Rapid biofilm eradication of the antimicrobial peptide 1018-K6 against *Staphylococcus aureus*: A new potential tool to fight bacterial biofilms

Angelo Colagiorgi, Rossella Festa, Pierluigi A. Di Ciccio, Marta Gogliettino, Marco Balestrieri, Gianna Palmieri, Aniello Anastasio, Adriana Ianieri

ABSTRACT

Staphylococcal food poisoning – caused by certain enterotoxigenic staphylococci – is one of the most common worldwide foodborne diseases. In this context, bacterial biofilms on food processing plant surfaces can represent critical sources of contamination, being more resistant to cleaning and disinfection procedures. Therefore, it is important to prevent and control biofilm formation in food facilities. In the last years, antimicrobial peptides (AMPs) have emerged as promising biofilm contrasting tools. The recently developed AMP, named 1018-K6, revealed a significant bactericidal (MBC 10 μ M) and biofilm-preventing efficiency (MBIC 50 μ M) against a reference ATCC strain of *Listeria monocytogenes* and remarkable stability under different environmental conditions. In this work, a kinetic of action of 1018-K6 against two strong biofilm-producing reference strains of *Staphylococcus aureus* (including a methicillin-resistant *S. aureus* strain) and a moderate biofilm producer enterotoxigenic *S. aureus* isolated from cheese, was performed. The peptide showed an impressive rapid mode of action, eradicating established biofilms within few minutes. Bactericidal activity against planktonic cells and inhibition of biofilm formation were also observed. The significant properties of 1018-K6 make it a promising candidate for applications in food-safety and quality control.

Introduction

Food safety is a global concern with significant implications for human health. It has been estimated from world health organization that at least 600 million people worldwide are subject annually to illnesses caused by unsafe food (World Health Organization, 2015). *Staphylococcus aureus* is a commensal and opportunistic pathogen that can cause contamination of food products during preparation and processing (Grace & Fetsch, 2018). It is a ubiquitous microorganism occurring on the skin and the mucous membrane of many warm-blooded animals, including human. For these reasons, food handlers are frequently implicated in transmission of such bacteria to food (Gutiérrez et al., 2012). *S. aureus* displays a high salt tolerance, so it can grow in ham and other meats and in dairy products. Although heat-treatment (e.g., cooking) easily kills *S. aureus* bacteria, some strains are able to produce enterotoxins that are resistant to heat, freezing and irradiation (Hennekinne, De Buyser, & Dragacci, 2012). Detectable levels of the staphylococcal enterotoxins (SEs) are produced when the enterotoxigenic strain grows to levels $> 10^5$ CFU/g, and their presence in food is responsible for the staphylococcal food poisoning (SFP), one of the most common foodborne diseases worldwide (Hennekinne, 2018). SFP symptoms usually develop within 30 min to 6 h, and generally include vomiting, nausea, stomach cramps, and diarrhea (Hennekinne, 2018).

The customer's awareness about chemical compounds used to contrast the growth of spoiling and pathogenic microorganisms, led to an increasing demand for natural preservatives. In this scenario, antimicrobial peptides (AMPs) are assuming remarkable interest because of their properties and natural origin (Keymanesh, Soltani, & Sardari, 2009). AMPs are components of the innate immune system of both prokaryotes and eukaryotes, and they are usually characterized by a broad antimicrobial spectrum activity, a low propensity for developing bacterial resistance, and a significant synergy with common antimicrobials (Palmieri et al., 2016, 2018; Wang, Zeng, Yang, & Qiao, 2016). The activity

of AMPs is related to their physicochemical properties, e.g. amphiphilicity, net charge, hydrophobicity, and conformational flexibility (Bechinger & Gorr, 2017).

Innate defense regulator peptide-1018 (IDR-1018) is a 12-mercationic peptide (VRLIVAVRIWRR-NH₂), deriving from the bovine host-defense peptide (HDP) batenecin, found in the bovine neutrophil granules and belonged to the cathelicidin's family. IDR-1018, which has been developed by Mansour and colleagues (Mansour, de la Fuente-Núñez, & Hancock, 2015), displays a broad-spectrum anti-biofilm activity versus Gram-negative and Gram-positive bacterial pathogens including *Pseudomonas aeruginosa*, *Escherichia coli*, *Staphylococcus aureus* and *Salmonella Typhimurium* (de la Fuente-Núñez et al., 2012; de la Fuente-Núñez, Reffuveille, Haney, Straus, & Hancock, 2014; Reffuveille, de la Fuente-Núñez, Mansour, & Hancock, 2014).

