay in routine care were enrolled from the Flatiron Health Oncology electronic medical record database. Associations between *LKB1*m, *LKB1/KRAS* and overall survival (OS) or progression-free survival (PFS) were evaluated by line of therapy (1L and second line [2L]) according to histology (non-squamous/squamous and non-squamous only) using multivariate Cox proportional hazards models. All analyses were stratified by IO or chemotherapy. **Result:** 2407 patients (1847 non-squamous) were included; average age was 66.1 years at 1L initiation. 328 (13.6%) patients harbored *LKB1m* and 157 (6.5%) harbored *KRAS/LKB1*. Among IO-treated patients in the 2L setting, *LKB1m* was associated with shorter OS and PFS versus wild type. A similar association was observed in the 1L setting and in the non-squamous only subgroup. In patients receiving chemotherapy, *LKB1m* was associated with worse outcomes only in the 1L setting. All associations were generally more pronounced among *KRAS/LKB1* compared with *LKB1m* patients.

Table. Association between LKB1m and OS or PFS in mNSCLC stratified by IO or chemotherapy and lines of therapy								
Mutation group								
LKB1m								
	All mNSCLC				*Non-Squamous*			
Outcome	*IO*		*Chemotherapy*		*IO*		*Chemotherapy*

Note: Bold text indicates significant results; reference group for *LKB1m* is *LKB1wt*; reference group for *KRAS/LKB1* is *KRASwt/LKB1wt* Median OS and PFS and IQRs are expressed in days								
Abbreviations: *KRAS* mutation*/LKB1* loss *(KRAS/LKB1),* Hazard ratio (HR), Interquartile range *(IQR),* Confidence interval (CI), Immunotherapy (IO), Overall Survival (OS), Progression-free survival (PFS), Wild type (wt)								

Conclusion: *LKB1m* and *LKB1/KRAS* were associated with numerically worse OS and PFS in the 1L setting, irrespective of treatment, and in IO-treated patients in the 2L setting. Results of this real-world study support previous clinical findings and suggest unique relevance of these mutations in 1L chemotherapy and for 1L and 2L IO.

OA07.03 CLINICAL OUTCOME OF NON-SMALL CELL LUNG CANCER WITH EGFR/HER2 EXON 20 INSERTIONS IDENTIFIED IN THE LC-SCRUM-JAPAN

H. Udagawa[1], S. Matsumoto[1], Y. Ohe[2], M. Satouchi[3], N. Furuya[4], Y.H. Kim[5], T. Seto[6], K. Soejima[7], D. Hayakawa[8], T. Kato[9], S. Miyamoto[10], K. Ohashi[11], S. Saeki[12], H. Ohta[13], D. Fujimoto[14], A. Sekine[15], K. Yoh[1], K. Goto[1]

[1]*National Cancer Center Hospital East, Kashiwa/Japan,* [2]*National Cancer Center Hospital, Tokyo/Japan,* [3]*Hyogo Cancer Center, Akashi/Japan,* [4]*St. Marianna University School of Medicine, Kanagawa/Japan,* [5]*Kyoto University, Kyoto/Japan,* [6]*National Organization Hospital Kyushu Cancer Center, Fukuoka/Japan,* [7]*Keio University School of Medicine, Tokyo/Japan,* [8]*Juntendo University, Tokyo/Japan,* [9]*Kanagawa Cancer Center, Yokohama/Japan,* [10]*Japanese Red Cross Medical Center, Tokyo/Japan,* [11]*Okayama University Hospital, Okayama/Japan,* [12]*Kumamoto University Hospital, Kumamoto/Japan,* [13]*Jichi Medical University Saitama Medical Center, Saitama City/Japan,* [14]*Kobe City Medical Center General Hospital, Kobe/Japan,* [15]*Kanagawa Cardiovascular and Respiratory Center, Yokohma/Japan*

Background: In-frame insertions in exon 20 (Ex20ins) of *EGFR/HER2* occur in 2-5 % of non-small cell lung cancer (NSCLC). There is no approved targeted therapy for patients with these mutations. Historical control data would be valuable for the development of novel targeted therapies for these rare cancers. **Method:** A nationwide genome screening project in Japan (LC-SCRUM-Japan) has been established for the development of molecular-targeted therapies for lung cancers. In this project, 161 cancer-related genes have been analyzed by a next-generation sequencing (NGS) system, Oncomine™ Comprehensive Assay. The therapeutic efficacy and survival of the patients with non-squamous (non-sq) NSCLC harboring *EGFR/HER2* Ex20ins were evaluated using a large-scale clinico-genomic database in the LC-SCRUM-Japan. **Result:** A total of 3441 advanced non-sq NSCLC patients were successfully analyzed from 2015 to 2018. *EGFR* Ex20ins were detected in 73 patients (2%; M766_A767insASV/A767_S768insSVD/H773_V774insH/D770_N771insNPH/N771_P772insPH/others=22/17/5/4/4/21) and *HER2* Ex20ins were detected in 128 patients (4%; A775_G776insYVMA/G776delinsVC/P780_Y781insGSP/others=95/16/10/7). The median age of the patients was 62 (range, 33-90) years. Eighty-one patients (40%) were male and 114 (57%) were never smoker. Two-hundred patients (99%) were diagnosed as adenocarcinoma and 1 as adenosquamous-cell carcinoma. Based on our database, the median overall survivals in patients with *EGFR* Ex20ins were 22.4 (95%CI, 15.3-36.8) months, and those with *HER2* Ex20ins were 18.8 (13.6-30.3) months. In the patients with *EGFR/HER2* Ex20ins, the objective response rate (ORR) and median progression-free survivals (mPFS) of 1st-line platinum-containing chemotherapies were 32% and 6.0 (5.7-7.0) months, respectively. The ORR and mPFS of docetaxel with or without ramucirumab were 26% and 5.1 (3.8-5.9) months, respectively. The ORR and mPFS of PD-1 inhibitor were 0% and 2.0 (1.6-2.6) months, respectively. No significant difference in the therapeutic efficacy of these drugs was observed between the patients with *EGFR* Ex20ins and *HER2* Ex20ins. In 19 patients with *EGFR* Ex20ins treated with 1st/2nd generation EGFR-TKIs, the ORR was 5% (a M766_A767insASV-positive tumor responded to afatinib) and the mPFS was 2.1 (1.3-4.2) months. **Conclusion:** The patients with *EGFR/HER2* Ex20ins-positive NSCLC showed poor responses to PD-1 inhibitors and 1st/2nd generation EGFR-TKIs. These historical data are highly informative in evaluating the efficacy of novel targeted therapies for *EGFR/HER2* Ex20ins-positive NSCLC.

OA07.05 HIGH-GRADE CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY (CIPN): AN ANALYSIS OF ECOG-ACRIN LUNG CANCER CLINICAL TRIALS

S. Rashdan[1], S. Dahlberg[2], D. Gerber[3], A. Sandler[4], J. Schiller[5], D. Johnson[3], S. Ramalingam[6]

[1]*UT Southwestern Harold C. Simmons Comprehensive Cancer Center, Dallas/United States of America,* [2]*Dana Farber Cancer Institute, Boston/United States of America,* [3]*UT Southwestern Medical Center, Dallas/United States of America,* [4]*Genentech, San Francisco/United States of America,* [5]*University of Virgnia Health System, Charlottesville/United States of America,* [6]*Emory University School of Medicine, Atlanta/United States of America*

Background: High-grade (CTCAE grade ≥3) CIPN implies severe symptoms and limitation of self-care activities of daily living (ADL). To date, studies characterizing the incidence of and factors associated with CIPN have been conducted almost exclusively in breast cancer populations. As such, they generally evaluate only women and lack assessment of platinum-based chemotherapy. We therefore examined the incidence and factors associated with high-grade CIPN among patients treated on ECOG-ACRIN advanced non-small cell lung cancer (NSCLC) clinical trials. **Method:** We included two completed trials in the analysis: E1594 (comparison of 4 chemotherapy regimens: cisplatin-paclitaxel, cisplatin-gemcitabine, cisplatin-docetaxel, carboplatin-paclitaxel) and E4599 (carboplatin-paclitaxel ± bevacizumab). We identified patients who developed treatment-related grade ≥3 CIPN. Multivariable logistic regression modeling was performed to estimate adjusted odds ratios. For the treatment variable, the reference group ended up combining the cisplatin+paclitaxel and cisplatin+docetaxel arms since their results were not significantly different from one another. Body-mass index (BMI) was categorized by median value (25.2 kg/m^2). **Result:** Among 1,989 total patients, 167 (8.4%) developed grade ≥3 CIPN. Incidence was highest for the carboplatin-paclitaxel regimen (9.9%) and lowest for cisplatin-paclitaxel (4.5%) (P=0.006). Grade ≥3 CIPN was associated with BMI (9.9% for ≥25.2 kg/m^2 vs 6.9% for <25.2 kg/m^2; P=0.02) and sex (6.9% for men vs 10.4% for women; P=0.006). There was a non-significant trend toward association with age (10.4% for ≥70 years versus 7.8% for <70 years; P=0.08). In multivariate analysis, chemotherapy regimen, sex, and BMI remained independently associated with grade ≥3 CIPN. **Conclusion:** Carboplatin-paclitaxel chemotherapy, female sex, and high BMI are associated with the development of high-grade CIPN. Given the clinical severity of this condition and the potential for long-term persistence, consideration of risk-based monitoring and treatment selection may be warranted.

Background: There is an unmet need to develop novel clinically relevant models of NSCLC to accelerate identification of drug targets and our understanding of the disease. Organoids, which are cells grown in three-dimensional environments in Matrigel, have emerged as novel preclinical models of cancer. Recently protocols for generating NSCLC organoids have been reported, but the growth, and molecular features of organoids as compared to their matching primary patient tumor or patient-derived xenografts (PDX) remain vague. **Method:** Thirty surgically resected NSCLC patient tumor and 35 PDX tissue of lung adenocarcinoma and squamous cell carcinoma subtypes were processed for organoid establishment. Organoids and matching tumor tissues were characterized by histology and immunohistochemistry, and molecularly profiled by whole exome and RNA-sequencing. Subcutaneous injection of organoids *in vivo* was performed to confirm tumorgenicity. Organoids were subjected to drug testing and drug response was verified in the matched PDX. **Result:** Using a novel culture condition that our laboratory developed, we have collected tumor samples from 16 primary and 13 PDX samples of adenocarcinoma (n=29) and 14 primary and 22 PDX samples of squamous cell carcinoma (n=36). Over 85% (57/65) of our patient and PDX tumor tissues formed organoids that exhibited a wide range of short-term (<3 months) and long-term (>3 months) growth. Specifically, the success rate of establishing short-term and long-term models are 74% (48/65) and 14% (9/65), respectively. The long-term propagable organoids recapitulated the histology of the patient and PDX tumor. They also retained the ability to form xenograft in NOD-SCID mice. The organoids preserved mutation, copy number aberrations and global gene expression profile of the parental tumors. We additionally showed the utility of short-term and long-term organoids for identifying biomarkers of sensitivity to drugs and combinational targeted therapies. **Conclusion:** NSCLC organoids are novel patient-derived ex-vivo tumor models for anti-cancer drug screening and biomarker discovery, thus could be incorporated into novel drug discovery pipelines. Further efforts are ongoing to increase the success rate of establishing long-term organoid lines.

Background: In the context of the MESOMICS and lungNENomics projects[1], we generated comprehensive molecular profiles of Malignant Pleural Mesothelioma (MPM)[2] and pulmonary carcinoids (PCa)[3]. We showed that a continuous molecular model can better explain the prognosis of MPM than the three histologies, with strong differences in the expression of immune checkpoints and pro-angiogenic genes across samples. We also identified a new entity of PCa (supra-carcinoids) with carcinoid-like morphology yet the molecular and clinical features of LCNEC, which challenges the general believe that PCa have no relationship or genetic, epidemiologic, and clinical traits in common with LCNEC and SCLC. These two studies suggest an important role of heterogeneity in the biology of these tumors. **Method:** Much progress has been made in revealing the evolutionary history of individual cancers, in particular using multi-region sequencing. However, most studies focused on a single 'omic technique, and lacked temporal samples. Here we present the results of an innovative approach to study spatial and temporal tumor evolution based on (i) integration of whole-genome and transcriptome sequencing and EPIC 850K methylation arrays on multiple regions from 12 MPM, and (ii) a novel tumor-derived organoid-based strategy for studying the evolution of PCa.

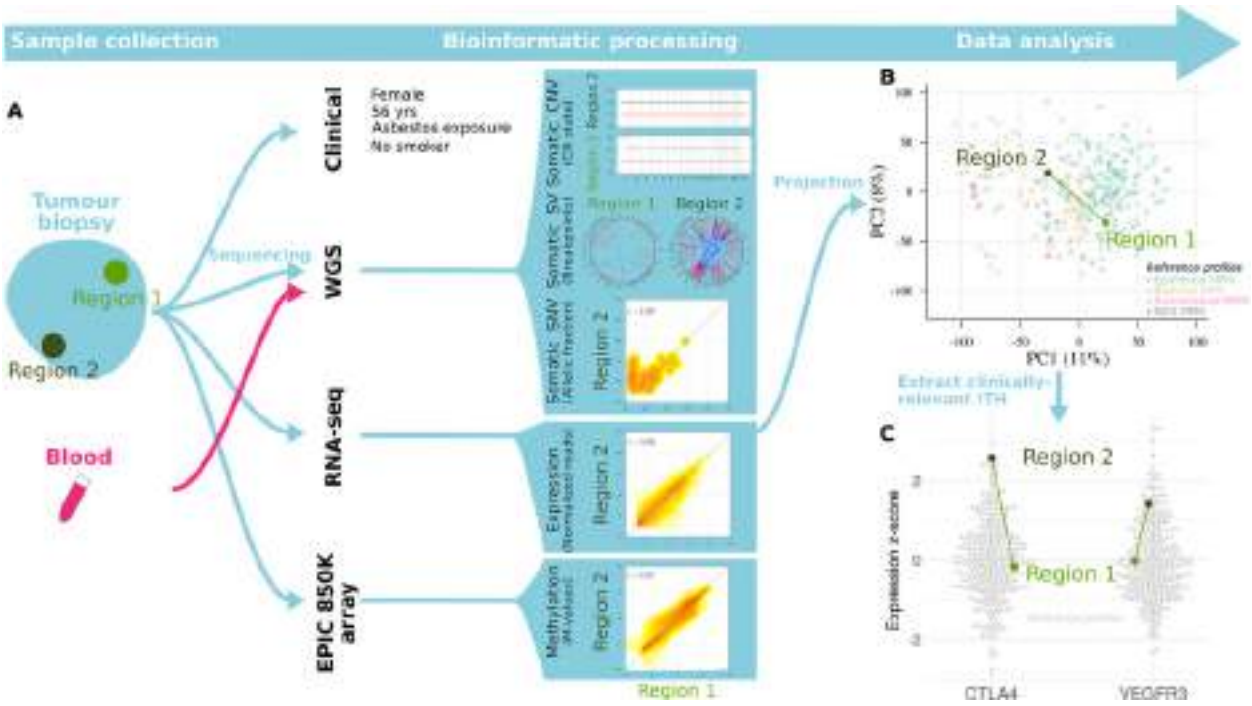

Figure 1. Multi-omic multi-regional profiling of a MPM patient. A) Somatic Copy Number Variants (CNV), somatic Structural Variants (SV), kernel density plots of (top) somatic single nucleotide variants (SNVs) allelic fractions, (middle) expression normalized read counts, and (bottom) methylation array *M*-values. B) Projection of the transcriptomic profile of two tumoral regions into the Principal Component Analysis (PCA) space computed from 284 malignant pleural mesotheliomas[2]C) Expression (*z*-score of normalized read counts) for two clinically relevant genes with substantial inter-regional differences. Biorepositories: French MESOBANK; LungNEN Network

Result: In the data analyses of the 12 MPM we detected significant intra-tumor heterogeneity (ITH) in the expression of immune checkpoints and pro-angiogenic genes (see example in Fig. 1). This might explain the modest and variable response to treatment in clinical trials assessing immunotherapies and antiangiogenic drugs. In the case of PCa, we are currently analysing the organoids genomic data and we will present the preliminary data for the temporal evolution of these diseases. **Conclusion:** We found that our approach can detect clinically and biologically meaningful ITH. All the computational methods we developed for these evolutionary studies are available to the scientific community[4]. OA08.03 A SINGLE-CELL RESOLUTION MAP OF EMT AND DRUG RESISTANCE STATES FOR EVALUATING NSCLC CLINICAL SPECIMENS

L. Karacosta, B. Anchang, N. Ignatiadis, S. Kimmey, J. Benson, J. Shrager, A. Sung, J. Neal, H. Wakelee, R. Tibshirani, S. Bendall, S. Plevritis

Stanford University, Stanford/United States of America

Background: The role of epithelial-mesenchymal transition (EMT) in NSCLC is well reported and has been shown to prime cells for metastasis. EMT can be adopted or reversed (i.e. mesenchymal-epithelial transition, MET) by cells, revealing plasticity that can also lead to drug resistance. Although it is appreciated that EMT is not a binary process of two extremes but instead a spectrum of intermediate states of EMT phenotypes, these are poorly defined at the single-cell proteomic level in NSCLC clinical specimens. Our overall goal was to dynamically capture and characterize EMT-related drug resistance states in lung cancer cells to construct a single-cell resolution state map of clinical applicability. **Method:** We used mass cytometry (CyTOF) time-course experimentation and novel computational tools to analyze TGFβ and drug treated NSCLC cell lines, as well as NSCLC clinical samples to identify clinically relevant drug resistant EMT and MET states and construct a single-cell resolution proteomic map of phenotypic states. **Result:** Through TGFβ treatment and withdrawal we resolved previously unrealized EMT and MET states in NSCLC cell lines by analyzing the expression of up to 30 surface and intracellular markers. Using a novel computational tool (TRACER) we also provide evidence that EMT and MET trajectories differ and exert differential drug sensitivity profiles. We used the identified EMT and MET states to construct a NSCLC reference EMT-MET state map, on which we projected NSCLC clinical samples to characterize their phenotypic profile in terms of our *in vitro* EMT-MET analysis. Finally, we extended our mass cytometry time-course analysis to NSCLC cells that underwent various drug treatments (e.g. Erlotinib, Docetaxel) and subsequent withdrawal to augment our EMT-MET state map with drug resistance phenotypic traits. We found that NSCLC resistant cells displayed through time overlapping morphological and cell signaling features with EMT and MET and were able to rebound from short-term drug-induced effects. These data are currently being used to evaluate EMT-related drug resistant cell states detected in pleural effusions during and after the course of treatment in different NSCLC patient therapy time-points. **Conclusion:** In summary, we provide a framework that can be extended to phenotypically characterize clinical samples with single-cell resolution in the context of *in vitro* studies showing differential EMT-MET traits related to drug sensitivity. This sets the foundation for developing tools towards evaluating–at a personalized level – disease status and response to treatment in NSCLC patients.

