

Use of a Transarticular Calcaneo-Tibial Locking Plate for Temporary  
Immobilisation of the Tarsocrural Joint Following Surgical Repair of Common  
Calcaneal Tendon Rupture in 8 Dogs

**Abstract**

**Objective:** The purpose of this clinical communication is to report the management of common calcaneal tendon rupture in dogs using a transarticular calcaneo-tibial locking plate as a method of temporary immobilization of the tarsocrural joint to support primary repair of the common calcaneal tendon.

**Study Design:** Dogs presented with partial or complete common calcaneal tendon rupture treated with primary tendon repair supported by the transarticular calcaneo-tibial locking plate technique from July 2016 to December 2019 were included. The tarsus was placed at a standing angle of 150° and the pre-contoured Fixin locking “L” or “T” plate was medially applied with two locking screws inserted in the calcaneus and two screws inserted in the distal tibia. Tendon healing judgement was mostly based on clinical palpation and ultrasound examination was not performed in all the cases. Plates were removed in all dogs 6 weeks postoperatively.

**Results:** All tendons healed and no complications at the level of the tenorrhaphy were noted in the postoperative period. All dogs returned to hunting activity with full function of the affected limb. No major complications requiring revision surgery were observed.

Minor complications occurred in two cases, osteomyelitis and screw pull-out.

**Conclusions:** The use of a transarticular calcaneo-tibial locking plate for temporary immobilisation of the tarsocrural joint after surgical repair of common calcaneal tendon rupture appears to be an effective technique with comparable results to other reported techniques.

## Introduction

The common calcaneal tendon attaches to the calcaneal tuberosity in domestic mammals. It includes the superficial digital flexor tendon, gastrocnemius, and common tendons formed from the biceps femoris, gracilis and semitendinosus muscles, and is bound down by the lamina propria of deep sheath of the crural fascia (1). Disruption of one or more components is a disabling injury in dogs that compromise the ability to maintain the extension of the tarsocrural joint. Common calcaneal tendon injuries are reported to occur as a result of a direct trauma or secondary to degenerative conditions (2, 3). In dogs the injury is classified according to the duration of the lesion as acute or chronic, and the amount of tendon involvement as partial or complete. Partial rupture, involving the gastrocnemius muscle tendon, the tendon of the biceps femoris, semitendinosus and gracilis muscles with an intact superficial digital flexor tendon, is reported to be more common in dogs (3). Dogs affected by degenerative insertional lesions present elongation of both gastrocnemius and the semitendinosus and gracilis tendons, with an intact superficial digital flexor tendon. Depending upon the degree and duration of the injury they usually present with a typical clawing posture (4). Surgical repair is the generally accepted recommendation for the effective return to function (4). Primary repair of a mid-body laceration of the calcaneal tendon typically involves suturing the severed ends directly together, whereas insertional injuries often require bone tunnels in the calcaneus. Different suture patterns are reported, of these, the three-loop pulley pattern is generally favored for the reattachment of round or semi-round tendons to bone. In addition to suturing, adjunctive bridging of the tendon has been described with a fascia lata autograft, semitendinosus flap, polypropylene mesh, porcine intestinal submucosa, epitendinous sutures, fascial grafts, tendon transfers and the use of biological and artificial implants (2, 5–15). Several methods have been described to avoid overstress of the anastomosis and to allow isometric muscle contraction during the early post-operative period. Use of trans-articular external fixation (4, 6, 7, 16), calcaneo-tibial screw (4, 8, 16), cast application (17), a single ring transarticular fixator (18) and a custom orthotic boot (19) has been reported.

The purpose of this clinical communication is to report the management of common calcaneal tendon rupture in dogs using a transarticular calcaneo-tibial locking plate technique as a method of

temporary immobilization of the tarsocrural joint to support primary repair of common calcaneal tendon injuries. It was our objective to determine whether this technique would provide adequate immobilisation of the tarsocrural joint during the initial phase of tendon healing with minimal morbidity and a low incidence of complications.