Recently, a new 1018-derivative antimicrobial peptide named 1018-K6, in which the alanine in position 6 was replaced with a lysine residue, was designed (Palmieri et al., 2018). This single point mutation was revealed to have a strong impact on the conformational status of 1018-K6, inducing an increased propensity to assume α -helix structures in membrane-mimetic models such as micellar solutions of SDS, differently from the parent IDR-1018, characterized by a predominant β -sheet structure (Palmieri et al., 2018). Furthermore, 1018-K6 was able to retain its structural integrity better than IDR-1018 in a wide range of pH and temperature conditions for prolonged incubation times showing also a significant bactericidal and biofilm preventing activity specifically against *Listeria monocytogenes* isolates from food-products and food-processing environments (Palmieri et al., 2018).

The present study was aimed at evaluating the antimicrobial and anti-biofilm activity of 1018-K6 on planktonic and biofilm growth of two reference and one food-isolate strains of *S. aureus* in order to assess the potential use and effectiveness of this peptide in the struggle against such critical foodborne pathogen able to cause diverse life-threatening infections.

Materials and methods

Materials

Two reference strains from ATCC collection were used in this study: the methicillin-sensitive *Staphylococcus aureus* (MSSA) ATCC 35556, a well-known strong biofilm producer on polystyrene (Di Ciccio et al., 2015; Thompson, Abraham, & Jefferson, 2010), and the methicillin-resistant *Staphylococcus aureus* (MRSA) ATCC 33591, also described as a strongly adherent strain (Gowrishankar, Kamaladevi, Balamurugan, & Pandian, 2016). Furthermore, a *S. aureus* strain isolated from cheese (SA1) carrying four SEs genes (sea, sed, sej, and ser) was also included in this study.

All culture media were purchased from Oxoid (Milan, Italy) unless otherwise specified. Phosphate buffered saline (PBS) was used for washing and rinsing bacteria. The derivative 12-mer peptide 1018-K6, reproducing the IDR-1018 sequence with the replacement of the alanine in position 6 with a lysine residue (A6→K6 mutation) (Palmieri et al., 2018), was purchased from SynPeptide Co., LTD (Shanghai, China).

Methods

Antibacterial activity assay

The Minimum Inhibitory Concentration (MIC) and the Minimum Bactericidal Concentration (MBC) were determined by the standard broth microdilution method following recommendations of the Clinical & Laboratory Standards Institute (CLSI, 2015). Briefly, tested bacteria cultures were cultured on Tryptic Soy Agar (TSA) at 37 °C for 24 h. Isolated

colonies were inoculated in Tryptic Soy Broth (TSB), growth for 16 h at 37 °C and diluted to 5×10^5 CFU/mL (CFU, colony forming units) in Muller Hinton II broth (MHB-II; Liofilchem, Italy). The bacteria were treated with 1018-K6 (ranging from 0.156 to 80 μ M) in 100 μ L culture medium (MHB-II) for 16 h at 37 °C. The cell growth was measured by the absorbance at 620 nm in a microplate reader (Victor, PerkinElmer, Waltham, MA). The MIC is defined as the lowest concentration of the peptide at which no bacterial growth was detected. To determine the MBC, 50 μ L of the bacterial cell suspension was taken based on the MICs and cultivated on a Tryptic Soy Agar (TSA) plates. The bacterial cells were enumerated after incubation at 37 °C for 24–48 h. MBCs is defined as the lowest concentration of peptide at which more than 99.9% of the bacterial cells are killed. At least six technical replicates were included for each group, and all experiments were performed in triplicate.