Background: EGFR mutated lung adenocarcinoma patients treated with gefitinib and osimertinib showed a therapeutic benefit limited by the appearance of secondary mutations, such as *EGFR*^{T790M} and *EGFR*^{C797S}. It has been generally assumed that these secondary mutations render EGFR completely unresponsive to the inhibitors, indicating that the use of single drug to treat efficiently EGFR-driven lung adenocarcinoma might have limited value while a strategy based on combinational drug therapy could be more effective at mitigating the effects of gatekeeper mutations. **Method:** We have combined the use of EGFR-driven genetic engineered mouse models and patient-derived xenografts, adenocarcinoma cell lines and primary samples from EGFR mutated patients. **Result:** We uncover here that gefitinib and osimertinib increase STAT3 phosphorylation (pSTAT3) in *EGFR*^{T790M} and *EGFR*^{C797S} tumoral cells. Interestingly, we also found that concomitant Notch inhibition with gefitinib or osimertinib treatment induces a pSTAT3-dependent strong reduction in the levels of the transcriptional repressor HES1. Importantly, we show that tyrosine kinase inhibitor resistant tumors, with *EGFR*^{T790M} and *EGFR*^{C797S} mutations, are highly responsive to the combined treatment of Notch inhibitors with gefitinib and osimertinib respectively. Finally, in patients with EGFR mutations treated with tyrosine kinase inhibitors, HES1 protein levels increase during relapse and correlate with shorter progression-free survival. **Conclusion:** Our results show that the Notch pathway plays a major role in the relapse of lung adenocarcinoma patients treated with EGFR TKIs, providing a rationale to treat patients that become resistant to EGFR TKI with a combination of the same TKI and Notch inhibitors.

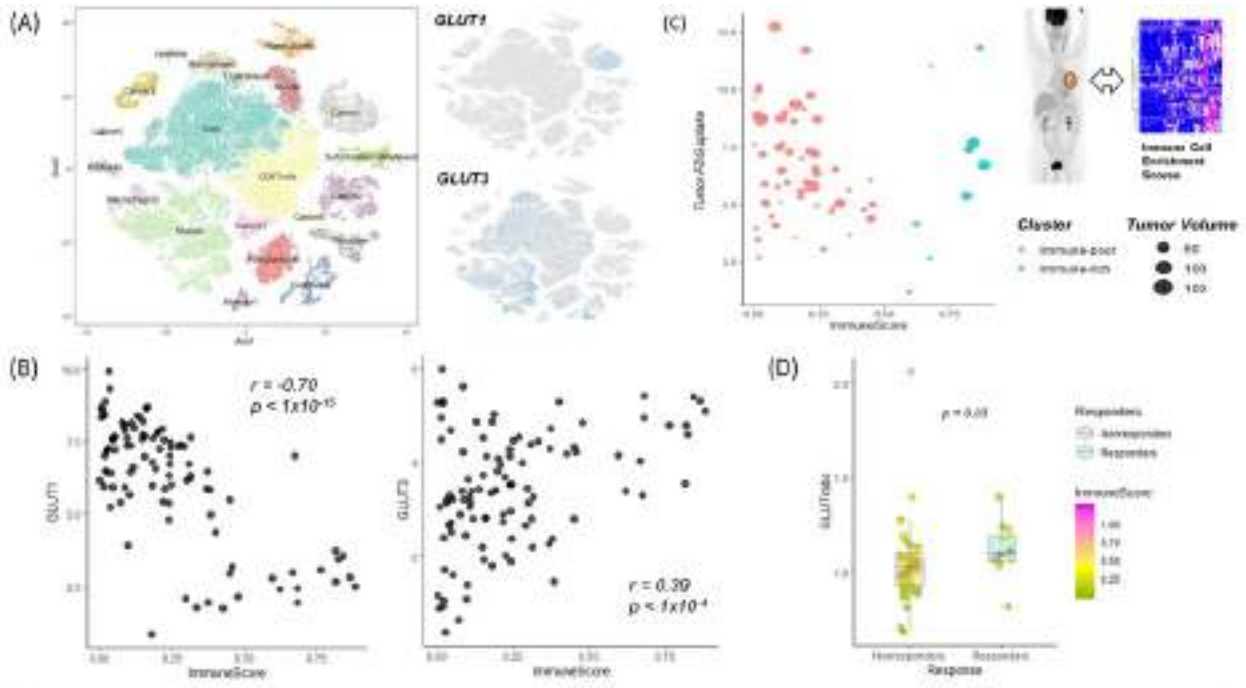
OA08.06 RECIPROCAL CHANGE IN GLUCOSE METABOLISM OF CANCER AND IMMUNE CELLS MEDIATED BY DIFFERENT GLUT PREDICTS IMMUNOTHERAPY RESPONSE

K.J. Na, H. Choi, Y.T. Kim

Seoul National University Hospital, Seoul/Korea, Republic of

Background: Tumor metabolism represented by aerobic glycolysis is dynamically changed in tumor microenvironment (TME) to achieve immune escape. However, *in vivo* properties of glucose metabolism in cancer and immune cells are poorly understood and their clinical implications are still lacking. We scrutinized the association of tumor metabolism and immune properties of TME by comprehensive analyses using tissue RNA-seq, positron emission tomography (PET), and single cell RNA-seq data. **Method:** Lung squamous cell carcinoma (LUSC) samples with both RNA-seq and ^{18}F-deoxyglucose (FDG) PET (n = 63) were collected to examine the association of *in vivo* glucose metabolism, gene expression levels related to glucose metabolism, and immune cell enrichment. An overall enrichment score of TME (ImmuneScore) was estimated from tissue RNA-seq data. The gene expression levels of each cell component of TME were analyzed by single cell RNA-seq from lung cancer patients. The expression patterns of glucose transporters (GLUTs) were evaluated in patients who underwent immunotherapy to investigate whether it can predict immunotherapy response. **Result:** Single cell RNA-seq showed that GLUT1 was mostly expressed in cancer cells while GLUT3 was mostly found in myeloid cells in TME. ImmuneScore showed a negative correlation with GLUT1 ($r=-0.70$, $p<0.01$) and a positive correlation with GLUT3 ($r=0.39$, $p<0.01$) in LUSC samples, and it was validated in TCGA cohort ($r=-0.44$, $p<0.01$ for GLUT1; $r=0.26$, $p<0.01$ for GLUT3). LUSC samples were divided into two distinct groups (immure-rich and immune-poor) by ImmuneScore. In immune-poor cluster, FDG uptake was positively correlated with GLUT1 ($r=0.27$, $p=0.04$), while not correlated with GLUT3. In immune-rich cluster, FDG uptake was positively correlated with GLUT3 ($r=0.78$, $p=0.01$), while not correlated with GLUT1. ImmuneScore was negatively correlated with FDG uptake in immune-poor cluster, while there was positive correlation in immune-rich cluster. We defined GLUT3-GLUT1 ratio (GLUTratio) as a metabolic biomarker representing immune status in TME. High GLUTratio indicates increased metabolic activity in immune cells and decreased metabolic activity in cancer cells in TME. For melanoma patients who underwent anti-PD-1 therapy, GLUTratio was significantly higher in responders than nonresponders ($p=0.03$).



(A) Two-dimensional projection of single cell RNA-seq data of 52,698 single cells from lung cancer patients with associated cell type were presented. Expression pattern of glucose transporters (GLUT1 and GLUT3) demonstrated that GLUT1 mostly expresses in cancer cell clusters and GLUT3 mostly expresses in myeloid cell clusters.
(B) The association between the expression level of glucose transporters (GLUT) and ImmuneScore in lung squamous cell carcinoma patients. ImmuneScore shows negative correlation with GLUT1 and positive correlation with GLUT3.
(C) The association between ImmuneScore and *in vivo* glucose metabolism measured by FDG PET in lung squamous cell carcinoma patients was presented. FDG uptake and ImmuneScore showed negative correlation in immune-poor cluster, while they showed positive correlation in immune-rich cluster.
(D) In melanoma patients who underwent immunotherapy, the GLUTratio (GLUT3/GLUT1) was significantly higher in responder group.

Conclusion: Our findings support a reciprocal change of glucose metabolism between cancer and immune cells within TME mediated by different GLUTs. A new glucose metabolism-based biomarker, GLUTratio, can reflect reciprocal metabolic activity of immune and cancer cells in TME, and be a feasible predictive biomarker for immunotherapy.

Background: Tumor-associated fibroblasts (TAFs) exhibit a fibrotic phenotype in non-small cell lung cancer (NSCLC) that has beeen associated with critical steps of cancer progression. Paradoxically, we reported that the profibrotic TGF-β transcription factor *SMAD3* was epigenetically downregulated through promoter hypermethylation in TAFs from NSCLC patients compared to patient-matched control fibroblasts. In addition, we reported that the antifibrotic drug nintedanib elicited a stronger inhibition of the fibrotic phenotype and its tumor-promoting effects in TAFs from adenocarcinoma (ADC) patients compared to squamous cell carcinoma (SCC) patients upon TGF-β1 stimulation *in vitro*, which was consistent with the selective therapeutic response to nintedanib observed in a clinical trial in ADC (but not SCC) patients. These previous results support the hypothesis that TGF-β1 signaling may be altered in lung TAFs according to their histologic subtype. **Method:** In this study we tested our working hypothesis by determining the expression and activity of SMAD3 and its closely related homologue SMAD2 in patient-derived TAFs and paired control fibroblasts, and by dissecting their potential contribution to the differential therapeutic responses to nintedanib observed in ADC and SCC using *in vitro* and *in vivo* preclinical models. **Result:** *In vitro* studies revealed a marked *SMAD3* epigenetic repression through promoter hypermethylation, a low pSMAD3/pSMAD2 ratio and a limited fibrotic phenotype selectively in SCC-TAFs. In contrast, ADC-TAFs overexpressed a panel of fibrotic markers upon TGF-β1 stimulation concomitantly with a high pSMAD3/pSMAD2 ratio and a limited *SMAD3* promoter methylation. Histologic analysis of a large patient cohort (112 ADC, 96 SCC) confirmed that the extent of fibrosis is larger in ADC than SCC patients. In addition, knocking-down *SMAD3* in ADC-TAFs was sufficient to reduce the antifibrotic and antigrowth effects of nintedanib *in vitro* and in tumor xenografts *in vivo*. On the other hand, long-term exposure of pulmonary fibroblasts to cigarette smoke condensate was sufficient to hypermethylate the *SMAD3* promoter. Since SCC and ADC tumors typically arise in the upper

airways and distal pulmonary sites, respectively, it is conceivable that fibroblasts might be more exposed to the smoking epigenetic effects on *SMAD3* in SCC. **Conclusion:** We report for the first time that tumor fibrosis is higher in ADC than SCC patients, in association with a selective therapeutic response to the antifibrotic drug nintedanib in the former, and identify the subtype-specific extent of *SMAD3* epigenetic repression in TAFs and the subsequent aberrant SMAD3/SMAD2 imbalance as major regulatory mechanisms of tumor fibrosis and response to nintedanib in NSCLC.

OA09.02 SMOKING CESSATION COUNSELING IN A SURGICAL CLINIC IS EFFECTIVE

C. Barone[1], P. Franklin[1], J. Muesse[2], N. Tingquist[2], M. Steliga[2]

[1]*WP Rockefeller Cancer Institute, Little Rock/United States of America,* [2]*University of Arkansas, Little Rock/United States of America*

Background: Many patients in a thoracic surgery oncology clinic are unable to quit despite referral for tobacco related illnesses and the knowledge that smoking is harmful. Continued smoking leads to poorer outcomes in cancer patients. We implemented individualized counseling for all patients in our ambulatory clinic as a standard part of their cancer care using an opt-out framework. All patients were surveyed for use, and cessation support consisted of individual counseling and pharmacotherapy tailored to the individual. **Method:** All patients in the thoracic surgery oncology clinic were surveyed for tobacco use at the intake for each visit. Any patient who was a current tobacco user met with a certified tobacco treatment specialist (CTTS) in the surgery clinic in the exam room before and/or after meeting with the surgeon. This was introduced as a standard part of the patient's treatment plan; patients could opt-out if they chose. Less than 5% of patients who were offered the counseling declined. The cessation counseling was reinforced by the surgeon, and patients were informed about how cessation could improve outcomes. On return visits, the patients met with the CTTS for follow up counseling and feedback. Data was prospectively entered in an IRB approved database for tracking smoking cessation outcomes at our institution. Retrospectively data was harvested for the prior 17 consecutive months. **Result:** Over a consecutive 17 months, a total of 275 patients who were currently smoking were seen in the thoracic surgery oncology clinic by two thoracic surgeons and met with a CTTS for individualized counseling which included a cessation plan and pharmacotherapy tailored to the individual. Follow up information was available on 87% of patients 240/275. Of the 240 patients who were smoking and met with a CTTS for an individualized plan, 2.9% increased their smoking (7/240), 23.3% had no change (56/240), 29.2 decreased (70/240), and 44.6% quit (107/240) on follow up visits. Cessation was validated by a handheld exhaled breath carbon monoxide (CO) detector whenever possible, and often decreased smoking rates were validated with lower CO readings as well. **Conclusion:** Patients in a thoracic surgery oncology are receptive to counseling by a CTTS when provided at the point of care. Despite heavy smoking histories, many of the patients in a thoracic surgery oncology clinic can quit smoking with evidence based support including counseling, pharmacotherapy, and follow up. As cessation improves treatment outcomes in many facets of lung cancer care, cessation support should be integrated in a standard workflow for all patients.

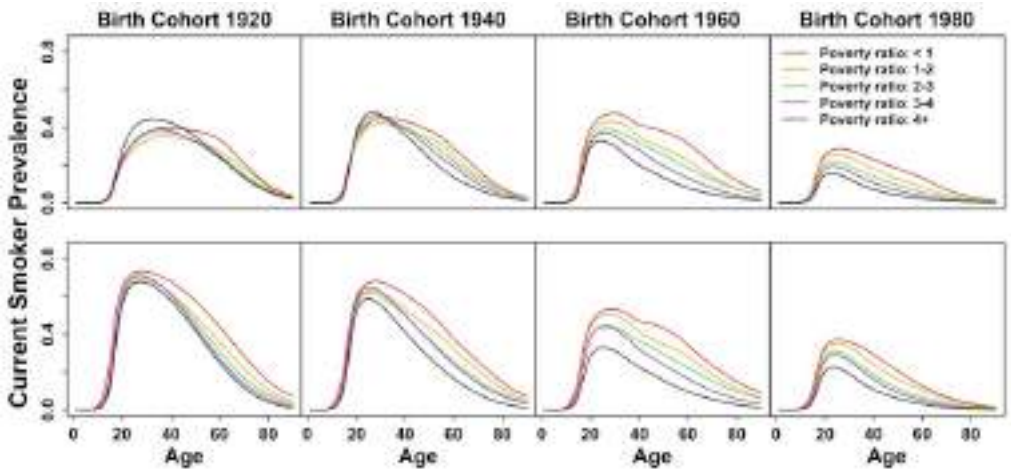
OA09.03 PATTERNS OF BIRTH COHORT-SPECIFIC SMOKING HISTORIES BY FAMILY INCOME IN THE USA, 1982-2017

J. Jeon[1], P. Cao[1], D. Luan[1], J. Tam[1], D. Levy[2], N. Fleischer[1], T. Holford[3], R. Meza[1]

[1]*University of Michigan School of Public Health, Ann Arbor/United States of America,* [2]*Georgetown University, Washington/United States of America,* [3]*Yale University, New Haven/United States of America*

Background: Although cigarette smoking has been declining significantly in the US over last several decades, disparities in tobacco use remain across different groups by race/ethnicity, education, socioeconomic status (SES), or regions. Specifically, people in lower family income have higher smoking prevalence, longer smoking durations and lower cessation rates than other income groups. However, little is known about how smoking patterns, including rates of initiation, cessation, and intensity, differ by birth cohort across various income levels. **Method:** Using the National Health Interview Survey (NHIS) family income data, we calculated individual income-to-poverty ratios from 1982-2017. Missing family income data from 1982-1996 was imputed using a sequential regression multivariate imputation method, the NHIS approach to impute missing continuous income from 1997-2017. Age-period-cohort models with constrained natural splines were used to estimate the annual probabilities of smoking initiation, cessation, and intensity by sex and birth-cohort for five income-to-poverty ratio groups (<1, 1-2,2-3,3-4 and 4+ times the poverty threshold). Age- and sex-specific smoking prevalence was also estimated for different income groups and birth cohorts. **Result:** Smoking prevalence and initiation rates are decreasing by birth-cohort in all income-to-poverty ratio groups, while cessation rates are increasing. However, the relative smoking prevalence between low- and high-income groups is markedly increasing by birth-cohort (Figure 1). Smoking initiation probabilities are highest among those living below the poverty threshold, and inversely associated with income level. Conversely, people living below the poverty threshold have the lowest probabilities of quitting, with increasing smoking cessation probabilities in higher income groups. Age-specific smoking cessation probabilities vary considerably by income, especially in recent birth-cohorts for both men and women. Figure 1. Age-specific current smoker prevalence for females (upper panels) and males (lower panels) for five income-to-poverty ratio groups (<1, 1-2,2-3,3-4 and 4+ times the poverty threshold) and selected birth cohorts.



Conclusion: Smoking prevalence has been decreasing in all income groups, however, disparities in smoking pattern between high and low-income populations are increasing with more recent birth-cohorts. Future studies evaluating disparities in smoking should account for differences by birth-cohort. The establishment of effective smoking intervention strategies specifically for low-income groups will be important to reduce tobacco-related health disparities.

OA09.07 IMPLEMENTING AN OPT-OUT APPROACH TO SMOKING CESSATION REFERRALS FOR CANCER PATIENTS IN ONTARIO, CANADA

E. Cameron[1], M. Haque[1], N. Schwartz[1], S. Khan[1], S. Rana[1], R. Truscott[1], W. Evans[2]

[1]*Population Health & Prevention, Cancer Care Ontario, Toronto/Canada,* [2]*McMaster University, Hamilton/Canada*

Background: Smoking is responsible for approximately 30% of all cancer deaths in Canada and more than 85% of lung cancer cases. Continued smoking results in decreased cancer treatment efficacy and safety, increased toxicities, greater risk of cancer recurrence and second primaries, poorer quality of life and decreased survival. Quitting smoking can reduce these adverse effects. In 2013, Cancer Care Ontario (CCO) implemented a smoking cessation program across 14 Regional Cancer Centres (RCCs) in the province of Ontario, Canada, employing a 3As (Ask, Advise, Act) brief intervention model. **Method:** In the first few years of the program, smokers could "opt-in" to smoking cessation services by stating a readiness to quit. However, the provincial rate of smokers accepting support was low. In 2018, CCO adopted an "opt-out" approach, based on emerging evidence and feedback from an expert Advisory Committee. With this approach, healthcare providers (HCPs) automatically refer all smokers to a cessation service, without assessing the patient's readiness to quit. Patients can refuse the referral if they choose. This program change was communicated to the RCCs through a revised program framework, site-specific action plans, and discussion during monthly knowledge exchange meetings with Regional Champions. Communications resources (posters and pocket cards) were created to support HCPs, with suggested scripts. **Result:** The Accepted a Referral (proportion of smokers accepting referral to cessation services) performance metric was used to monitor program implementation. With an opt-in approach, the annual provincial rate of Accepted a Referral improved only slightly over three years (18.1% in 2015/16 to 22.5% in 2017/18). Just prior to launching the opt-out approach in Q3 of 2017/18, the provincial rate of Accepted a Referral was 23.3% (range 9.2% to 37.9% amongst 14 RCCs). One year later, the provincial rate had increased substantially to 31.9% (range 12.9% to 88.7%). Several RCCs showed dramatic increases, while others demonstrated little or no improvement. **Conclusion:** In an effort to help more patients quit smoking and to achieve the best treatment outcomes possible, CCO adopted an opt-out approach to cessation referrals. Overall, there has been a substantial increase in the provincial rate of smokers accepting support, but implementation has varied amongst RCCs. Feedback indicates that while some HCPs

found the approach relatively easy to implement, others have been resistant to change, expressing concern about the ethics of referring patients without assessing willingness to quit. Further research into the reasons behind the variable uptake of the opt-out approach will inform future implementation efforts.