## **Materials and methods**

All dogs presented with partial or complete common calcaneal tendon rupture at three different clinics ( Centro Veterinario Imperiese, the Clinica Albese per Animali da Compagnia and the Clinica Veterinaria Serravalle), treated with primary tendon repair supported by the transarticular calcaneo-tibial locking plate technique from July 2016 to December 2019 were included. The diagnosis of partial or complete disruption to the common calcaneal tendon mechanism was based on orthopaedic examination and radiographic findings (Figure 1). Only cases with a complete medical record, orthopaedic examination performed by the surgeon, pre-operative, immediate post-operative and follow up radiographs performed at four weeks and after plate removal, were included in the study. Dogs with concomitant neurologic or orthopaedic pathologies without a complete medical record were excluded from the study.

The following parameters were recorded for all patients: breed, age (months), body weight (kg), duration of lameness, localisation (body, tendon insertion on the calcaneus, musculotendinous junction), if the tendon lesion was traumatic or degenerative, partial or complete, and the type of plate used.

Dogs were premedicated with fentanyl (4 mcg/kg IV; Fentanest, Actavis Italy S.p.A, Nerviano, Italy), morphine (0.15 mg/kg IM; Morfina Cloridrato, Molteni, Italy) and acepromazine (0.02 mg/kg IM; Prequillan, Fatro SpA, Ozzano Emilia, Italy).

Anaesthesia was induced with propofol (3mg/kg IV; PropoVet; Ecuphar Italia S.p.A, Milano, Italy) and maintained with a mixture of isoflurane (IsoFlo: Zoetis Italia S.r.l, Roma, Italy) in 2% oxygen after endotracheal intubation. A constant rate infusion of fentanyl (10 mcg/kg/hr IV; Fentanest, Actavis Italy S.p.A, Nerviano, Italy) provided analgesia, and cefazolin (20 mg/kg, IV; Cefazolina Dorom, Teva Pharma Italia, Milano, Italy) was administered one hour before surgery and repeated

120 minutes later. The anaesthetized dogs were positioned in dorsal recumbency, and the limbs were aseptically prepared in a hanging position. A caudo-medial surgical approach to the tarsocrural joint was performed. The retinaculum was incised caudal to the plantar nerve, the flexor hallucis longus and the medial saphenous artery and vein (Figure 2). Immobilisation of the tarsocrural joint in extension was achieved by medial application of a locking bone plate (FIXIN, Intrauma s.r.l., Rivoli, TO) (20). Plate benders (20) designed for 97 this system were used to avoid deformation of the titanium bushings during contouring of the stainless steel implant. The tarsus was placed at a standing angle of 150°. The pre-contoured locking plate was medially applied with two locking screws inserted in the calcaneus and two screws inserted in the distal tibia. A “L” or “T” plate was selected according to the surgeon preference. In both cases the plate was positioned with the shorter side over the calcaneus (Figure 3). A caudo-lateral approach was performed in cases of proximal lesion to suture the musculotendinous junction, while all the other lesions were treated through a proximal extension of the caudo-medial approach. In traumatic cases, primary repair of individual tendons was performed. All of the tendons were repaired with a modified three-loop pulley or locking loop suture pattern (3, 21), using non absorbable 3-metric monofilament nylon suture or 3-metric monofilament polypropylene suture (Prolene, Ethicon Ltd, Edinburgh, UK). All the knots were tied with a double throw followed by 3 single throws. All the sutures were tightened until the tendon ends were anatomically apposed and there was no slack within the suture. In degenerative cases, the chronic avulsion injury of the common calcaneal tendon was treated using sutures passed through bone tunnels. A 1.5 mm transverse bone tunnel was drilled through the lateral process of the calcaneal tuberosity just distal to the insertion of the gastrocnemius tendon to allow the suture to be anchored to the calcaneus. In the tendon, the far bite was taken 15 mm, the middle bite 10 mm and the near bite 5 mm from the tendon bone junction. Each bite was placed to create 3 loops, each at a 60° angle from the other loops (3). If contamination of the surgical site was suspected due to a traumatic injury, bacterial culture and susceptibility test was performed. The surgical wound was routinely flushed with saline without antibiotics. Reconstruction of the retinaculum after plate application was performed in a simple interrupted pattern, using 3.0 metric polydioxanone monofilament suture (PDS II, Ethicon Ltd,

Edinburgh, UK) over the plate. The fascia and subcutis were closed in a simple interrupted pattern, using 3.0 metric polydioxanone (PDS II, Ethicon Ltd, Edinburgh, UK) monofilament suture. The skin was closed in a simple interrupted pattern. No cast was applied post-operatively. Postoperative orthogonal radiographs were obtained. All dogs were treated with meloxicam (0.1 mg/kg orally, q12h; Meloxidolor, Dechra Veterinary Products S.r.l, Torino, Italy) for seven days and cephalixin (22 mg/kg orally, q8h; Icfvet, I.C.F. Industria Chimica Fine S.r.l, Cremona, Italy) for 7 days. When the result of bacterial culture was available, positive dogs were treated with antibiotic medications according to the sensitivity. All the dogs were restricted to short lead walks during the post-operative phase (average 10 to 15 minutes three times a day).