Inhibition of biofilm formation

The ability of 1018-K6 to prevent biofilm formation was evaluated in 96-wells flat bottom polystyrene microtiter plates (SPL Life Sciences, Korea). Biofilms were allowed to form in absence or in presence of 1018-K6, according to a previously described method (Stepanović et al., 2007), with slight modifications. Briefly, 200 μ L of *S. aureus* ATCC 35556, MRSA ATCC 33591, or SA1 bacterial cultures, serially diluted to 5×10^6 CFU/mL in TSB, were distributed in each well of the microtiter plates and the peptide was added in order to reach the concentration of 80 μ M. Plates were incubated at 37 °C for 24 h. After incubation, the supernatant was discarded and each well was washed three times with 300 μ L of sterile PBS. The remaining bacteria were heat-fixed (60 °C, 60 min) and stained with 150 μ L of 2% crystal violet (Conda laboratories, Madrid, Spain) for 20 min. After staining, bacteria were rinsed under running tap water. Therefore, the microplate was air dried at room temperature, and the dye bound to the cells was resolubilized with 150 μ L of 95% ethanol (Carlo Erba reagents, Milan, Italy) per well. The optical density (OD) of each well stained with crystal violet was measured at 540 nm using a microtiter-plate reader (Victor, PerkinElmer, Waltham, MA). At least six technical replicates were included for each group, and all experiments were performed in triplicate. According to the OD values of negative controls, the cutoff value (OD_c) was established as follow: $OD_{mean} + 3 \times St. deviation$. The OD value of a tested condition (control, 1018-K6 treated) is expressed as OD mean value of the condition reduced by OD_c value.

Minimum biofilm eradication concentration determination

Minimum biofilm eradication concentration (MBEC) assay was used to test susceptibility of the pre-formed *S. aureus* ATCC 35556, MRSA ATCC 33951, or SA1 biofilms to 1018-K6 (Ceri et al., 2001). Briefly, 150 μ L of bacterial cultures diluted to 10⁵ CFU/mL were added to the wells of 96-wells flat-bottom microtiter plates (Nunc, Roskilde, Denmark). Then, plates were covered with a 96-peg lid (Immuno TSP lids; Nunc, Roskilde, Denmark), sealed with Parafilm®, and placed on an microtiter shaker (MTS 2/4 digital microtiter shaker, IKA-Works, Staufen im Breisgau, Germany), set to 150 revolutions per min (rpm), in a humidified atmosphere (40%) at 37 °C (G-Cell 115, Fratelli Galli, Milan, Italy) for 24 h, to allow biofilm formation on the pegs under batch conditions. Subsequently, planktonic bacteria were removed by rinsing the peg lid in 200 μ L of sterile PBS. Biofilms on the pegs were exposed to 1018-K6 (0.25–80 μ M) in 200 μ L PBS for 24 h at 37 °C. After exposure, the peg lid was rinsed, as described previously, for 1 min, and then transferred to a new microtiter plate containing 200 μ L/well of fresh TSB and sonicated for 15 min (Ultrasonik 57H; NEY, USA),

in order to disperse the cells from the peg surface (recovery plate). After sonication, an aliquot (50 µL) was used for preparing serial dilutions that were spot plated (20 µL) on TSA. The peg lid was then discarded and the recovery plate was covered with a normal lid and incubated for 24 h at 37 °C. The MBEC is defined as the lowest concentration of 1018-K6 required to eradicate the biofilm of a selected isolate after a recovery period of 24 h at 37 °C. At least four technical replicates were included for each group, and all experiments were performed in triplicate.

Biofilm eradication assay

Biofilm eradication was assayed using the previously described protocol. Briefly, 150 µL inoculum of *S. aureus* ATCC 35556, MRSA ATCC 33591, and SA1 were prepared at 10⁵ CFU/ml concentration. Biofilms were grown for 24 h at 37 °C, 150 rpm, on TSP peg lid. Then, cells were exposed to 1018-K6 (80 µM) at different times of contact ranging from 1 min to 48 h at 37 °C. Cells were recovered in fresh TSB by sonication at room temperature for 15 min. An aliquot from each well was spot plated on TSA, then the microtiter plate was incubated at 37 °C for 24 h. Following incubation, OD was detected using a micro-titer-plate reader (Victor, PerkinElmer, Waltham, MA). Cells spot plated were counted after 24 h incubation at 37 °C. Log₁₀ CFU/peg was calculated as follow: $\text{Log}_{10} [(X \cdot B - 1) (D) + 1]$, where X is CFU counted on spot plate, B is the volume plated, and D is the dilution. At least six technical replicates were included for each group, and all experiments were performed in triplicate.