OA10.01 IMPACT OF PRE-ORDERED STAGING TESTS ON TIMELINESS OF LUNG CANCER DIAGNOSIS AND STAGING: A QUALITY IMPROVEMENT INITIATIVE

M. Mullin[1], A. Tran[1], C. Noseworthy[2], C. Stone[1], C. Parker[1,3], G. Digby[1,3,4]

[1]*Department of Internal Medicine, Kingston/Canada,* [2]*Cancer Centre of Southeastern Ontario, Kingston/Canada,* [3]*Department of Respirology, Kingston/Canada,* [4]*Department of Oncology, Kingston/Canada*

Background: Timely care for patients undergoing evaluation for suspected lung cancer (LC) is critical to optimize clinical outcomes and minimize patient anxiety. We identified delays in local LC evaluation pathways and sought to improve the timeliness of care provided by the Lung Diagnostic Assessment Program (LDAP), a rapid assessment clinic. We launched a Quality Improvement (QI) initiative consisting of Standardized Triage Pathways (STP) with pre-ordered staging tests for LDAP-referred patients with a high suspicion of LC and seek to evaluate the impact on timeliness of care. **Method:** Data were collected retrospectively for all LDAP-referred patients to establish baseline (January–April 2018) and prospectively for improvement (May–October 2018), including: LDAP referral date, triage pathway, pre-ordered tests (PET, CT/MRI brain) including date of completion, and reasons for not completing pre-ordered testing. Mean data are reported, with significance determine by special cause variation using Statistical Process Control (SPC) XbarS charts; unpaired t-tests assess for differences between independent groups. **Result:** We reviewed 553 consecutive LDAP referrals (185 baseline, 368 post-STP). Compliance with STP and pre-ordered testing for patients with suspicion of LC improved to 100% and 93%, respectively. Post-STP, mean time from referral to PET decreased from 40.5 to 26.0 days, significant by SPC, and was 21.8 days for patients completing pre-ordered testing (p=0.0001). Time from referral to CT/MRI Brain decreased from 35.8 to 19.9 days, significant by SPC, and was 18.5 days for patients completing pre-ordered testing (p=0.0001). While there was a non-significant trend to improvement in time from referral to diagnosis (41.4 to 30.4 days), the improvement was significant for patients completing pre-ordered testing (28.4 days, p =0.0001). Of the 166 (45%) LDAP-referred patients triaged to receive pre-ordered testing, 134 (80.5%) completed pre-ordered tests. Those completing pre-ordered tests experienced more timely care, on average, than those who did not: mean time from referral to PET was 13.9 days faster (p=0.0001), referral to CT/MRI Brain was 15.9 days faster (p=0.0001), and referral to diagnosis was 10.2 days faster (p=0.0004). Main patient barriers to completing pre-ordered testing were preference for physician consultation prior to testing, (10, 31.3%), and barriers regarding travel and cost, (6,18.8%). **Conclusion:** A standardized triage process with pre-ordered staging tests at the time of LDAP referral is associated with improved time from referral to completion of staging tests and diagnosis. Strategies to improve compliance with pre-ordered testing are ongoing, including collaboration with primary care physicians and nurses to support patients and navigate barriers.

OA10.02 RECOMMENDED CHANGE FOR N DESCRIPTOR PROPOSED BY THE IASLC: A VALIDATION STUDY FROM A SINGLE-CENTER EXPERIENCE

B.J. Park, T.H. Kim, S. Shin, H.K. Kim, Y.S. Choi, J. Kim, J.I. Zo, Y.M. Shim, J.H. Cho

Samsung Medical Center, Seoul/Korea, Republic of

Background: The International Association for the Study of Lung Cancer (IASLC) recently proposed changes for N descriptor based on the location and number of involved lymph node stations. The aim of our study was to evaluate the discriminatory ability and prognostic performance of the proposed N descriptor in a large independent non-small cell lung cancer (NSCLC) cohort. **Method:** IASLC proposals include: a classification of N descriptor by combining the present nodal categories and number of involved lymph node stations into: N0; single-station N1 (N1a); multiple-stations N1 (N1b); single-station N2 without N1 involvement (N2a1); single-station N2 with N1 involvement (N2a2); multiple-stations N2 (N2b) and N3. A total of 1128 patients who underwent major pulmonary resection for pathologic N1 or N2 NSCLC between 2004 and 2014 were analyzed in this study. survival analysis was performed using Cox proportional hazard model to assess the prognostic significance of the N descriptor. **Result:** From 2004 to 2014, 7437 patients were operated on for non-small-cell lung carcinoma (NSCLC). Among those, patients who underwent preoperative treatment for stage IIIA-N2 NSCLC were excluded (N=-698, 9.4%). Patients who were confirmed as pathologic N1 (N=676) or N2 (N=452) after surgery were included in this study. Invasive mediastinal staging (EBUS or mediastinoscopy) was done in 614 patients (54.4%). After surgery, adjuvant treatments were performed in 901 patients (81.7%). The mean total number of dissected lymph node was 25.7 ± 11.0, and the mean number of involved (metastatic) lymph node was 3.0 ± 3.2. The 5-year overall survival rate was 64.7 % in N1a, 57.1% in N1b, 68.0% in N2a1, 50.1% in N2a2, and 46.7% in N2b. Based on our study about the overall survival and recurrence-free survival, N2a1 is not clearly divided into N1a and N1b is not clearly divided with N2a2.

Conclusion: Based on the proposed N stage classification by combining the LN station number with the proposed anatomic location in IASLC, all 5 groups were not clearly identified. According to our analysis, it would be better to classify similar prognostic group as 3 or 4 group to divide the group. The new N classifications should be considered for future revisions of TNM staging system for lung cancer.

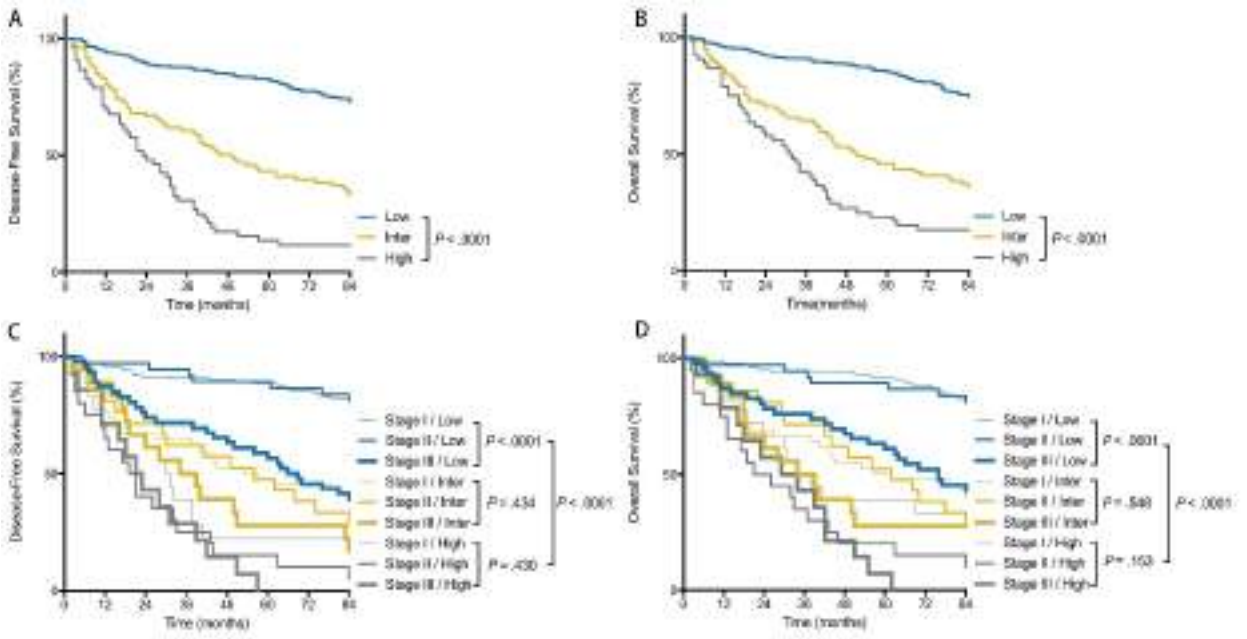
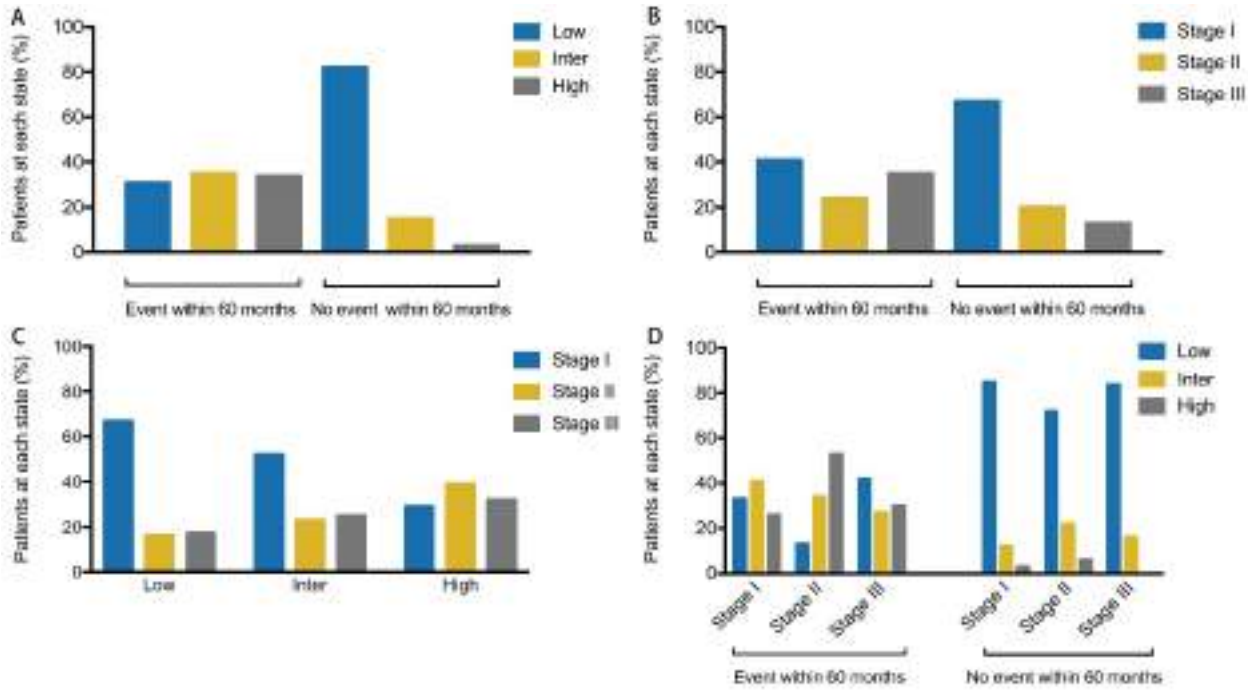
OA10.03 MACROSCORE: A PROGNOSTIC MODEL FOR SUPPLEMENTING THE TNM STAGE IN RESECTABLE NON–SMALL CELL LUNG CANCER

R. Mao[1], M. Li[2], C. Chen[1], R. Wang[3], H. Guo[4], J. Gao[3]

[1]*Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/China,* [2]*St. Vincent Hospital, Massachusetts/United States of America,* [3]*Tongji University, Shanghai/China,* [4]*Tongji University School of Medicine, Shanghai/China*

Background: We aim to establish a prognostic model based on the macrophage status to supplement the TNM stage and increase the predictive accuracy for the prognosis of NSCLC patients. **Method:** The macrophage infiltration at the center of the tumor and its invasive margins in stage I to IIIA NSCLC patients (n=368) was evaluated, and a Macroscore model was constructed (Low/Intermediate/High). The relationship between the Macroscore and the clinical outcome was analyzed and validated by 2 additional cohorts. **Result:** The Macroscore was significantly associated with disease-free survival rates and overall survival rates at each TNM stage (all $p < .0001$). The TNM stage could not, however, determine survival rates in patients with the same Macroscore (figure 1). In patients experienced a 5-year event, the Macroscore is usually in high level (26.0%-53.1%). Patients have not experienced a 5-year event usually have a low Macroscore (71.7%-84.8%), regardless of the TNM stage (figure 2). Furthermore, the Macroscore could improve the area under the curve values for the DFS and OS; the values of DFS increased from 0.651 for the TNM system model to 0.822 for the TNM stage plus Macroscore model.





Conclusion: The Macroscore provides an accurate prediction of the clinical outcome in resectable NSCLC tumors, and it complements the prognostic value of the TNM stage.

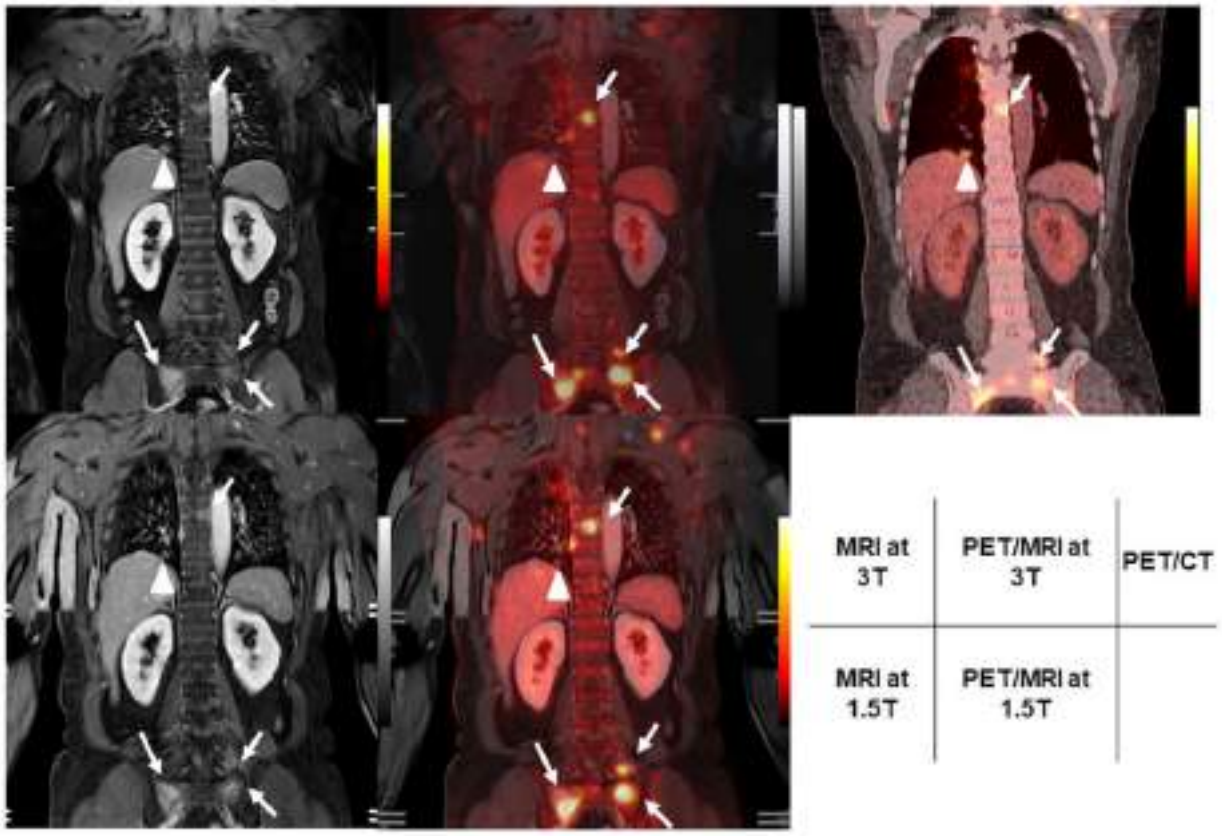
ORAL SESSIONS

OA10.05 WHICH IS BETTER FOR TNM STAGE ASSESSMENT AMONG WHOLE-BODY MRI AND PET/MRI AT 1.5 TESLA AND 3 TESLA AND FDG-PET/CT IN NON-SMALL CELL LUNG CANCER?

Y. Ohno[1], K. Aoyagi[2], M. Yui[2], D. Takenaka[3], T. Yoshikawa[4]

[1]*Fujita Health University School of Medicine, Toyoake/Japan,* [2]*Canon Medical Systems Corporation, Otawara/Japan,* [3]*Hyogo Cancer Center, Akashi/Japan,* [4]*Kobe University Graduate School of Medicine, Kobe/Japan*

Background: Accurate tumor staging is essential for choosing the appropriate treatment strategy for non-small cell lung cancer (NSCLC) patients. In 1990s, positron emission tomography (PET) or PET combined with CT (PET/CT) using 2-[fluorine-18]-fluoro-2-deoxy-D-glucose (FDG) were suggested as useful for TNM stag evaluation in NSCLC patients in routine clinical practice. Since 2007, whole-body magnetic resonance imaging (MRI) with diffusion-weighted imaging (DWI) at 1.5T or 3T systems and PET/MRI have been continuously testing in this setting. Moreover, PET fused with MRI (PET/MRI) with FDG has been suggested as a new tool for TNM stage and postoperative recurrence evaluations since 2015. However, all PET/MRI has been generated by MRI at 3T MR system and not tested that at 1.5T system. No one reported direct comparisons for TNM staging capability among whole-body MRI and PET/MRI at 1.5T and 3T systems and PET/CT in NSCLC patients. We hypothesize that whole-body MRI and PET/MRI at 1.5T and 3T MR systems have better potential for TNM stage assessment than whole-body FDG-PET/CT in NSCLC patients. The purpose of this study was to prospectively and directly compare TNM stage classification capability among whole-body MRI and PET/MRI at 1.5 and 3T MR systems and PET/CT in NSCLC patients. **Method:** 104 consecutive pathologically diagnosed NSCLC patients (62 men, 42 women; mean age 71 years) prospectively underwent whole-body MRI at 1.5T and 3T systems, integrated PET/CT, and surgical, pathological and/ or follow-up examinations. Final diagnoses of T, N and M factors and clinical stage in each patient were determined according to all examination results. Then, each factor and clinical stage were visually assessed on both whole-body MRIs, PET/MRIs and PET/CT with contrast-enhanced brain MRI. Kappa statistics were used to determine agreements for assessment of all factors and clinical stage with final diagnoses, and McNemar's test was used to compare each diagnostic accuracy among all methods. **Result:**



On each factor and clinical stage assessments, agreements between all methods and final diagnosis were substantial or almost perfect ($0.60<\kappa<0.98$). Diagnostic accuracies of N factor and clinical stage on whole-body MRI as well as PET/MRI at both field strengths were significantly higher than those of PET/CT ($p<0.05$). **Conclusion:** Whole-body MRIs and PET/MRIs at 1.5T and 3T systems have significantly better potential for N factor and clinical stage assessments than PET/CT in NSCLC patients.