Patient outcome was evaluated based on the information obtained from surgeon's clinical evaluation, follow-up radiographs and long term telephone follow-up. Time to follow-up examination was recorded in days. Clinical re-examinations were planned at one, four, six weeks. The degree of lameness and post-operative complications were recorded. Lameness was graded by the surgeon on a scale from 0 (no lameness) to V (consistently non-weight-bearing) (22).

Complications were recorded and were classified as either major or minor. Major complications were defined as those requiring revision surgery, or plate or screw breakage even if the breakage was treated conservatively (4). Minor complications were defined as complications not requiring revision surgery which resolved with medical or conservative management (4, 23).

Radiographs of the affected tarsus were taken 4 weeks post-operatively (Figure 4) to assess the tarsal angle, implant related complications or fracture. If tendon healing was judged satisfactory by ultrasound evaluation or palpation, dogs were anaesthetized and surgically prepared as previously, for planned removal of the temporary plate at 6 weeks post immobilization. After plate removal dogs were gradually encouraged to controlled loading with restricted activity for four weeks and were gradually returned to normal exercise over four to six weeks. Long term evaluation was subjectively performed by the surgeon one year post155  
operatively or by telephone interview.

## Results

The temporary transarticular calcaneo-tibial locking plate technique was used in 9 dogs following common calcaneal tenorrhaphy. One dog died after 5 weeks due to acute renal failure secondary to an acute leishmaniasis infection and was excluded from the study (Appendix Table 1). Included breeds were two Beagles, four mixed breed dogs, one Dobermann and a Belgian Malinois. Four out of eight dogs were hunting dogs. All dogs were males and ranged in age from 4 years to 16 years. Their weights ranged from 8 kg to 32 kg with a mean of 23.5 kg.

All dogs had been presented with the complaint of hindlimb lameness. The duration of lameness ranged between 2 and 21 days in traumatic cases and between 1 and 6 months in degenerative cases. All dogs had swelling of the common calcaneal tendon and signs of pain upon manipulation of the tarsocrural joint and upon direct pressure of the tendon. Six cases were presented for a complete traumatic rupture of the common calcaneal tendon with a plantigrade stance. Traumatic tendon ruptures were midbody in 5/6 cases and at the musculotendinous junction in 1 case. Two cases were presented for a partial degenerative lesion at the level of tendinous insertion on the calcaneus with hyperflexion of the digits. Additional significant orthopaedic or neurological abnormalities of the thoracic or pelvic limbs were not observed. Locking-loop suture tenorrhaphy (n=4) or a modified three-loop pulley suture technique (n=2) was performed (4). Non-absorbable suture passed through bone tunnels was used to reappose insertional avulsions in two dogs. Temporary tarsocrural immobilisation in extension was performed using four different plate types: a 3.5 mm “T” shaped plate (V3003, V3043), a “L” shaped 3.5 mm plate (V3034), and a 2.5 mm cuttable plate (V2207). All plates were applied to the medial side of the tarsus and the plate-bone contact was visually assessed. Bicortical screw insertion was performed in all cases. No intra-operative complications occurred. Aerobic and anaerobic bacteria culture was performed in 3 cases and yielded a positive culture result in two cases. *Enterobacter cloacae* and *Burkholderia cepacia* were cultured from the surgical site, and based on the results of culture and sensitivity, the combination of amoxicillin and clavulanic acid (20mg/kg, orally, q12h; Synulox, Pfizer, Rome, Italy) was administered. Reconstruction of the retinaculum after plate application was performed in a simple interrupted pattern, using 3.0 metric polydioxanone (PDS II, Ethicon Ltd, Edinburgh, UK)