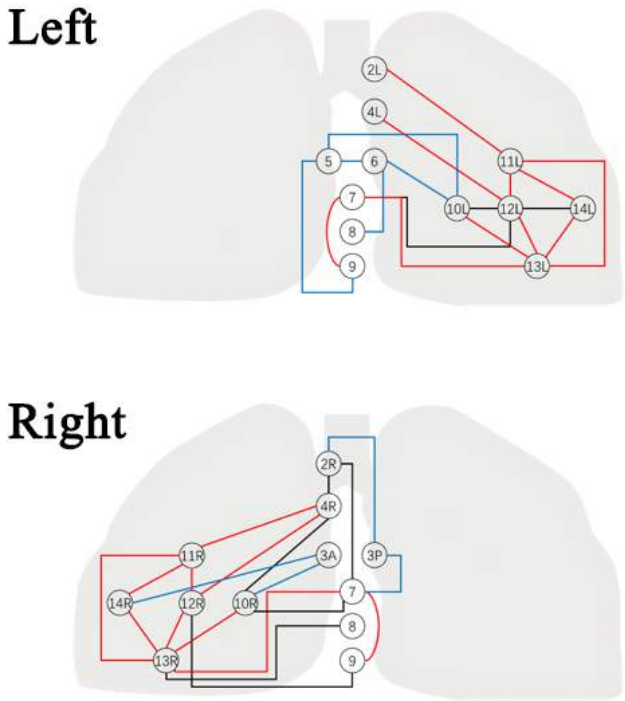
OA10.06 TRANSITION PATTERNS BETWEEN N1 AND N2 STATIONS DISCOVERED FROM DATA-DRIVEN LYMPHATIC METASTASIS STUDY IN NON-SMALL CELL LUNG CANCER

X. Wang[1], N. Wu[1], Q. Chen[2], X. Li[3], Q. Li[4]

[1]*Key Laboratory of Carcinogenesis and Translational Research (Ministry of Education), Beijing/China,* [2]*Center for Data Science, BEIJING/China,* [3]*MGH/BWH Center for Clinical Data Science, Boston/China,* [4]*MGH/BWH Center for Clinical Data Science, Boston, Beijing/China*

Background: N staging process was essential for evaluation of outcome and indication of following adjuvant therapies in Non-small-cell lung cancer treatment. Various clinical observations on the potential transition patterns of lymph node drainage are reported, however, most of the previous conclusions were made by clinical physicians and focused on specific empirical transition patterns. The fact that there is no definitive and holistic map for lymphatic metastasis transition patterns, and the patients were suffering from either excessive nodes collection along with more damage, or insufficient nodes collection with potential recurrent risks. **Method:** We perform complete lymph node examination of a total of 936 subjects diagnosed with NSCLC lung cancer. Lymph nodes sampling or dissection are performed according to NCCN guidelines. A probabilistic model is developed due to the presence of these missing values. Using the maximum likelihood estimation and proximal gradient algorithm, the summarization of dataset is obtained, which were several explicit metastases and their corresponding probabilities. The metastasis graph is constructed from the summarization result with greedy algorithm and a given threshold. Besides, numerical simulation experiments are conducted to validate the stability of algorithms. **Result:** Lymph node sites are shown as round circles according to their anatomical locations. The inferred transition paths are shown as edges connecting them. Edges colored in red are those consistently found in the left and right lung, and blue for unique nodes at each side thus cannot be compared, and black for different patterns between left and right lungs. Closely connected intra-lobar (N1) nodes: strong connections among intra-lobar nodes (10~14). Over 78% among all the patients have more than 7 edges connecting the 5 intra-lobar nodes. Jumping metastasis from N1 to N2 stations: We found that there exists several jumping metastasis at both sides of the lobes which has not been well-studied yet posing a challenge for the diagnosis and accurate staging (eg. 12 to 4, 13 to7, 11 to 2), revealing potential long-range transition pathways. Correlation among N2 lymph nodes: We discovered the presence of certain metastatic groups, including node 5/6, 5/9, 7/9, 6/8 for left lung, and 2/4,2/7,7/9, 2/3p, 3p/7 for right lung.



Conclusion: So we drew a map precisely to make a better understanding for metastatic pathways and provide a potential tool for the prediction of involved nodes pre/ or intro-operatively,so that an individualized surgical planning strategy could be made.

OA10.07 CONCORDANCE BETWEEN ROSE AND FINAL DIAGNOSIS IN PATIENTS UNDERGOING EBUS- TBNA FOR NON-SMALL CELL LUNG CANCER STAGING

C. Caupena Auledas, M. Martinez Palau, B. García Cabo, T. Pribic, L. Esteban Tejero, F. Perez Ochoa, R. Albero Gonzalez, C. Ferrer Cassado, P. Forcada Guiu, S.P. Pontes De Sousa, X. Tarroch Sarasa, J. Sanz Santos

Hospital Mutua de Terrassa, Terrassa/Spain

Background: In patients with non-small cell lung cancer (NSCLC) undergoing mediastinal staging through endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) clinical decision making is based in rapid on-site evaluation (ROSE) findings. We aimed to analyze the accuracy of ROSE determining the rate of concordance between ROSE and final diagnosis. **Method:** Prospective study that included patients undergoing EBUS-TBNA for NSCLC staging. Results of ROSE were compared with final diagnosis. **Result:** Sixty-four patients were included and 637 lymph nodes (LN) were sampled: a median of 10 (IQR 8-12) LNs and a median of 5 (IQR: 4-6) nodal stations per patient were sampled. The diagnoses of ROSE were concordant with the final diagnoses in 612 (96.1%) cases and non-concordant in 25 (3.9%). There were 7 (1.2%) LNs in which the diagnosis of ROSE was non-malignant with a final diagnosis of malignancy. On the contrary, there was a single case (0.2%) in which the diagnosis of ROSE was malignant with the final diagnosis being normal LN. Considering final diagnosis as the gold standard, the sensitivity, specificity and overall accuracy of ROSE were 98.6, 97.2 and 98.5% respectively. Table 1:

DIAGNOSIS ROSE FINAL DIAGNOSIS	Non-diagnostic/ Inadequate (82)	Benign/ Normal lymph node (520)	Malignancy (36)
Non-diagnostic/ Inadequate (70)	67	3	0
Benign/ Normal lymph node (526)	14	511	1
Malignancy (42)	1	6	35

Conclusion: The preliminary diagnoses (ROSE) are concordant with the final diagnoses in a high percentage. Consequently, clinical decisions based on the ROSE can be taken with confidence.

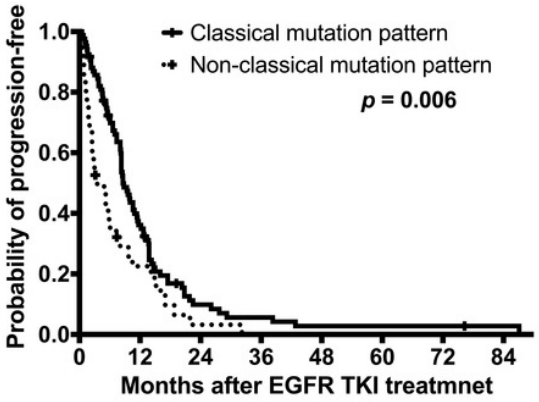
OA11.01 COMPLEX EGFR MUTATIONS IN LUNG ADENOCARCINOMA

S.-G. Wu[1], C.-J. Yu[1], J. Yang[2], J.-Y. Shih[1]

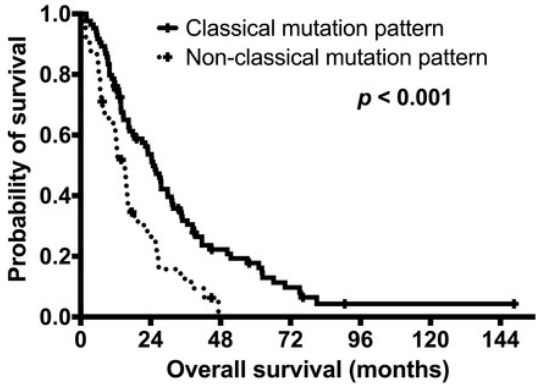
[1]*National Taiwan University Hospital, Taipei/Taiwan,* [2]*Department of Oncology, National Taiwan University Hospital and National Taiwan University Cancer Center, Taipei/Taiwan*

Background: Epidermal growth factor receptor tyrosine kinase inhibitors (EGFR TKIs) provides a favorable treatment efficacy for *EGFR*-mutant lung cancer patients. Majority of *EGFR* mutations are a single mutation, including deletion in exon 19 (del-19) or L858R in exon 21. There is a subset of patients with complex *EGFR* mutations which contains two or more *EGFR* mutation types. It is unclear the treatment efficacy to different EGFR TKIs and survival prognosis for the complex *EGFR*-mutant patients due to small sample sizes of the prior studies. This study aimed to improve the understanding of the clinical characteristics and the prognosis of EGFR TKI treatment in lung adenocarcinoma patients with complex *EGFR* mutations. **Method:** Between June 2005 to July 2018, patients harboring lung adenocarcinoma with complex *EGFR* mutations who were treated with EGFR TKIs were collected for *EGFR* mutation analysis by direct Sanger sequencing. Patients' clinical characteristics, *EGFR* mutation status, treatment response, progression-free survival (PFS) and overall survival (OS) were analyzed. Patients harboring tumor with de novo T790M mutations were excluded for evaluation of EGFR TKI effectiveness. **Result:** There were 175 patients (6.3%) with complex *EGFR* mutation from 2390 *EGFR*-mutant patients. Of the 175 complex *EGFR*-mutant patients, 122 patients who received EGFR TKIs were enrolled for evaluation of TKI effectiveness. Patients with the classical mutation pattern (del-19 or L858R) had higher treatment response rate (78.6% vs. 47.4%; p = 0.001) and PFS (8.6 months vs. 3.3 months; p = 0.006) than those without the classical mutations patterns (Fig-A). In multivariate analysis, female (p = 0.002), patients with disease relapse status, and the classical mutation patterns (p < 0.001) were associated with prolonged PFS. Compared with gefitinib and erlotinib, afatinib had a longer PFS, especially for patients without the classical mutation patterns. For OS, multivariate analysis revealed that female (p < 0.001), patients harbored classical mutation pattern (p = 0.001) (Fig-B), and patients with disease relapse status had longer OS. There were 51 patients who had re-biopsy tissue samples after acquired resistance to EGFR TKIs, 17 (33.3%) samples harbored T790M. In addition, small cell lung cancer transformation was detected in 3 (2%) patient's re-biopsy tissue samples.

(A)



(B)



Conclusion: Female patients with complex *EGFR*-mutant lung adenocarcinoma and the classical mutation patterns have higher response rate, longer PFS and OS than those without the classical mutation patterns. Afatinib was active in lung adenocarcinoma harboring complex *EGFR* mutations, and may especially benefit patients without the classical mutation patterns due to longer PFS results.

OA11.02 CHANGES OF BRAIN STRUCTURE IN ADVANCED NSCLC PATIENTS RECEIVING EGFR-TKIS: DYNAMIC ANALYSIS BASED ON SERIES MRI IMAGES

C. Luo[1], B. Yang[2], X. Zhou[1], L. Zhou[1], Y. Zhou[1], J. Zhu[1], M. Huang[1], F. Peng[1], Y. Liu[1], Y. Wang[1], Z. Li[3], Y. Lu[1], S. Lui[2], Y. Gong[1]

[1]*Department of Thoracic Oncology and State Key Laboratory of Biotherapy, Cancer Center, West China Hospital, Sichuan University, Chengdu, sichuan province/China,* [2]*Department of Radiology, West China Hospital, Sichuan University, Chengdu, Sichuan Province/China,* [3]*Department of Radiation Oncology, West China Hospital, Sichuan University, Chengdu, Sichuan Province/China*

Background: EGFR-TKI was the standard care for metastatic NSCLC patients harboring positive EGFR mutation, which might inhibit EGF signaling pathway and consequently have effect on differentiation, maturation and rehabilitation of neural cells. For the first time, we evaluated the dynamic changes of white matter lesion (WML) and gray matter volume (GMV) among such patients based on series of MRI images. **Method:** We retrospectively identified 778 patients with pathologically diagnosed advanced NSCLC receiving first-generation EGFR-TKIs in our hospital from 2010 to 2017, and 75 patients without brain metastasis and else comorbidity (hypertension, *etc.*) were analyzed. The modified Scheltens visual scale were performed to evaluate the changes of WML based on the series (baseline, 12 months' point and 24 months' point) of MRI images, and CBM (cluster-based morphometry) method based on SPM12 were adopted to identify GMV loss. The statistical methods were performed using SPSS software 22.0. **Result:** During the 24-month EGFR-TKI treatment, the patient's WML visual scores showed a progressive worsen. Comparing to the baseline (6.680±3.636), the scores were significantly changed at the 12 months' point (8.650±3.857; Mean scores increasing 1.973, 95% CI 1.595-2.352, p<0.001) and changed more obviously at the 24 months' point (10.110±3.854; Mean scores increasing 3.427, 95% CI 2.979-3.874, p<0.001), respectively. Also, the significant GMV loss were found in subregions of the right occipital lobe (mean decrease 76.714, 95% CI 40.739-112.690), left occipital lobe (mean decrease 93.476, 95% CI 37.483-149.469) and left basal ganglia (mean decrease 37.571, 95% CI 21.576-53.567), respectively (all p<0.005, the cluster level FDR<0.05). **Conclusion:** Dynamic structural analysis of series brain MRI images showed the significant worsen of the WML and GMV loss in patients with advanced NSCLC receiving EGFR-TKIs chronically. Perspective studies are warranted to verify its impact on the cognitive deficiency and hypomnesis among these patients in future.

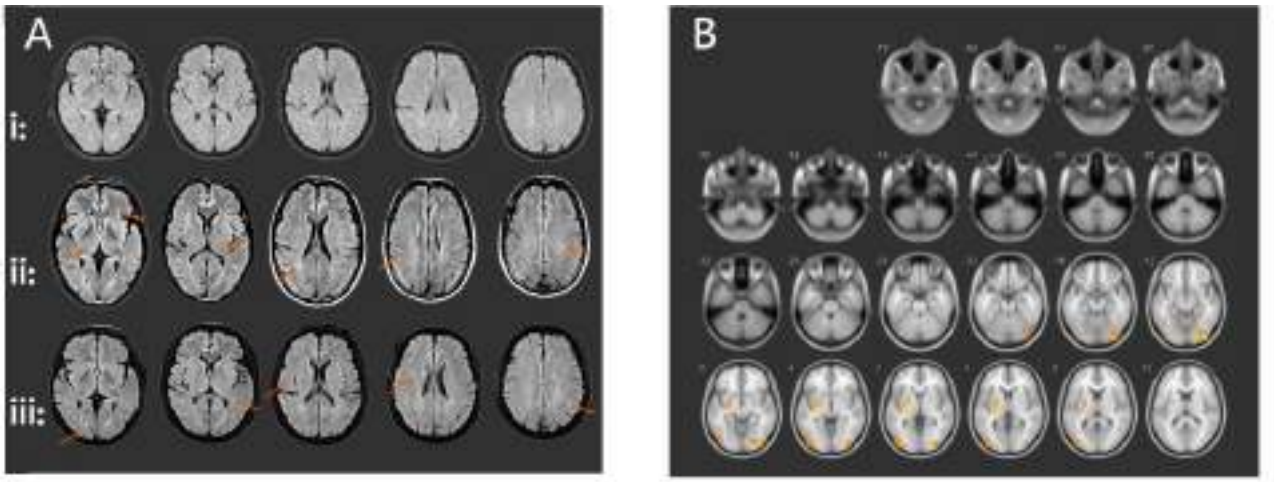

Figure . A. Series MRI images of one representative patient receiving long-term EGFR-TKI. (i. Baseline; ii. 12 months' point; iii. 24 months' point). New white matter lesions were identified in T2 FLAIR images (with yellow arrows). B. Significant loss of gray matter volume (colored areas) was identified by cluster-based morphometry method in the brain subregions among the studied population.

OA11.03 SURVIVAL DISPARITIES BETWEEN ACADEMIC AND COMMUNITY CENTERS IN ADVANCED LUNG CANCER IN THE US: CAN WE BRIDGE THE GAP?

S. Ramalingam, M. Dinan, J. Crawford

Duke Cancer Institute, Durham/United States of America

Background: Lung cancer causes the most cancer deaths in the US. Our prior study found widening 2-year survival (2YS) disparity between academic and community-based centers (ACs and CCs) prior to 2010, most apparent in adenocarcinoma, suggesting a treatment-related effect. We hypothesized this disparity continued to widen in more recent years. **Method:** Retrospective study of outcomes through 2015 within the National Cancer Database. The primary outcome was 2YS. We used multivariable regression modeling, incorporating diagnosis year, facility type, age, gender, Charlson-Deyo score, and histology to compare AC/CC. A third facility type was identified, Integrated Network Cancer Programs (IC); we did a separate analysis incorporating AC/CC/IC. We formed six cohorts by 1)facility type and 2)time period (2004 through 2008, and 2011 through 2015). Hazard ratios were computed to compare survival between these six cohorts. **Result:** 98,069 patients were included. Treatment in ACs had superior 2YS compared to treatment in CCs, increasing from 16.1% versus 10.3% for those diagnosed in 2004(+5.8%), to 23.7% versus 16.2% for those diagnosed in 2013(+7.5%). Our multivariable model found growth in 2YS disparity of 0.34%-per-year (95% CI 0.18% to 0.50%, p<0.001). This was histology-related: Difference in adenocarcinoma 2YS rose from 7% in 2004 to 9% in 2013(p=0.0023), while squamous carcinoma 2YS difference was 2.7% in 2004 and 0.8% in 2013(p=0.6). 9047 patients were treated at ICs. In the 2004-2008 cohort treatment at ICs had similar outcomes to CCs, however by 2011-2015 ICs had superior histology-related survival, suggesting treatment-related improvements in ICs over CCs (Table 1). **Conclusion:** Survival disparities in metastatic lung cancer between academic and community-based centers in the US continued to widen through 2015. Treatment at integrated centers, a group of facilities with at least one hospital that can include community and academic centers, may help to bridge the divide. Treatment related disparities in other health systems warrant further study globally.

Comparison with 2004 through 2008 Community Center Cohort	Overall	Adenocarcinoma	Squamous
2004-2008 AC	0.80*	0.78*	0.86*
2004-2008 IC	0.93, p=0.0013	0.95, p=0.116	0.94, p=0.29
2011-2015 CC	0.82*	0.82*	0.89*
2011-2015 AC	0.64*	0.62*	0.81*
2011-2015 IC	0.74*	0.72*	0.89,p=0.0218

OA11.05 OPTIMIZING RESOURCES WITH IMMUNOTHERAPY IN DEVELOPING COUNTRIES: EXPERIENCE IN A REFERENCE CENTER IN MEXICO

O. Macedo-Perez[1], I. Lyra Gonzalez[2], L. Bornstein[3], K. Campos-Peralta[1], J. Aguilar-Ponce[1], A. Gomez-Ponce[1], A. Herrera-Gomez[1], E. Jimenez-Fuentes[1]

[1]*Instituto Nacional de Cancerologia, Ciudad de Mexico/Mexico,* [2]*Princess Margaret Cancer Centre, Toronto/Canada,* [3]*Inmuno Q S.C., Ciudad de Mexico/Mexico*

Background: Immunotherapy has proven clinical benefit in several tumors as a first line therapy or after standard treatment failure. Pivotal trials with immunotherapy were designed using a weight-based dose. However, recently as part of an effort to standardize the dose of the most common drugs (Nivolumab and Pembrolizumab) the Regulatory Agencies and Pharmaceutics have changed its prescription to fixed doses. In those pivotal studies, the median weight was around 70 to 80 kg. Our hypothesis estimates that a fixed dose increases the use of drug above effective thresholds increasing unnecessary expenses. **Method:** We analyzed a cohort of patients treated with immunotherapy due to lung cancer (NSCLC) diagnosis either during first or second-line of treatment between 2016 and 2018 in the Thoracic Tumors Clinic at National Cancerology Institute in Mexico. We analyzed and estimated the median body in our population. Then, we compared treatment costs between weight-based doses (Nivolumab 3mg/Kg q.2 weeks and Pembrolizumab 2mg/Kg q.3 weeks) versus flat dose treatment (Nivolumab 240mg q.2 weeks and Pembrolizumab 200mg q.3 weeks). **Result:** 792 patients were included with and a median weight of 65 kg (SD ±13.11) was determined. Fixed dose of pembrolizumab administered during one year (17 applications) had an annual cost of $135,218 dlls. while the cost with weight-based dose was $87,913 dlls. with a net difference of $47,305 dlls. In the case of Nivolumab, an annual fixed-dose treatment (26 applications) has a cost of $114,816 dlls, while the weight-based dose has a cost of $93,392 dlls. with a net difference of $21,424 dlls (table1).

PEMBROLIZUMAB (2 mg/Kg) Q3W vs 200mg Q3W						
Comparison	**Total dose per cycle**	**Cost per cycle**	**Excess cost per cycle**	**Dose difference**	**Annual cost treatment (17 cycles)**	**Net difference annual cost per patient**
Weight based dose (Median 65Kg)	130 mg	$5171.4	$2,782.6	70mg	$87,913	$47,305
Fixed-dose	200mg	$7,954	NA	NA	$135,218	NA
NIVOLUMAB (3mg/Kg) Q2W vs 240mg Q2W						
Comparison	Total dose per cycle	Cost per cycle	Excess cost per cycle	Dose difference	Annual cost treatment (26 cycles)	
Weight based dose (Median 65Kg)	195mg	$3,592	$824	45mg	$93,392	$21,424
Fixed-dose	240mg	$4,416	NA	NA	$114,816	NA

Conclusion: General population in developing countries like Mexico are experiencing serious difficulties to get access to immunotherapy due to lack of coverage through Public Health Care System based in costs. According with our study, optimization of resources with weight-base dose could allow us to increase the rate of treated patients. Then, according with our analysis, in the case of Pembrolizumab we calculated coverage of 154 treatments instead of 100 using same budget and favoring the use of weight-based dose. While, in the case of Nivolumab we could increase the number of patients treated from 100 to 126 using weight-based dose. Therefore, our results support that therapies like immunotherapy should be calculated based on body weight as an attempt to increase access and avoid unnecessary expenses in Health Care Systems with limited resources.

OA11.06 ALTERNATIVE NIVOLUMAB (N) DURATION AND SCHEDULING IN ADVANCED NON-SMALL CELL LUNG CANCER (ANSCLC): REAL-LIFE DATA

E. Dudnik[1], M. Moskovitz[2], A. Agbarya[3], T. Kuznetsov[4], T. Shochat[5], D. Urban[4], M. Wollner[6], A. Zer[1], O. Rotem[1], N. Peled[7], J. Bar[4]

[1]*Davidoff Cancer Center Rabin Medical Center, Petah Tikva/Israel,* [2]*Rambam Health Care Campus, Haifa, Israel/Israel,* [3]*Bney Zion Medical Center, Haifa/ Israel,* [4]*Chaim Sheba Medical Center, Tel HaShomer, Ramat Gan/Israel,* [5]*Rabin Medical Center, Petah Tikva/Israel,* [6]*Rambam Health Care Campus,, Haifa, Israel/Israel,* [7]*Soroka Medical Center, Beer Sheva/Israel*

Background: Little is known regarding the optimal scheduling and treatment (Tx) duration of N in aNSCLC. Stopping N after 1 year of Tx negatively affects outcomes. **Method:** 45 consecutive aNSCLC patients (pts) receiving N for ≥2 years (y) were identified in the electronic databases of 4 Israeli cancer centers. These were divided into Groups A (N continued for >2y at a dose 3mg/kg q2w/240mg q2w; n-21), B (N continued for >2y at a dose 3mg/kg q3w-q8w/480mg q4w; n-17), and C (N stopped at 2y for reason other than progressive disease or intolerable toxicity; n-7). PFS (RECIST 1.1) and safety since 2y after N initiation were assessed. **Result:** Baseline, treatment characteristics and outcomes are presented in the Table and the Picture. Allocation to Group B and C was associated with HR for PFS-2.4 (95%CI, 0.3-18.8, p-0.4) and HR for PFS-3.3 (95%CI, 0.3-30.9, p-0.3), respectively. After 2y since N initiation, new N-related toxicity developed in 24%, 18%, and 28% of pts in Groups A, B, and C, respectively (p-NS).

Conclusion: A trend for worse outcomes was observed with alternative N scheduling/N quitting 2y after initiation. So far, continuing N at a standard dose until disease progression/ intolerable toxicity remains the standard treatment option.

OA11.07 CHEMOTHERAPY PLUS EGFR-TKI AS FIRST-LINE TREATMENT PROVIDES BETTER SURVIVAL FOR EGFR MUTATION NSCLC PATIENTS: UPDATE DATA FOR NCT02148380

W. Zhang, J. Xu, Y. Lou, Y. Zhang, B. Han

Shanghai Chest Hospital, Shanghai Jiao Tong University, Shanghai/China

Background: Previously, we did a prospective study to compare pemetrexed plus carboplatin and gefitinib to either pemetrexed plus carboplatin or gefitinib alone as first-line therapy for lung adenocarcinoma patients harboring sensitive EGFR mutations (NCT02148380). The primary endpoint PFS was met at Oct 1, 2016. However, the OS of combinational group was not mature then [Han B, *et al*. Int J Cancer. 2017;141:1249-1256]. In the present study, we continued the OS follow-up until Sep 28 2018. **Method:** The survival curves for OS were estimated with the Kaplan-Meier method and were compared between combination and gefitinib groups using the log-rank test. 2-years, 3-years survival rates were compared between combination and gefitinib groups using Pearson Chi-Square. **Result:** Baseline characteristics of the intent-to-treat (ITT) population have been reported. At last day of follow-up (Sep 28 2018), 30 (75.0%) patients in the combinational group, 35 (85.4%) patients in the gefitinib group died. 2-year survival rates of combinational and gefitinib groups were 85.0% (34/40), 56.1% (23/41) (P=0.004), respectively. 3-year survival rates of combinational and gefitinib groups were 52.5% (21/40), 24.4% (10/41) (P=0.009), respectively. The median OS was 37.9 months (95%CI: 17.3-58.6) for the combinational group, which was substantially longer than the median OS for first-line gefitinib group (25.8 months [95%CI: 19.2-32.3]). The HR of combinational group versus gefitinib group was 0.56 (95%CI:0.34-0.91, P=0.02). 19del: The median OS was 51.0 months (95%CI: 36.6-65.5) for the combinational group, which was substantially longer than the median OS for first-line gefitinib group (29.8 months [95%CI: 26.7-32.9]). The HR of combinational group versus gefitinib group was 0.61 (95%CI:0.30-1.25, P=0.18). 21L858R: The median OS was 32.3 months (95%CI: 27.8-36.7) for the combinational group, which was substantially longer than the median OS for first-line gefitinib group (22.8 months [95%CI: 13.1-32.5]). The HR of combinational group versus gefitinib group was 0.50 (95%CI:0.25-1.00, P=0.05). Totally, 15 patients had baseline central nervous system (CNS) metastases. The median OS of patients who had baseline CNS metastases was 25.6 months (95%CI: 15.1-36.1); the median OS of patients who had no baseline CNS metastases was 31.7 months (95%CI: 28.2-35.2). The HR of CNS metastases group versus no CNS metastases group was 2.80 (95%CI:1.51-5.18, P=0.001). Among the combinational group, 20% (8/40) percent of patients had baseline CNS metastases. 17.1% (7/41) percent of patients in the gefitinib group had baseline CNS metastases. CNS: The median OS was 27.0 months, (95%CI: 21.8-32.3) for the combinational group, which was substantially longer than the median OS for first-line gefitinib group (15.5 months, 95%CI: 6.8-24.3). The HR of combinational group versus gefitinib group was 0.17 (95%CI:0.04-0.68, P=0.013). No CNS: The median OS was 47.4 months, 95%CI: 27.2-67.7 for the combinational group, which was substantially longer than the median OS for first-line gefitinib group (27.4 months, 95%CI: 23.0-33.7). The HR of combinational group versus gefitinib group was 0.57 (95%CI:0.32-0.99, P=0.044). **Conclusion:** The current study on lung adenocarcinoma patients harboring sensitive EGFR mutations showed that the combined treatment with pemetrexed plus carboplatin with gefitinib provide better survival benefits than gefitinib alone.

OA12.01 PCI FOR RADICALLY TREATED NON-SMALL CELL LUNG CANCER: A META-ANALYSIS USING UPDATED INDIVIDUAL PATIENT DATA OF RANDOMIZED TRIALS

W. Witlox[1], D. De Ruysscher[2], B. Lacas[3], C. Le Pechoux[3], J.-P. Pignon[3], M. Guckenberger[4], A. Sun[5], M. Redman[6], S.-Y. Wang[7], C. Hu[8], V. Van Der Noort[9], N. Li[7], H. Van Tinteren[9], H. Groen[10], M. Joore[1], B. Ramaekers[1]

[1]*Maastricht University Medical Center, Maastricht/Netherlands,* [2]*Maastricht University Medical Center, Netherlands/Netherlands,* [3]*Gustave Roussy, Villejuif/France,* [4]*University Hospital Zurich, University of Zurich, Zurich/Switzerland,* [5]*Princess Margaret Cancer Centre, Toronto/Canada,* [6]*Fred Hutchinson Cancer Research Center, Seattle/United States of America,* [7]*Sun Yat-sen University Cancer Center, Guangzhou/China,* [8]*NRG Oncology Statistics and Data Management Center, Philadelphia/United States of America,* [9]*Netherlands Cancer Institute, Amsterdam/Netherlands,* [10]*University Medical Center Groningen, Groningen/Netherlands*

Background: In localized non-small cell lung cancer (NSCLC), prophylactic cranial irradiation (PCI) reduced the incidence of brain metastases (BM) (relative risk 0.35), but without a demonstrated effect on overall survival (OS). This may be due to the small sample size in these individual randomized clinical trials (RCTs). Therefore, we aimed to assess the impact of PCI on long term OS for radically treated stage III NSCLC patients compared to observation using updated individual patient data (IPD) from RCTs. **Method:** The main endpoint was OS and secondary endpoints were progression-free survival (PFS), BM-free survival (BMFS) and toxicity. All analyses were performed based on the intention-to-treat principle. The median follow-up was estimated using the inverse Kaplan-Meier method. The log-rank observed minus expected number of events and its variance were used to calculate individual and overall pooled hazard ratios (HRs) and 95% confidence intervals (95% CIs) with a fixed effects model. Heterogeneity was studied using the Cochrane test and I^2. Survival curves and 5-year difference between arms were estimated using the Peto method. Interaction between prognostic factors (age, performance status, and histology) and treatment allocation were assessed using Cox proportional hazards models. Toxicities grade $\geq$ 3 were reported descriptively. **Result:** Data on four of the seven eligible trials (SWOG 8300, RTOG 0214, Guangzhou 2005 and NVALT-11) were available for this IPD meta-analysis. In total, 924 patients were analyzed of which 68% was male, median age was 61 years, 94% of the patients had a performance status $\leq$ 1 and 37% had squamous histology. The median follow-up was 8.1 years. All trials provided sufficient IPD for the three endpoints, except for the SWOG 8300 trial (OS only). This trial explained inter-trial heterogeneity. Because of the qualitative interaction with the other trials (p=0.0062) it was separately analyzed (N=254). Compared to observation, OS was significantly lower for PCI in the SWOG 8300 trial (HR 1.38, 95% CI [1.07 to 1.79] p=0.013, 5-year absolute difference -0.9%, 95% CI [-5.9 to 4.1]). However, for the other trials (N=670) no significant OS difference was observed (HR 0.90, 95% CI [0.76 to 1.07] p=0.228, 5-year absolute difference 1.8%, 95% CI [-5.2 to 8.8]). PFS (HR 0.78, 95% CI [0.65 to 0.92] p=0.004, 5-year absolute difference 4.8%, 95% CI [-1.2 to 10.8]) and BMFS (0.38, 95% CI [0.27 to 0.53] p<0.001, 5-year absolute difference 20.7%, 95% CI [12.2 to 29.2]) were significantly higher in the PCI arm. There was no interaction between prognostic factors and treatment allocation for OS. Toxicity data for the PCI arm was available in all trials except the SWOG 8300 trial. The total number of patients with at least one grade $\geq$3 toxicity (for the adverse events pre-specified in the protocol) in the PCI arm was 19/456, including 11/86 in the NVALT-11 trial. Toxicity for the observation arm was only available in the NVALT-11 trial, including 4/88 patients with at least one grade $\geq$3 toxicity. **Conclusion:** Although PFS and BM-free survival were improved for patients who received PCI, no significant PCI benefit for OS was observed.

Background: SPECTRA, a multicenter, randomized phase II study of CDDP+S-1 versus CDDP+pemetrexed (PEM) combined with thoracic radiotherapy (TRT) for locally advanced non-squamous non-small cell lung cancer (NSCLC), previously reported that toxicities were tolerable and manageable in both arms; however, febrile neutropenia was more frequently observed in the CDDP+S-1 arm (9.6%/2%). Completion rate of TRT (60Gy) and chemotherapy (4 cycles) was 92%/98% and 73%/86%, respectively. Response rate was 60%/64% (WCLC 2017, MA17.06). Here, we present primary analysis of 2-year survival data. **Method:** Patients were randomly assigned to receive CDDP+S-1 (CDDP 60mg/m^2, d1, and S-1 80mg/m^2, d1-14, q4w, up to 4 cycles) or CDDP+PEM (CDDP 75mg/m^2, d1, and PEM 500mg/m^2, d1, q3w, up to 4 cycles) combined with TRT 60Gy in 30 fractions. The primary endpoint was 2-year progression-free survival (PFS) rate. The sample size was set at 100 patients. **Result:** Between Jan 2013 and Oct 2016, 102 patients were enrolled in this study from 9 institutions in Japan. All 102 patients were eligible and assessable, of whom 52 were assigned to CDDP+S-1 and 50 to CDDP+PEM. Baseline characteristics were similar (CDDP+S-1/CDDP+PEM): median age (range) 64.5 (39-73)/63.5 (32-74) years; women, n=17 (33%)/n=17 (34%); stage IIIB, n=21 (40%)/n=20 (40%); ECOG PS of 1, n=14 (27%)/n=14 (28%); never smoker, n=12 (23%)/n=12 (24%); and adenocarcinoma, n=47(90%)/n=45(90%); activating EGFR mutation, n=9 (17%)/n=4 (8%); ALK fusion, n=2 (4%)/n=3 (6%). A total of 72 PFS events were observed at the data cut-off (28 November 2018). After a median follow-up of 32.1 months, median PFS was 12.7/13.8 months (HR=1.16, 95% CI, 0.73-1.84, p=0.538), and 2-year PFS rate was 36.5% (95% CI, 23.5-49.6)/32.1% (95%CI, 18.9-45.4). Disease progression was observed in 33 and 36 patients. Distant metastases were the first site of failure in 24 and 31 patients. Local relapse as the first site of failure was observed in 14 and 13 patients. After a median follow-up of 34.6 months, 44 OS events were observed. Median OS was 48.3/59.1 months (HR=1.05, 95%CI, 0.58-1.90, p=0.883), and 2-year OS rate was 69.2% (95%CI, 56.7-81.8)/66.4% (95%CI, 53.0-79.9). 27 patients in each arm received post-study chemotherapy including EGFR-TKIs (n=7/n=5), ALK-TKIs (n=0/n=3), and immune checkpoint inhibitors (n=6/n=10). **Conclusion:** 2-year PFS rate in the CDDP+S-1 arm was better than that in the CDDP+PEM arm. We will select the CDDP+S-1 arm as the investigational arm in a future phase III study. UMIN000009914 (release date: 31/Jan/2013)

Background: Preclinical and retrospective clinical data, have shown that metformin, an inexpensive diabetes drug, has the potential to improve response to chemotherapy and radiation in several solid tumors, including non-small cell lung cancer (NSCLC). These findings led to NRG-LU001, a multi-institutional, international randomized Phase II clinical trial to determine whether metformin can improve outcomes of curative chemoradiation (CRT) in locally advanced NSCLC (LA-NSCLC). **Method:** Unresectable stage IIIA/B NSCLC patients were randomized to either concurrent chemoradiation to 60 Gy with weekly carboplatin-paclitaxel (CP), followed by consolidation CP (Control) or the same regimen combined with metformin (2000 mg/day) (Experimental). The primary endpoint was 1-year progression free survival (PFS). PFS and overall survival (OS) were estimated using the method of Kaplan-Meier. Time to loco-regional progression (TTLRP) or distant metastasis (TTDM) were estimated using the cumulative incidence method. Adverse events (AEs) were graded using CTCAE v4.0. **Result:** 170 patients were randomized between Aug. 2014-Dec. 2016, with planned analysis at 102 events. No significant difference in toxicity was observed between Control and Experimental arms. 1- and 2-year PFS was 60.4% (95% CI: 48.5, 70.4) and 40.1% (95% CI: 29.0, 51.0) in Control vs 51.3% (95% CI: 39.8, 61.7) and 34.5% (95% CI: 24.2, 45.1) in the Experimental arm (multivariable Cox proportional HR=1.20 (95% CI: 0.81, 1.78), p=0.36). On multivariable analysis including treatment arm, performance status, histology and stage, only higher stage (IIIA vs. IIIB) was associated with worse PFS (HR 1.79, 95% CI:1.19, 2.69, p=0.0054). OS at 2 years was 65.4% (95% CI: 53.5, 75.0) for Control vs 64.9% (95% CI: 53.1, 74.5) for the Metformin arm (HR=1.03 (95% CI: 0.64, 1.68)), while deaths due to disease were 90% vs 71%, respectively. No significant differences were found for TTLRP (HR 1.01, 95% CI: 0.57, 1.79, p=0.98) or TTDM (1.38, 95% CI: 0.76, 2.5, p=0.29). 63.4% of patients in the experimental arm received the complete course of metformin, with the most common cause of discontinuation being side effects or complications (13.4%). **Conclusion:** In NRG-LU001, concurrent CRT and metformin presented no noticeable safety concerns. However, this combination failed to improve PFS at the hypothesized effect size. Additionally, no effect on OS or patterns of failure were identified. Blinded central review of imaging based PFS is ongoing. Somewhat unexpectedly, 37% of patients did not complete the prescribed course of metformin. Additionally, deaths due to disease were less in the experimental arm compared to control.