monofilament suture over the plate. In the case of troublesome suturing of the medial flexor digit superficial retinaculum, we used the two calcaneal locking screws to anchor the suture in position. There were no cases of superficial digital flexor tendon luxation in the post-operative period due to this procedure (24). All wounds, surgical and traumatic, were closed primarily and did not require additional bandages. In all cases the immediate post-operative radiographs showed satisfactory hock extension, adequate implant position and correct screw length. Clinical evaluation after 7 days showed partial weight bearing of the affected limb in all dogs with II/V lameness in five cases and a III/V lameness in three cases. After 4 weeks no lameness was present at the walk in two cases, I/V lameness was present in three cases, II/V lameness in two cases, while in one case III/V lameness was present with clinical signs of local infection. No major complications were observed in any dogs necessitating revision surgery. Minor complications occurred in two cases. Osteomyelitis of the calcaneus developed subsequent to surgery in one dog which had a pre-existing infected wound, secondary to the dog's plantigrade stance. This was despite bacterial culture performed during surgery failing to yield bacterial growth. Radiographic follow-up at 4 weeks post-operatively showed bone resorption at the level of the tibial and calcaneal screw holes. A second bacterial culture confirmed *Staphylococcus aureus* infection and antibiotic therapy with clindamycin (11 mg/kg orally, q12h; Zodon, Ceva Salute Animale S.p.a, Monza Brianza, Italy) was administered for 4 weeks. Implant removal was performed at 6 weeks postoperatively. Later radiographs showed increased bone density and reduced periosteal reaction on the calcaneal cortex. Screw pull-out from the tibia because of bushing loosening, without concurrent bone failure, was observed in another dog (Figure 5) at 6 weeks radiographic follow-up. Plates were removed in all cases after 6 weeks without intra or post-operative complications (Figure 6). An initial reduction of range of motion in flexion was observed, but all dogs were free from lameness 12 weeks postoperatively. Long term follow-up was clinically performed by the surgeon in 5/8 cases and tarsocrural function was judged subjectively satisfactory. All owners were available for follow-up contact, and in all instances the owners reported that they had not observed any recurrence of lameness.

## Discussion

The use of a temporary transarticular stabilization with a locking plate has previously been described in a dog affected by medial shoulder luxation (25). It was our objective to determine whether that technique could be modified to provide adequate immobilisation of the tarsocrural joint during the initial phase of tendon healing.

Our case series demonstrates that a temporary transarticular calcaneo-tibial stabilization with a locking plate maintains the tibia-tarsal joint in extension for 6 weeks to allow offloading of the common calcaneal tendon, was associated with relatively low morbidity in small cohort of dogs and leads to a satisfactory functional outcome. All four hunting dogs returned to hunting activity with subjectively assessed full function of the affected limb. Most of the cases were presented acutely, with the injury having occurred while the dogs were hunting and five out of nine cases also had a concomitant wound. All tendon ends were directly sutured without the need for augmentation techniques (10, 26). All tendons healed and no complications at the level of the tenorrhaphy were noted in the postoperative period. With medial locking plate application, adequate visibility of the caudal calcaneal cortex is mandatory for precise locking screw insertion, cutting through and elevating the caudo distal part of the superficial digital flexor retinaculum without lateral dislocation of the superficial digital flexor tendon. The caudo proximal part of the retinaculum should be preserved to reduce the risk of tendon luxation in the post-operative period (24).

Most of the locking plates used in this study were “T” or “L” shaped plates and we noticed that the “L” plates allow easier plate contouring and positioning. We recommend that the surgeon has a range of options available intraoperatively, in order to choose the implant that better fits with the fully extended hock joint.

In most of our cases we selected implants of 1.5 or 2.0 mm thickness. Thin plates allow the surgeon to perform the complex anatomical plate contouring around the medial malleolus that is necessary for correct plate application. Moreover, the locking plate is applied on the tension side of the hock joint and seemed to be adequate in resisting to the tensile forces applied (27).

Despite the weight limit suggested by the company based on a published study (28), the 1.9-2.5 mm MINI system was applied in dogs up to 15kg of weight and the 3.0-3.5 mm LARGE system

was applied in dogs more than 15kg. To reduce the risk of iatrogenic fractures we suggest insertion of 3.0 mm screws in the calcaneus of dogs ranging in weight between 15kg and 20kg, however this requires further clinical investigation.

The locking mechanism allows placement of a plate at a given distance to the bone, but a plate-bone distance less than 2 mm is recommended to reduce bending forces over the screw neck and to increase the fixation stiffness (29).