Background: Advanced medical imaging offers a chance for target volume reduction in modern radiotherapy, which may lead to more effective local treatments with reduced toxicity and offer the protection of draining lymph nodes and large vessels, possibly of importance for the upcoming combination of radiotherapy and immunotherapy. Locally advanced non-small cell lung cancer (NSCLC) with improvable local control and high toxicity is an excellent model to investigate this topic. **Method:** In the prospective randomised controlled PET-Plan trial (NCT00697333), patients with inoperable stage II/III NSCLC and an indication for radiochemotherapy were randomized at a 1:1 ratio. In conventional arm A target volumes were informed by FDG-PET and CT plus elective nodal irradiation and in experimental arm B they were solely informed by FDG-PET. In both arms, quality assured isotoxically dose-escalated IMRT or 3D-CRT (60–74Gy, 2Gy per fraction) was planned and applied to the respective target volumes along with simultaneous platinum-based chemotherapy. The primary objective was time to locoregional progression (LRP) in terms of non-inferiority of experimental arm B. **Result:** 311 patients were recruited, 205 patients included in the intent to treat (ITT) (A: n=99, B: n=106) and 172 patients in the per protocol (PP) analysis (A: n=84, B: n=88). Median FU time in the PP set was 16 months. Non-inferiority of experimental arm B was confirmed for the pre-specified non-inferiority margin. The risk of LRP was lower in the experimental arm B (2y-LRP 0.20 vs. 0.39; HR=0·57; 95% CI: 0·30–1·06; p=0·039) with no difference between study arms concerning survival (2y-OS 0.57 vs. 0.54), out-field recurrence and toxicity. **Conclusion:** In radiochemotherapy for locally advanced NSCLC PET-Imaging based reduction of radiotherapy target volumes is feasible and may improve local control without increasing toxicity. However, in this trial there was no impact on survival. The procedures established in this clinical trial provide a radiotherapy standard for future NSCLC-trials including immunotherapy and may furthermore inspire trials on imaging based target volume reduction for other types of tumours.

OA12.06 A PROSPECTIVE RANDOMIZED PHASE III STUDY OF PRECISE PORT FOR PATIENTS WITH PIIIA-N2 NSCLC AFTER COMPLETE RESECTION AND ADJUVANT CHEMOTHERAPY

Z. Hui[1], Y. Men[1], C. Hu[2], Z. Zhou[1], J. Liang[1], Q. Feng[1], B. Nan[1], X. Wang[1], D. Chen[1], Z. Xiao[1], J. Lv[1], L. Deng[1], T. Zhang[1], W. Wang[1], S. Gao[1], J. He[1], L. Wang[1]

[1]*National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing/China,* [2]*Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins University School of Medicine, Baltimore/United States of America*

Background: For patients with completely resected pIIIA-N2 non-small cell lung cancer (NSCLC), the role of postoperative radiotherapy (PORT) is not well defined. 3D-conformal or simplified intensity modulated radiotherapy (3D-CRT/sIMRT) can precisely deliver high dose to the target volume while decreasing the toxicity of normal tissues, which may improve the treatment outcomes. This phase III randomized clinical trial (NCT00880971) is designed to evaluate the effect of precise PORT on survival and failure pattern in patients with pIIIA-N2 NSCLC after complete resection and adjuvant chemotherapy. **Method:** After complete resection and four cycles of platinum based chemotherapy, patients with pIIIA-N2 NSCLC were randomized equally into PORT group or observation group. Using 3D-CRT/sIMRT techniques, PORT of 50 Gy by 25 fractions was given to the ipsilateral hilum, subcarinal region and ipsilateral mediastinum. The primary endpoint was disease free survival (DFS). Secondary endpoints include overall survival (OS), loco-regional recurrence free survival (LRFS), distant metastasis free survival (DMFS) and toxicity. Targeted accrue was 360 patients. With at least 230 DFS events it was designed to detect an improvement in 3-year DFS from 30% to 44% (equivalent to HR=0.69) at 1-sided type 1 error of 0.025 with 80% power. Intent-to-treat populations is used for primary analyses, supplemented with sensitivity analyses using per-protocol population. Log-rank test is used for time-to-event data comparisons. **Result:** Between Jan. 2009 and Dec. 2017, 364 consecutive eligible patients were randomized, including 184 in the PORT group and 180 in the observation group. For this initial reporting of planned final analysis, as Jan 31, 2019, 230 DFS events were reported and the median follow up time was 53.3 months. The clinical features were comparable between the two groups. The 3-year DFS rates in PORT and observation were 42.7% vs. 34.5% (mDFS: 26.5 vs 22.7 months, HR=0.85, 95% CI: 0.65-1.10, 1-sided p=0.10), with OS of 81.5% vs. 85.4% (mOS: not reached vs 90.9 months, HR=1.01, 95% CI: 0.68-1.51, 2-sided p=0.94), LRFS of 69.8% vs. 62.4% (HR=0.71, 95% CI: 0.51-0.97, 2-sided p=0.03), and DMFS of 44.8% vs. 43.5% (HR=0.93, 95% CI 0.71-1.22, 2-sided p=0.60), respectively. For 310 per-protocol patients (140 with PORT and 170 without PORT), PORT marginally improve the DFS (44.8% vs 32.6%, HR=0.76, 95% CI: 0.57-1.00, 2-sided p=0.05), but not OS (85.7% vs 85.0%, HR=0.83, 95% CI: 0.53-1.30, p=0.41). Relapses of any type were observed in 110 (59.8%) and 116 patients (64.4%) in the PORT and observation groups, respectively. Forty-seven over 50 deaths (94.0%) in the PORT group and 42 over 47 deaths (89.4%) in the observation group died of cancer progression, respectively. No radiotherapy-related grade 5 AE was observed. **Conclusion:** For pIIIA-N2 NSCLC patients after complete resection and adjuvant chemotherapy, precise PORT has not been shown to significantly improve DFS or OS , though it can significantly improve LRFS.

OA12.07 RADICALITY OF LYMPHADENECTOMY IN LUNG CANCER ACCORDING TO SURGICAL APPROACH. RESULTS FROM THE SPANISH GROUP OF VIDEO-ASSISTED THORACIC SURGERY

C. Obiols[1], S. Call[1], R. Rami-Porta[1], A. Jaen[2], D. Gomez De Antonio[3], S. Crowley[3], I. Royo[4], R. Embún[4]

[1]*Hospital Univeristari MútuaTerrassa, Terrassa/Spain,* [2]*Hospital Universitari MútuaTerrassa, Terrassa/Spain,* [3]*Hospital Universitario Puerta de Hierro-Majadahonda, Madrid/Spain,* [4]*Hospital Universitario Miguel Servet, Zaragoza/Spain*

Background: The minor standard of systematic nodal dissection (SND) in lung cancer surgery, which is the minimum recommended by the Union for International Cancer Control, requires the resection/sampling of, at least, 3 mediastinal (including subcarinal station) and 3 hilar/intrapulmonary lymph nodes (LN). The objective of this study is to analyze differences in intraoperative LN assessment in patients with surgically treated non-small cell lung cancer (NSCLC) according to surgical approach (open vs VATS), from the results of the Spanish Group of Video-Assisted Thoracic Surgery (GEVATS) database. **Method:** Prospective multicenter cohort study of anatomic pulmonary resections (n=3533) performed from 20/12/16 to 20/03/18. Exclusions criteria were: indications different from NSCLC, previous lung cancer, synchronous tumors and induction therapy. Patients who did not meet the criteria for SND but had no nodal involvement were coded as pathologic (p)Nx (instead of pN0). Corresponding tests for homogeneity were performed. Multiple logistic regression analysis was used to determine the odds ratio (OR) and 95% confidence interval (95%CI). Stata/SE vs 13 statistical package was used for data analysis. Significance was considered when p<0.05. **Result:** 2532 patients were analyzed (1801 men [71.1%]; median age: 67 years). SND was performed in 65%, with a median of LN resected/sampled of 7 (IQR 4-12) and a rate of pN2 of 9.5%. Table1 summarizes results from bivariate analysis.Independent risk factors for thoracotomy at multivariate analysis (OR; 95%CI) were: squamous cell carcinoma vs adenocarcinoma (1.3; 1.04-1.68), staging mediastinoscopy (2.8; 1.83-4.22), LN resected (1.02; 1.00-1.04), SND (1.4; 1.07-1.8), tumour >3cm (1.8; 1.5-2.2), central tumour (2.5; 2.0-3.1); pN1 (1.5; 1.1-2.1) and pN2 (1.6; 1.1-2.3). A significantly higher proportion of nodal upstaging was observed in thoracotomy group: from cN0 to pN1/pN2, and from cN1 to pN2 (table1).

Conclusion: The intensity of lymphadenectomy in GEVATS was superior in the thoracotomy approach. Therefore, intraoperative lymph node evaluation performed at VATS should improve to have better prognostic information and indicate adjuvant therapy.

Keywords: surgical approach, intraoperative lymphadenectomy

OA13.01 SPECS2 LUNG CANCER CONSORTIUM PROSPECTIVE MULTICENTER VALIDATION OF PROGNOSTIC SIGNATURE FOR EARLY STAGE SQUAMOUS LUNG CANCER

R. Bueno[1], D. Harpole[2], M. Tsao[3], D. Beer[4], M. Watson[5], F. Shepherd[3], W. Richards[1], K. Ballman[6], X. Wang[7], Z. Chen[6], R. Govindan[8], G. Chen[4], C. Rivard[9], F.R. Hirsch[10]

[1]*Brigham and Women's Hospital and Harvard Medical School, Boston/United States of America,* [2]*Duke University, Durham/United States of America,* [3]*University Health Network, Toronto/Canada,* [4]*University of Michigan, Ann Arbor/United States of America,* [5]*Washington U, st louis/United States of America,* [6]*Cornell College of Medicine, New York/United States of America,* [7]*Duke University Medical Center, Durham/United States of America,* [8]*Alvin J Siteman Cancer Center at Washington University School of Medicine, St Louis/United States of America,* [9]*University of Colorado, aurora/United States of America,* [10]*university of colorado, aurora/United States of America*

Background: Squamous Lung Cancer (SC) which constitutes 30% of all non-small cell lung cancers (NSCLC) has few targeted therapy options for advanced disease. Surgery for early SC is the best treatment strategy; however, even patients who undergo surgery for stage IA or IB disease are still at a substantial risk for recurrence and death. Adjuvant therapy is not currently indicated for stage I SC smaller than 4 cm. Prior reports suggest gene expression-based signatures that may predict recurrence in patients with stage I SC, but none has been validated or is in clinical use. The SPECS2 Lung Cancer Consortium was assembled to compare and attempt to validate previously published prognostic signature(s) according to the guidelines proposed by Subramanian and Simon (J Natl Cancer Inst 2010; 7:327). **Method:** The multi-institutional team assembled 249 frozen SC samples representing six participating institutions (cohort 1). These samples were fully annotated in a redcap database hosted by the independent statistical core. Cohort 2 was assembled utilizing 234 frozen SC samples from a prospective multi-institutional NCTN lung biobanking protocol (NCT00899782). RNA was extracted and profiled with U133A microarrays (Affymetrix) in independent core facilities. The data was transferred directly to the SPECS2 Lung statistical core in collaboration with the Alliance Statistical core and the performance of 6 most promising candidate signatures was evaluated relative to a base model that included only age, gender and AJCC stage (editions 6, 7, 8). **Result:** Analysis of Cohort 1 demonstrated that only one signature (Raponi et al, Cancer Res 2006; 66:7466) significantly enhanced prognosis relative to the base model, independent of AJCC edition. This was also observed in Cohort 2, where Uno's C index associated with AJCC 8th edition stage, sex and age (0.561; 0.468-0.654) was significantly ($p < 0.05$) increased when the prognostic signature was added to the model (0.683; 0.611-0.755). **Conclusion:** The SPECS2 Lung Cancer Consortium was successful in validating a previously published prognostic molecular signature for early stage SC using rigorous experimental design. To our knowledge, this is the first unbiased validation of a lung cancer prognostic signature using multi-institutional prospective specimens. These results support a clinical trial designed to evaluate the potential role of adjuvant therapy in completely resected early stage SC.

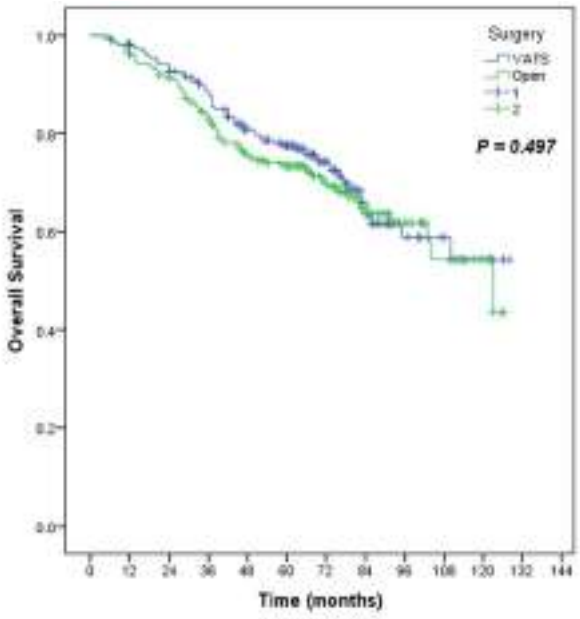
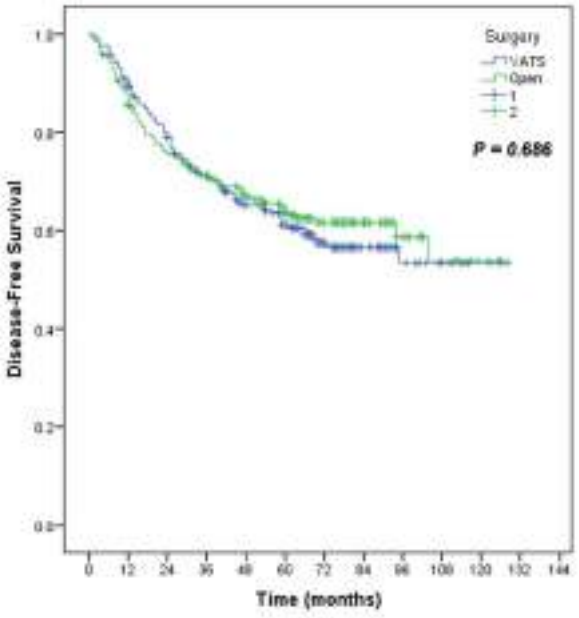
OA13.02 VIDEO-ASSISTED THORACOSCOPIC SURGERY VS. THORACOTOMY FOR NON-SMALL CELL LUNG CANCER: SURVIVAL OUTCOME OF A RANDOMIZED TRIAL

D. Situ[1], H. Long[1], Q. Tan[2], Q. Luo[3], Z. Wang[4], G. Jiang[5], T.-H. Rong[6]

[1]*Lung Cancer Research Institute, Sun Yat-sen University, Guangzhou/China,* [2]*Daping Hospital of the Third Military Medical University, Chongqing/China,* [3]*Shanghai Chest Hospital, Shanghai Jiaotong University, Shanghai/China,* [4]*Shenzhen People's Hospital, Jinan University, Shenzhen/China,* [5]*Shanghai Pulmonary Hospital, Tongji University, Shanghai/China,* [6]*Lung Cancer Research Institute, Sun Yat-Sen University, Guangzhou/China*

Background: Video-assisted thoracoscopic surgery (VATS) has been widely used in the treatment of early-stage non–small cell lung cancer (NSCLC). However, there has not been a robust randomized control trial (RCT) to confirm the non-inferiority of VATS to open lobectomy in term of oncologic efficacy. Therefore, a large multicenter RCT in China was designed and initiated to verify the role of VATS. **Method:** A phase 3 RCT was undertaken at five thoracic surgery tertiary centers in China. Patients aged 18-75 years old who were diagnosed of clinically early-stage NSCLCs were randomized in a 1:1 ratio into VATS and thoracotomy groups. Radical lobectomy plus hilar and mediastinal lymph node dissection was the standard surgical intervention. The primary end-point of study was 5-year overall survival (OS). The secondary end-points including 5-year disease-free survival (DFS) and cancer relapse rates would also be reported here. Analysis was by intention to treat. This study is registered with the ClinicalTrials.gov, number NCT01102517. **Result:** A total of 508 patients were recruited between January 2008 and March 2014. The final follow-up for 5-year survival analysis was completed in March 2019. And 432 patients were eligible for analysis (222 cases in VATS group and 210 cases in thoracotomy group). The cancer relapse (recurrence and metastasis) rates were 39.2% in VATS group and 36.7% in thoracotomy group respectively (P=0.621). Patients who received VATS lobectomies had a similar 5-year DFS to those who underwent open surgery (58% versus 62%, P=0.686). Finally, the 5-year OS rates were of no significant difference between VATS and thoracotomy groups (74% versus 71%, P=0.497).





Conclusion: The non-inferiority of VATS to thoracotomy lobectomy was confirmed in our RCT in terms of oncologic efficacy for clinically early-stage NSCLCs.

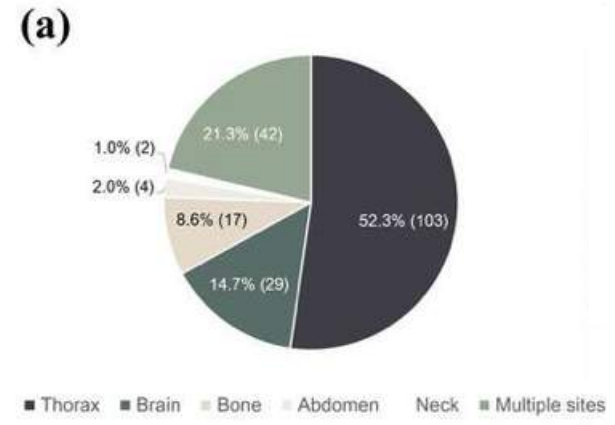
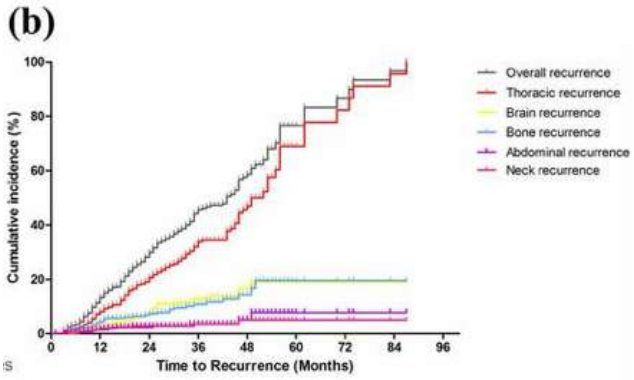
OA13.03 PREDICTING POSTOPERATIVE RECURRENCE IN COMPLETELY RESECTED EGFR-MUTANT NON-SMALL CELL LUNG CANCER: VALUE OF IHC MARKERS

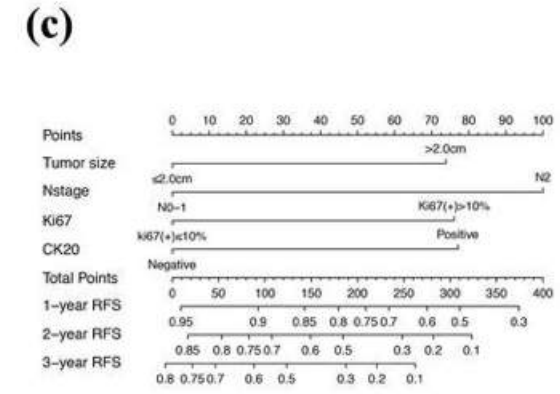
T. Guo[1], J. Ni[2], Y. Li[3], Z. Zhu[3]

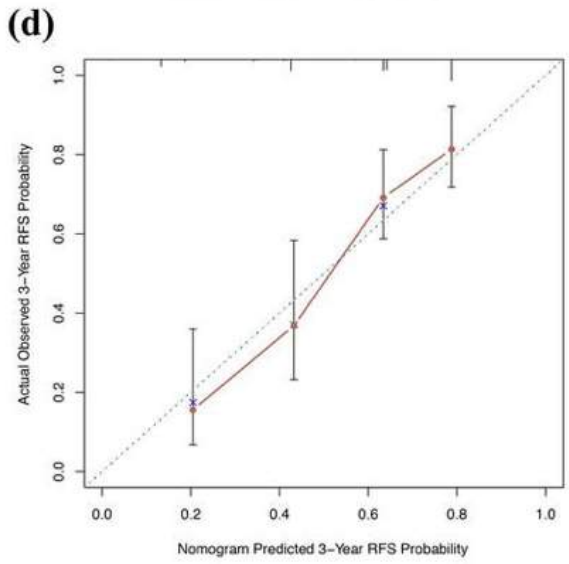
[1]Department of Radiation Oncology, Shanghai/China, [2]Department of Radiation Oncology, Fudan University Shanghai Cancer Center, Shanghai/China, [3]Fudan University Shanghai Cancer Center, Shanghai/China

Background: EGFR mutations are detected in up to 50% of non-small cell lung cancer (NSCLC) and recent studies indicate that EGFR-mutant NSCLC is a heterogeneous disease with varying co-mutations, diverse histologic subtypes and distinct expression of oncoproteins. However, the risk factors and clinical patterns of postoperative recurrence among patients with completely resected EGFR-mutant NSCLC have not been fully understood. Moreover, the prognostic values of routinely used immunohistochemical (IHC) markers in NSCLC are seldom reported. **Method:** Consecutive patients with curative resected NSCLC and confirmed EGFR mutations at Fudan University Shanghai Cancer Center from January 2007 to December 2017, were retrospectively enrolled. The initial recurrence sites were recorded and categorized into five groups: thoracic recurrence, brain recurrence, neck recurrence, abdominal recurrence, and bone recurrence. The indicators of overall and site-specific recurrence were identified using the Cox regression model, where a panel of routinely used IHC markers (including Her2, Ki67, TTF-1, CK20, CK7, CK5/6, p53, RRM1, NapsinA, p40, syn, Bcl-2, CDX2, ERCC1 and p63) were incorporated. A nomogram was developed based on variables selected in multivariate analysis. The bootstrapping method (1000 repetitions) was applied to internally validate the nomogram **Result:** After a median follow-up of 32 (range, 5-122) months, disease recurrence was observed in 197(37.1%) out of the 531 patients, with a median recurrence-free survival (RFS) of 19 (95% CI, 16.63-21.37) months. Most patients (n=136; 69.0%) had thoracic recurrence, followed by brain recurrence (n=41; 20.8%), bone recurrence (n=41; 20.8%), abdominal recurrence (n=14; 7.1%), and neck recurrence (n=13; 6.6%). Sex, tumor size, Ki67, and N stage were independent indicators of thoracic recurrence. Tumor size, N stage, CK20, and Syn were independent indicators of brain recurrence. N stage and Ki67 were independent indicators of bone recurrence. N stage was the independent indicator of abdominal recurrence and neck recurrence. Tumor size, Ki67, CK20, and N stage were independently associated with overall recurrence, and thus a nomogram predicting the 1-, 2-, and 3-year RFS probability was developed based on these four factors. The concordance index (C-index) was 0.723 (95% confidence interval, 0.675 to 0.771) and the calibration curves displayed good agreement between the predicted RFS and the actual observation.









ORAL SESSIONS

Conclusion: Independent prognostic indicators based on clinic-pathological parameters and routinely used IHC markers were identified to predict overall and site-specific recurrence, which may help to identify optimal candidates for adjuvant therapies and design individualized surveillance strategies among patients with completely resected EGFR-positive NSCLC

The University of Texas MD Anderson Cancer Center, Houston/United States of America

Background: Surgical outcomes following neoadjuvant immune checkpoint inhibitors (ICIs) are limited. We report 90-day perioperative results of the NEOSTAR phase II trial of neoadjuvant nivolumab or nivolumab/ipilimumab in resectable non-small cell lung cancers (NSCLCs). **Method:** 44 pts with stage I-IIIA NSCLC (AJCC 7th) were randomized to nivolumab (3 mg/kg IV, days 1, 15, 29, n=23) or nivolumab/ipilimumab (1 mg/kg IV, day 1, n=21) with resection planned between 3-6 weeks after last dose. Surgical approach and extent of resection were at surgeons' discretion. **Result:** 39 (89%) patients underwent R0 resection, of those 2 (5%) were resected off trial after additional induction chemotherapy (1 nivolumab, 1 nivolumab/ipilimumab). Among 37 patients, 21 underwent surgery following nivolumab and 16 following nivolumab/ipilimumab. Median age 66 (43-83) years, 24 (65%) male, 33 (89%) white, 22 (59%) adenocarcinoma, 22 (59%) stage I, 9 (24%) stage II, 6 (16%) stage IIIA. 5 (11%) were not resected, 1 (1/23, 4%) after nivolumab (stage II), 4 (4/21, 19%) after nivolumab/ipilimumab (1 stage I, 1 stage II, 2 stage IIIA). Reasons for unresectability were change in surgeon's judgement (n=2), toxicity (n=1), progression (n=1), and declining pneumonectomy (n=1). Median time to surgery was 31 days (range 21-87). 8 (22%) operations were delayed beyond 42 days, 5 after nivolumab/ipilimumab (5/16, 31%) and 3 after nivolumab (3/21, 14%). 33 (89%) underwent lobectomy, 2 (5%) pneumonectomy, 1 (3%) segmentectomy and 1 (3%) wedge resection. 27 (73%) had thoracotomy, 7 (19%) thoracoscopy, 3 (8%) robotic approach. 2 (5%) were electively converted from thoracoscopy to thoracotomy. Median operative time was 147 minutes (71-315), median blood loss was 100cc (50-1000), and median length of stay was 4 days (1-18). Perioperatively, pulmonary complications occurred in 8 (22%) patients: 8 (22%) prolonged air leak, 2 (5%) pneumonitis/pneumonias, 1 (3%) empyema, and 1 (3%) bronchopleural fistula (BPF). 1 (3%) died from complications of BPF and steroid therapy for pneumonitis. 4 (11%) developed atrial fibrillation, 1 (3%) diarrhea, 1 (3%) ileus, and 1 (3%) transient ischemic attack. Surgeons subjectively judged 15/37 (40%) of operations to be more complex than usual with 7/37 (19%) lasting > 4 hours. **Conclusion:** Following three cycles of neoadjuvant ICIs 89% of patients underwent complete R0 resection, including two patients who received additional induction chemotherapy off trial. Five marginally operable patients who didn't proceed to resection, and one perioperative mortality highlight the importance of cautious patient selection for neoadjuvant ICIs in the management of operable NSCLC.

Background: The immune mechanisms dictating response and resistance to PD-(L)1 blockade are not well understood in early stage non-small cell lung cancer (NSCLC). Understanding these mechanisms will be key to improve outcomes and identify the next generation of predictive biomarkers of response to these therapies. Here, we present updated immunophenotyping at time of interim analysis of LCMC3, a multicenter trial of neoadjuvant atezolizumab in resectable NSCLC (NCT02927301). **Method:** Patients received 2 cycles of atezolizumab before resection. Tumor, LN biopsies and PB were obtained pre-atezolizumab and at surgery. Paired PB, screening and surgical LN were analyzed using IMMUNOME flow

cytometry. Plasma-based cytokine arrays were performed on a subset of patients. Immunophenotypic analyses were correlated with treatment effect, major pathologic response (MPR, primary endpoint) and preoperative treatment-related adverse events (preop-TRAE). **Result:** We report on 55 patients with paired PB samples (analyzed within 72h after collection) and completed surgery. We observed preop-TRAE in 32/55 patients (18 grade 1, 13 grade 2, 1 grade 3). CD1c+ and CD141+ myeloid cells (MC) were lower at baseline in patients developing preop-TRAEs, while monocytic M-MDSCs were higher in those patients. Senescent T cells decreased in patients with preop-TRAE and increased in patients with non-preop-TRAE. After treatment, the absolute cell counts of late activated CD4+and CD8+T cells decreased in patients achieving MPR. LN IMMUNOME data, cytokine data and 12-month follow-up (DFS, OS) will be reported.

Conclusion: Preliminary immunophenotyping data from the interim analysis showed significantly lower baseline immunosuppressive cell subsets in patients with preop-TRAE and decreased late activated CD4+and CD8+T cells from PB in patients with MPR.These results, together with additional LN IMMUNOME and cytokine analyses, may improve our understanding of immunophenotypic features associated with outcome, and changes induced by neoadjuvant atezolizumab in early stage NSCLC patients.

Keywords: NSCLC, neoadjuvant anti-PD-L1 treatment, immunophenotyping

Table 1

Preop TRAE vs. non-Preop TRAE Patients at Baseline				
Representative Immune Cell Subset(s) in PB	Surface Markers	Median (min, max) cells/µl blood		Nominal p-value **
		Preop TRAE (n=32)	Non-Preop TRAE (n=23)	
CD141+ myeloid cells	CD141+ LIN- HLA DR+ CD33+ CD16+ CD11b+ CD15+	66.52 (0, 576)	95.77 (0, 380)	0.0162
CD1c+ myeloid cells	CD1c+ LIN- HLA DR+ CD33- CD16- CD11b- CD15+	45.14 (0, 507)	101 (0, 271)	0.0029
Monocytic M-MDSCs	CD33+ HLA DR- CD124- CD14+ CD11b+ CD66b- CD16- CD33+ CD15+	13.58 (0, 163)	4.73 (0, 30.96)	0.0253
Change in Preop TRAE vs. Non-Preop TRAE Patients after Treatment				
Representative Immune Cell Subset(s) in PB	Surface Markers	Median change (min, max)*		Nominal p-value
		Preop TRAE (n=32)	Non-preop TRAE (n=23)	
Senescent T cells	CD28- CD16- CD56- AND CD8+	-35.38 (-2445, 1930)	120 (-2193, 2175)	0.0265
Change in MPR vs. Non-MPR Patients after Treatment				
Representative Immune Cell Subset(s) in PB	Surface Markers	Median change (min, max)*		Nominal p-value
		MPR (n=9)	non-MPR (n=46)	
Late activated CD8+ T cells	CD107a/b- CD274- CD14- CD13- CD63- CD49a+ CD4- CD3+ CD8+	-16.44 (-192, 111)	1.62 (-255, 385)	0.0273
Late activated CD4+ T cells	CD107a/b- CD274- CD14- CD13- CD63- CD49a+ CD4+ CD3+ CD8-	-69.31 (-1420, 27.54)	2.61 (-1153, 1405)	0.0169
DC inducing Th1 response	CD141+ LIN- HLA DR+ CD33+ CD16+ CD11b- CD15-	27.78 (0, 152)	0 (-266, 947)	0.0490
CD141+ myeloid cells	CD141+ LIN- HLA DR+ CD33+ CD16- CD11b+ CD15+	319 (-49.57, 1550)	49.86 (-686, 851)	0.0122

Abbreviations:
DC- dendritic cell; TRAE – treatment-related adverse event; Th -T helper cell; M-MDSC- Monocytic myeloid-derived suppressor cell; MPR- major pathologic response; NK – natural killer cells; *cells/µl at surgery – cells/µl at screening; ** unadjusted for multiple comparisons

Background: Hyperprogressive disease (HPD) is a paradoxical boost in tumour growth described in a subset of cancer patients treated with immune checkpoint inhibitors (ICIs). **Method:** We retrospectively collected data about all consecutive patients with advanced Non-Small Cell Lung Cancer (aNSCLC) treated with ICIs at our Institution between 04/2013 and 12/2018. Patients were classified according to our previously published clinical/radiological criteria for HPD (Lo Russo G, *Clin Canc Res 2018*). (Table). All ICIs administered for ≥1 cycle were admitted. Chi-square test was used to compare qualitative variables. Survival was estimated with Kaplan-Meier method. Log-rank test was used to compare curves. Multivariate analyses were performed with Cox hazard model.

Table HPD definition on the basis of 3 concomitant out of the five possible criteria

HPD CLINICAL & RADIOLOGICAL CRITERIA
Time-to-treatment failure < 2 months
Increase of ≥ 50% in the sum of target lesions major diameters between baseline and first radiological evaluation
Appearance of at least two new lesions in an organ already involved between baseline and first radiological evaluation
Spread of the disease to a new organ between baseline and first radiological evaluation
Clinical deterioration with decrease in ECOG performance status ≥ 2 during the first 2 months of treatment

Result: We reviewed 301 cases and 257 were evaluable for response. We identified four categories: responders (R, 57 cases, 22.2%), patients with stable disease as best response (SD, 69 cases, 26.8%), patients with progressive disease as best response (P, 78 cases, 30.4%) and patients with HPD (53 cases, 20.6%). Clinical/pathological variables were uniformly distributed among groups, except for a higher rate of patients with *Eastern Cooperative Oncology Group Performance Status* (ECOG-PS) >1 in HPD group (p = 0.0141). After a median follow-up of 23.49 months (IQR 10.72–44.21 months), median Progression-Free Survival (mPFS) and median Overall Survival (mOS) were 14,2 vs 6,5 vs 2,3 vs 1,5 months (p < 0.0001) and 32,5 vs 17,8 vs 7,8 vs 4,1months (p < 0.0001) in R, SD, P and HPD group, respectively. The multivariate analyses, between P and HPD groups, adjusted for ICIs line, number of metastatic sites and ECOG-PS according to PFS (HR 2.448, 95% CI 2.137-2.899, p<0.0001) and OS (HR 2.481, 95%CI 2.092-2.950, p < 0.0001) confirmed the worse outcome of HPD group. **Conclusion:** Our updated analysis confirmed patients with HPD as a distinct category that performs significantly worse than other groups, including P patients. The incidence of HPD in our cohort is relevant. The ICIs' detrimental effect has to be taken into account and further investigated.

Background: Hyperprogressive disease (HPD), characterized by accelerated tumor progression, has been proposed as a new pattern of progression following immune checkpoint inhibitor (ICI) treatment. The aim of this study was to describe the characteristics of HPD and investigate its predictive markers. **Method:** Clinical and radiological findings of 335 advanced non-small cell lung cancer (NSCLC) patients treated with ICI monotherapy were retrospectively analyzed. Radiological data were quantitatively and longitudinally analyzed for tumor size and volume by comparing baseline and follow-up computerized tomography results. The findings were matched to individual genomic profiles generated by deep sequencing of 380 genes. **Result:** Among 135 patients with progressive disease (PD), as assessed by RECIST, 48 (14·3% of total and 35·6% among PD) and 44 (13·1% of total and 32·6% among PD) were found to have HPD by volumetric (HPD_V) and one-dimensional (HPD_R) analysis, respectively. HPD_V patients were associated with significantly inferior overall survival (OS) compared with non-HPD_V PD patients (median OS (months), 4·7 [95% confidence interval (CI), 3·5–11·9)] vs. 7·9 [95% CI, 6·0–13·5], p=0·004); OS did not differ between HPD_R and non-HPD_R patients. HPD_V status was an independent OS factor. Derived neutrophil-to-lymphocyte ratio (dNLR) greater than 4 and lactate dehydrogenase (LDH) greater than the upper normal limit were significantly associated with HPD_V. Moreover, we identified coinciding *KRAS* and *STK11* mutations in the HPD_V cohort (3/16), while none were found in the non-HPD_V cohort (0/28). **Conclusion:** Defining HPD treated with ICI based on volumetric measurement is more precise than that based on one-dimensional analysis. Pre-ICI dNLR, LDH, and concurrence of *STK11* and *KRAS* mutations could, thus, be used as potential biomarkers for HPD prediction.

Background: DNA damage repair inhibition is an emerging strategy for treating small cell lung cancer (SCLC). Combining poly(ADP-ribose) polymerase (PARP) inhibition with the DNA alkylating agent temozolomide has shown activity in both preclinical models and early phase clinical trials. **Method:** This is a single-arm phase 1/2 study combining the PARP inhibitior olaparib (tablet formulation) with temozolomide in patients with SCLC. Key eligibility criteria include histologically or cytologically confirmed incurable SCLC which progressed following ≥ 1 platinum-based chemotherapy. In cohort 1, olaparib and temozolomide are administered orally on days 1-7 of 21-day cycles. After cohort 1 completed enrollment, cohort 2 was added in a protocol amendment, in which olaparib is administered continuously days 1-21 and temozolomide is administered days 1-7 of 21-day cycles. For each cohort, the phase 1 portion is a conventional 3+3 design, with the primary objective to determine the maximum tolerated dose (MTD) or recommended phase 2 dose (RP2D). The primary objective of the phase 2 dose expansion portion is to determine the objective response rate (ORR). Response assessments are performed every 6 weeks, with treatment continued until progression, unacceptable toxicity, or investigator's discretion. Treatment post-progression is allowed for patients with ongoing clinical benefit. **Result:** Between October 2015 and April 2018, 50 patients were enrolled to cohort 1. The median age was 63 (range 39-85), median number of prior therapies was 2 (range 1-7), and 72% were platinum sensitive. The RP2D was olaparib 200 mg PO BID d1-7 and T 75 mg/m2 QD d1-7. The confirmed ORR was 41.7%. After a median follow-up of 7.1 months among 22 surviving patients, the median progression-free survival (mPFS) was 4.2 months, median overall survival (mOS) was 8.5 months, and median duration of response (mDoR) was 4.3 months. The ORR among platinum-sensitive and platinum-resistant patients was 47.1% and 28.6%, respectively, with no significant differences in mPFS, mOS or mDOR. The most common grade 3/4 treatment related adverse events were neutropenia (38%), anemia (28%) and thrombocytopenia (26%). Among 41 pts treated at the RP2D, dose reductions occurred in 44% overall and 64% of those who received at least 3 cycles. Enrollment to the phase 1 portion of cohort 2 began in November 2018 and is ongoing. Updated results from cohorts 1 and 2 will be presented at the meeting. **Conclusion:** Combination olaparib and temozolomide has an acceptable tolerability profile and shows promising clinical activity in relapsed SCLC. Clinical trials identifier NCT02446704.