Screw loosening is less likely to occur than with conventional plating, and resistance to displacement is greater when only a few screws are used (28). In our case series, screw pull out occurred in one case (case 6) and we speculate that it was related to an excessive plate contouring that lead to a failure of the conical coupling between the screw head and the bushing during screw tightening. We recommend therefore using the company's plate benders in order to protect the titanium bushings of the stainless steel plate.

We suggest inserting the screws as close as possible to the caudal cortex of the calcaneus to preserve enough bone stock and reduce the risk of avulsion fractures. Attention must be paid during screw insertion due to the converging direction of the two tibial screws. Accurate plate contouring leads (20) to a precise locking screw insertion and reduces the potential risk of postoperative tibial or calcaneal fractures.

It is important that a tendon anastomosis is not subjected to tensile forces exceeding the limits of the repair site strength during the early postoperative phase since this stress can lead to gap formation or repair failure, accordingly to primary tendon repair method used. Tendons with a gap >3mm heal at a slower rate and have a decreased ultimate tensile resistance at six weeks after repair, compared with results for tendons healing with no gap or a gap <3 mm (5).

In the present study, joints were immobilised for six weeks, as recommended by Braden (30). Studies have shown that repaired tendons regained only 56 per cent of normal breaking strain by six weeks, and 79 per cent of normal breaking strain after one year (31). Longer rest of an injured tendon can be counterproductive, as some loading of the tendon is required to stimulate repair and appropriate remodelling of collagen fibres (32). Optimum tendon healing requires some degree of

strain along the length of the tendon to stimulate proper recovery because the strength of collagenous tissue is positively affected by exercise and lessened with immobilisation (33).

Different tibiotarsal immobilisation methods following common calcaneal tendon repair have been described (4, 6-8, 16-18). Most complications after tenorrhaphy are considered to be related to the immobilisation technique rather than to the method of tendon repair (23, 34). Despite the high incidence of open injuries, no significant effect on complication rate or outcome was noted with the use of an internal fixation technique for temporary tarsocrural joint immobilisation.

No major complications were observed. Minor complications occurred in two cases (case 1, case 6), osteomyelitis and screw pull-out (Figure 5). A complication rate of up to 35% has been described by Corr and colleagues in 38 dogs treated with calcaneo-tibial positional screws and external coaptation (4). Cast application with or without other stabilisation methods often results in minor complications such as skin lesions and infection (23). Meeson and colleagues (21) reported the development of soft-tissue injuries in 63% of cases, 20% of which were severe.

The incidence of postoperative minor complications in our case series may be lower than previously reported due to the castless management of the postoperative phase, but further cases are required to see if this result is reproduced in a bigger cohort. In Corr's study (4) implant related major complications occurred in 8% of cases and required screw replacement. In our case series no major complications occurred and no skin lesions were reported during postoperative evaluations.

As described, this method of temporary stabilisation incurs the additional costs of 4 locking screws and a Fixin plate, which is significantly higher than the cost of a single calcaneo-tibial screw or cast application. A dedicated implant could significantly reduce surgical time, whilst helping the surgeon that is learning the technique to insert the two calcaneal locking screws with the optimal direction.

There are several limitations to this study, mostly deriving from its retrospective design. The small number of cases limits the significance of the study and makes it difficult to draw broad conclusions about the incidence of complications.

Prospective studies are preferred, but are logistically difficult particularly with a relatively uncommon injury. Assessment of tendon healing judgement was mostly based on clinical palpation

as ultrasound examination was not performed in all cases. There was no objective outcome evaluation such as goniometric range of motion measurements before and after temporary hock joint immobilisation or gait analyses to assess the effects of such a stiff temporary fixation on joint mobility and cartilage health. Clinical functional outcome was judged in all the cases by the surgeon and may have introduced bias. Although the 12 week outcome of all the eight cases was favourable, a limitation of our study was that long-term follow-up relied on owner observations. Future biomechanical studies, to evaluate the strength of the temporary internal fixation technique and to compare it with other reported techniques, would be desirable.

In conclusion, the use of a transarticular locking plate for temporary immobilisation of the tarsocrural joint after surgical repair of common calcaneal tendon rupture appears to be an effective technique with comparable results to other reported techniques. Further focused evaluation is warranted to evaluate calcaneo-tibial locking plate fixation through a prospective clinical trial with assessment on long term outcome and occurrence of complications in a larger number of dogs.