Background: Topotecan is currently the only drug approved in Europe in second line setting for small-cell lung cancer (SCLC). This study investigates whether the doublet carboplatin-Etoposide was superior to topotecan monotherapy as second-line treatment in patients with sensitive relapsed SCLC. **Method:** this open-label, multicenter, phase 3 trial randomized patients with SCLC that responded to first-line platin etoposide doublet treatment but showed evidence of disease relapse or progression at least 90 days after completion of the first-line treatment. Enrolled patients were randomly assigned (1:1) to receive combination chemotherapy (Six cycles of 3-weeks Carboplatin, AUC 5, day 1 and Etoposide 100 mg/Sqm/d 1-3, intra-venous) or oral Topotecan (2.3 mg/Sqm/d 1-5, every 3 weeks). Primary endpoint was progression free survival (PFS). Secondary endpoints were overall survival (OS), objective response rate (ORR), quality of life and tolerance in the intention-to-treat population, (clinical trialgouv: NCT02738346) **Result:** 178 patients were screened and 164 randomized in 36 centers, with 82 assigned to each treatment group (age: 64.5 ± 7.2 years, men: 72.8%, PS 0/1/>1: 34.7%/56.3%/ 9%. Median PFS was significantly longer in combination chemotherapy group (4.7 months, 95% CI: 3.9-5.5) compare to topotecan group (2.7 months, 95% CI: 2.3-3.2), HR: 0.6, 95% CI 0.4-0.8, p < 0.002. The ORR were significantly more important in the combination chemotherapy than in topotecan arm (ORR 49 % vs 25 %, p < 0,002), but without difference in term of median OS, 7.5 months (95% CI: 5.4-8.7) in combination chemotherapy group

versus 7.4 months (95% CI.6.0-9.3) in topotecan arm. Grade 3/4 neutropenia were significantly more common in the topotecan group than in the combination chemotherapy group (35.8% vs 19.7 %, p < 0.001. There is a non-significant trend for more febrile neutropenia in topotecan arm compare to combination arm (13.6 % 6.2 %, p = 0.19, and no difference for grade 3/4 thrombopenia, 35.8 % *vs* 30.9 %, and anemia, 24.6 % vs 21 %, for topotecan and combination arms, respectively. Two treatment-related deaths occurred in the topotecan arm (febrile neutropenia with sepsis), none in the combination arm. Results of quality of life outcomes will be presented at the meeting. **Conclusion:** platin–etoposide re-challenge can be considered as a standard second-line chemotherapy for sensitive relapsed SCLC.

[1]*University of Texas MD Anderson Cancer Center, Houston/United States of America,* [2]*Zhejiang Cancer Hospital, Hangzhou/China,* [3]*The University of Texas MD Anderson Cancer Center, Houston/United States of America*

Background: Small cell lung cancer (SCLC) is an aggressive cancer. Although sensitive to initial therapy, recurrence is almost inevitable. The molecular mechanisms underlying recurrence are unknown. We have previously demonstrated that complex genomic and T cell receptor (TCR) intratumor heterogeneity (ITH) was associated with increased risks of relapse in non-small cell lung cancers (NSCLC). Genomic ITH and TCR architecture of SCLC and its clinical impact have not been well studied, largely due to lack of tumor specimens as surgery is rarely used to treat SCLC. **Method:** We performed multiregion whole-exome sequencing and TCR sequencing of 49 tumor samples from 18 resected limited-stage SCLCs to delineate the immunogenomic ITH of SCLC. We compared the results to those in NSCLC and assessed the association of genomic and TCR attributes with patient's survival. **Result:** On average, 544 mutations/sample were detected. The median proportion of trunk mutations (mutations identified in all regions within the same tumors) was 80.4% versus 70% in NSCLC (TRACERx, Jamal-Hanjani, NEJM, 2017, p=0.08) and all *TP53* and *RB1* mutations were trunk mutations, suggesting these mutations were early events during carcinogenesis of this cohort of SCLCs. A higher non-synonymous tumor mutational burden (TMB) was associated with a higher T cell density (infiltration) in the tumor (r=0.46, p=0.005). Compared to the TCR repertoire of NSCLC (Reuben, WCLC, 2017), these SCLC tumors demonstrated significantly lower T-cell density (0.05 *versus* 0.24, p<0.0001), richness (diversity, 1,043 *versus* 3,666, p<0.0001) and clonality (reactivity, average 0.02 *versus* 0.15, p<0.0001) despite similar non-synonymous TMB (average 187 in SCLC versus 176 mutations/sample in NSCLC). Only 0.2% to 14.6% of T cells were detectable across all regions from the same tumors, suggesting substantial TCR ITH. Jaccard index (JI), a parameter quantifying TCR ITH was significantly lower in SCLC than in NSCLC (0.06 versus 0.1, p<0.0001) implying higher level of TCR ITH in SCLC than NSCLC. Interestingly, higher T-cell density, richness or clonality appeared to be associated with lower risk of recurrence numerically. Furthermore, higher TCR JI (less degree of ITH) was associated with significantly longer overall survival (HR=0.15, p=0.04). **Conclusion:** Limited-stage SCLC tumors have distinct TCR repertoire and genomic ITH architecture. Overall, SCLC may have a more pronounced immunosuppressive microenvironment and higher level of TCR repertoire ITH than NSCLC. Nevertheless, higher degree of T cell infiltration and clonal expansion as well as more homogeneous T cell response may be associated with more favorable clinical outcome in patients with limited-stage SCLC.

Background: Therapeutic options and prognosis for patients with small-cell lung cancer (SCLC) remain poor. Treatment with checkpoint inhibition can achieve remarkable responses, but this holds true for a small percentage of SCLC patients only. Recently, tumor mutation burden (TMB) emerged as promising predictive biomarker for nivolumab and ipilimumab combination therapy in terms of tumor response and overall survival in SCLC patients. Here, we present the SCLC TMB cohort of the BIOLUMA trial, which prospectively evaluates TMB as predictive biomarker in SCLC patients. **Method:** BIOLUMA is an investigator initiated multicentre non-randomised phase II trial in 2nd line patients with SCLC. The initial all-comer SCLC cohort was recently amended for inclusion of patients with high TMB only. FFPE tumor tissue is used for TMB pre-screening by whole exome sequencing (WES) at time of first diagnosis. After progression on platinum-based therapy, 4 cycles of nivolumab 1 mg/kg q3w in combination with ipilimumab 3 mg/kg q3w and subsequent nivolumab 240 mg flat dose as monotherapy are given. Primary endpoint is overall response rate (ORR) of the combination therapy. Analysis of sequential tumor biopsies, blood and gut microbiome is performed at different timepoints. **Result:** The SCLC cohort was amended to include TMB high patients only, after two treatment-related deaths in the SCLC all-comer cohort had occurred and emerging data indicated treatment benefit depends on high TMB status for the combination therapy. TMB analysis seems to be feasible for most patients without the necessity of performing an additional tumor biopsy as evaluation of TMB on FFPE tumor tissue which was obtained at first diagnosis was sufficient in 90.1% of cases. To date, 53 patients are enrolled for pre-screening, sequencing result ist pending for 33 and TMB status has been determined for 20 patients. Of these, 45% belong to the TMB high group, while 55% have low or medium TMB. TMB pre-screening for the amended cohort is ongoing and enrolment of TMB high patients in the BIOLUMA trial recently started. **Conclusion:** Combination therapy of nivolumab and ipilimumab shows remarkable clinical results, but is accompanied by high toxicity rates. Thus, in order to ensure a reasonable balance of risks and treatment benefits, it is an unmet need to evaluate predictive biomarker with TMB being the most promising which recently emerged in SCLC. To our knowledge, this is the first clinical trial which prospectively evaluates tumor mutation burden as predictive biomarker in SCLC patients. TMB screening is feasible on tumor material which is routinely obtained at first diagnosis.

Background: Pembrolizumab has demonstrated safety and efficacy in a broad range of tumors. However, safety concerns exist around the combination of pembrolizumab and high dose radiotherapy to the lung, particularly as both have independent risk of pneumonitis. In this interim analysis we assess the safety profile of combination pembrolizumab and SABR to pulmonary oligometastases. **Method:** As part of the ongoing prospective dual-institutional RAPPORT clinical trial (clinicaltrials.gov ID NCT02855203), patients with 1-5 oligometastases from renal cell carcinoma were enrolled between Nov 2016- April 2019. All participants had ECOG performance status 0-1, and signed informed consent. Patients with at least 1 lung oligometastasis were included in this analysis. All patients were planned for a single fraction of 20Gy SABR to each lung oligometastasis, followed 5 days (+/-3 days) later by 8 cycles of 200mg i.v. 3-weekly pembrolizumab (total 24 weeks). When SABR dose constraints were not achievable, conventional hypofractionated radiotherapy could be delivered. At least 1 oligometastasis needed to receive SABR. Adverse events (AEs) were recorded using CTCAE V4.03 until 30 days post last dose of pembrolizumab, and late AEs atrributable to SABR for 24 months after SABR. **Result:** 20 patients with a combined total of 41 lung oligometastases were included in this analysis. The mean age was 61 years, with 15 (75%) male. The number of lung oligometastases were 1 in 9 (45%), 2 in 3 (15%), 3 in 6 (30%), 4 in 2 (10%) patients. SABR was delivered to 39 lung oligometastases (95%) and conventional radiotherapy to 2 oligometastases (5%) using 10 fractions of 3Gy. Twelve patients have completed all eight cycles of pembrolizumab, with five patients having ongoing treatment. Three patients ceased treatment early due to grade 3 pneumonitis (15%) after 3, 6 and 7 cycles of pembrolizumab respectively. These patients had 1, 2 and 1 lung oligometastases, respectively. The worst grade of any treatment related AEs was grade 3 in 4 pts (20%), with 3 attributed to both SABR and pembrolizumab, and 1 atributed to pembrolizumab alone. Three of the four grade 3 events were pneumonitis. A further 3 patients had grade 2 AEs(15%), and 8 patients had grade 1 AEs(40%). There were no grade 4 or 5 adverse events, and five patients (25%) had no treatment related adverse events. **Conclusion:** SABR to lung oligometastases in combination with pembrolizumab was well tolerated, with clinically acceptable rates of grade 3 pneumonitis compared to historical rates reported with pembrolizumab monotherapy.

Background: Radical treatment of metastases with stereotactic body radiotherapy (SBRT) in patients with advanced malignancies is an emerging treatment paradigm. SBRT is increasingly used in patients receiving immune checkpoint inhibition (ICI); however, limited toxicity data for this treatment approach exists. The purpose of this study was to evaluate the safety and tolerability of lung SBRT with concurrent ICI. **Method:** Records from a single academic institution were reviewed to identify patients treated with lung SBRT and concurrent (within 30 days) ICI; a contemporaneous cohort receiving lung SABR without ICI were included as a reference cohort. Treatment-related adverse-effects (AE) occurring within 30 days (acute) and 180 days (subacute) of SBRT were graded via CTCAE v5.0. **Result:** 110 patients were included; 47 received SBRT with concurrent ICI (49 SBRT courses, 61 lesions) between August 2015 and January 2019. 63 received SBRT without ICI (68 courses, 79 lesions). For the SBRT+ICI cohort, median age at treatment was 64 years, median follow-up was 6.7 months. 70% were lung, 15% were melanoma, 6.4% were from head and neck primaries. 90% were treated for metastatic consolidation/oligo-progression, 10% received SBRT for locally advanced/recurrent disease. 65.3% of patients received prior RT. 36.7% received prior lung RT, 40% of which were overlapping. 67% received ICI monotherapy, 16% ICI/chemotherapy, and 16% ICI/ICI combinations. 24.5% received ICI between SBRT fractions; 38.8% received ICI both before and after SBRT. Grade 3 (G3) and any grade pneumonitis rates were 8.2% and 30.6%; there were no G4-5 events. ICI was discontinued due to toxicity in 22.4% of patients. Receipt of ICI/ICI combinations increased the risk of any grade pneumonitis (62.5% vs 24.4%, p=0.04); but not G3 pneumonitis. Risk of G3 pneumonitis was higher in the SBRT+ICI vs SBRT alone cohort (8.2 vs 0%, p=0.03); but not any grade pneumonitis (30.6% vs 29.9%, SBRT+ICI vs SBRT p=0.75). Median time to onset was 3.4 months from end of SBRT in both groups. Risk of G3 and any grade pneumonitis was not predicted by ICI agent, timing of ICI administration, prior RT, prior lung RT, lesion centrality, number of target lesions, or smoking status. Overall acute G3+ AE rates were 2% (SBRT+ICI) and 0% (SBRT). Subacute G3+ AEs occurred in 26.5% (SBRT+ICI) and 2.9% (SBRT) of patients. **Conclusion:** Concurrent ICI, especially ICI/ICI combinations, increased the risk of G3 pneumonitis with lung SBRT. However, SBRT+ICI appears safe and tolerable compared to SBRT alone. Strategies integrating SBRT and ICI warrant additional investigation.

MA01.03 INTERIM SAFETY ANALYSIS OF THE PHASE IB TRIAL OF SBRT TO ALL SITES OF OLIGOMETASTATIC NSCLC COMBINED WITH DURVALUMAB AND TREMELIMUMAB

T. Leal, J. Lang, Z. Morris, J. Eickhoff, A. Traynor, T. Campbell, A. Baschnagel, M. Bassetti

University of Wisconsin Carbone Cancer Center, Madison/United States of America

Background: Oligometastatic NSCLC represents a unique subset of patients (pts) with limited burden of metastatic disease. Prior early studies have demonstrated that combining local ablative and systemic therapies in pts with oligometastatic disease leads to improved progression-free survival (PFS). The immunostimulatory effects of SBRT and potential synergy with immune checkpoint inhibitors has prompted enthusiasm in combining the two; however, the toxicity is unknown. **Method:** In this phase Ib study, a cohort of 21 pts with oligometastatic NSCLC receive SBRT to all sites of disease between 30 and 50 Gy in five fractions and durvalumab 1500 mg IV + tremelimumab 75 mg IV every 4 weeks x 4 cycles in a sequential fashion, followed by durvalumab maintenance until progression, unacceptable toxicity or patient wishes. Eligible patients had 1-6 metastatic extracranial lesions, all of which were suitable for SBRT, ECOG performance status 0-1, no actionable driver mutation, and no prior immunotherapy.The primary endpoint is safety of this combination. The period for evaluating dose-limiting toxicities (DLTs) is from the time of first administration of SBRT until 28 days post completion of the first dose of durvalumab and tremelimumab. Grading of DLTs follows CTCAE version 4.03. A DLT will be defined as any Grade≥ 3 toxicity. Secondary endpoints include PFS and overall survival. Correlative studies of baseline TMB, PD-L1 expression on post-SBRT biopsy and immune biomarkers on circulating tumor cells will be correlated with outcomes. In this interim analysis, we assess the safety of the first nine patients enrolled. **Result:** Nine pts enrolled from 2/2018-3/2019. Median follow-up: 2.8 months (range 1.5-8.2 months). Characteristics included: median age 72 years (range 56-

81 years), female/male 2/7, squamous/nonsquamous 2/7, median number of sites treated 2, CNS involvement 3/9. Most toxicities were Grade (G) 1/ 2. Severe adverse events (AEs) included: G4 elevated CK (1). Severe immune-related (ir)AEs: G3 rash (1), G3 AST (2), G3 ALT (1), G3 amylase (1), G3 lipase (1). One DLT reported due to grade 3 AST > 7 days (recovered). One additional pt discontinued treatment due to grade 3 irAE. There were no treatment-related deaths. Two patients (22%) died of disease progression. **Conclusion:** There were no unexpected safety signals in the first nine patients enrolled. The incidence of grade 3 or greater irAEs was similar to those seen in the treatment of advanced NSCLC, and no additional toxicity is observed with the addition of SBRT to date. The study continues to enroll and results will be updated.

Background: The aim of this retrospective study was to review the natural course of synchronous ground-glass nodule (GGN), which was left after the curative resection of non-small cell lung cancer (NSCLC) in other lobe. **Method:** Between 2008 and 2017, a prospectively collected retrospective data of 2276 patients who underwent curative resection for NSCLC was reviewed. Among them, GGN was detected in 126 patients beside resected lung. Defined by high-resolution computed tomography (HRCT) or thin-section of computed tomography (CT), twenty patients with nearly solid nodule or GGN with higher CT ratio (> 0.75) was excluded, thereafter the data of 98 patients (4.3%) was included in the study. Demographic data of patients including age, gender, and smoking history were collected for analysis. In addition, risk factor including characteristics of GGN, histopathology and staging of resected tumor, adjuvant treatment, and any other medical history were evaluated for risk factor analysis. **Result:** Median duration of follow-up was 36 months (range; 11 – 120). The size of GGN has been decreased in 10 patients (10.2%), stationary 48 patients (50.0%), while an increasing in size of GGN was observed in 40 patients (40.8%). Among them, five patients were recommended reoperation (12.5%), and the other 35 patients were in clinical observation (87.5%). In mutivariate analysis, existence of solid component, smoking history, and multiple GGNs in one lobe were independent prognostic factor.

Table : Multivariate binary logistic analysis of tumor growth

Variables	All tumor[a]			Adenocarcinoma		
	HR	CI	p-Value	HR	CI	p-Value
Age at diagnosis	1.04	0.98 – 1.09	0.174	1.03	0.97 – 1.09	0.356
Part-solid GGN	3.22	1.08 – 9.56	0.036	4.11	1.29 – 13.12	0.017
Male gender	1.81	0.56 – 5.83	0.320	1.68	0.50 – 5.63	0.397
Smoking[b]	3.45	1.33 – 8.98	0.011	5.10	1.76 – 14.80	0.003
Multiple GGNs in one lobe	0.08	0.01 – 0.74	0.026	0.07	0.01 – 0.69	0.023

a. Histopathology of primary resected tumor

b. Smoking history more than 10 pack-year

GGN : ground-glass nodule

HR : hazard ratio

CI : confidence interval

Conclusion: During the follow-up, 40.8% of GGN showed a growth in size, emphasizing that patients with part-solid GGN and with smoking history should be in careful observation.