Circular dichroism spectroscopy

The secondary structure of the peptides was investigated by circular dichroism spectroscopy (CD) using a Jasco J-810 spectropolarimeter (Tokyo, Japan). The peptide samples at different concentrations (40, 60 and 80 µM in PBS) were loaded into a quartz cuvette of 0.1 cm path length (Hellma Analytics, Milan, Italy) and the spectra were recorded at 25 °C in the 190 nm–260 nm range at 20 nm/min scanning speed, by averaging 5 scans and in presence of 3 mM SDS as membrane-mimicking environment. To analyze the circular dichroism spectra obtained under the different experimental conditions, the relative contribution of three secondary structure elements (α-helix, β-structure and random coil) to the overall structure of the peptide was estimated by the DICHROWEB site (Lobley, Whitmore, & Wallace, 2002; Whitmore & Wallace, 2004, 2008), using the CDSSTR algorithm (Sreerama & Woody, 2000; van Stokkum, Spoelder, Bloemendal, van Grondelle, & Groen, 1990) and the BeStSel (Beta Structure Selection) web server, which is freely accessible at <http://bestsel.elte.hu/index.php> (Micsonai et al., 2018).

Scanning electron microscopy

Three-dimensional architecture of *S. aureus* ATCC 35556 biofilms exposed to 1018-K6 was studied by using the scanning electron microscope (SEM). Biofilms were grown for 24 h and then exposed to 1018-K6 (80 µM), as previously described, for 16 h at 37 °C. Pegs were removed from TSP lid using a flamed sterilized blade, and cells were fixed with 2.5% glutaraldehyde (Polysciences Inc., Warrington, PA, USA) in PBS at 4 °C for 16 h. Samples were washed three times with PBS (5 min each) and dehydrated at room temperature through a series of alcohol (50%–99% ethanol; Carlo Erba reagents, Milan, Italy). Samples were left to dry in a fume hood for 72 h, then were sputter-coated with a gold-palladium layer using a SCD 040 coating device (Balzer Union, Liechtenstein). Samples were observed using a Zeiss DSM 950 scanning electron microscope at an accelerating voltage of 10 kV

(Zeiss, Oberkochen, Germany). The images were processed for display using Photoshop (Adobe Systems Inc., San Jose, CA).

Statistical analysis

Statistical analyses were carried out using GraphPad Prism version 7.04 for Windows (GraphPad Software, La Jolla California USA, www.graphpad.com). Rate of biofilm inhibition (OD_{540nm} mean) for each strain were examined using unpaired t-test. Rate of biofilm eradication (biofilm viable count (Log₁₀ CFU/peg) at each time point) for each strain were examined using a Kruskal–Wallis test, with a Dunn's post- hoc test used to identify individual differences relative to the untreated control (PBS) for each strain at each time point. In all cases, significance was denoted with a probability of $p < 0.05$.

Results and discussion

Antimicrobial activity of 1018-K6 on planktonic *S. aureus* cells

The MIC values of 1018-K6 against planktonic *S. aureus* strains were first determined. Overall, 1018-K6 managed to inhibit the growth of the two reference *S. aureus* strains, MSSA ATCC 35556 and MRSA ATCC 33591, as well as that of the wild SA1 strain, with MIC values of 20 μ M. To investigate further the bactericidal activity of the peptide, the MBC was evaluated. Specifically, the MBC was found to be 20 μ M, a value that was on a par with the corresponding MIC, thus indicating that the tested compound should be considered to have bactericidal mode of action against *S. aureus* ATCC 35556, MRSA ATCC 33591 and SA1 cells. In addition, a comparison between 1018-K6 and the parent peptide IDR-1018 revealed that the MIC value of the AMP used in this study was half the concentration required by IDR-1018 to completely inhibit the growth of a MRSA strain (i.e., 40 μ M), as reported by de la Fuente- Núñez et al. (2014), showing an improvement in cell-inhibiting performance of the modified peptide 1018-K6.

Evaluation of the activity of 1018-K6 against biofilm formation of *S. aureus*

Considering the difficulty of treating contaminations associated with staphylococcal biofilms, we decided to test the ability of 1018-K6 to prevent biofilm formation. To this aim, the three strains included in this study were cultured in planktonic form in absence or presence of a peptide concentration of 80 μ M. As shown in Fig. 1, the biomass quantification confirmed the strong capacity of the two reference strains (MSSA ATCC 35556 and MRSA ATCC 33591) to produce bio- film, as well as the moderate biofilm formation ability of the enterotoxigenic SA1. Interestingly, a striking ability of 1018-K6 to reduce the biofilm biomass of all the *S. aureus* strains was observed compared to control cells incubated in medium without 1018-K6 (unpaired t-test; $p < 0.0001$). The peptide successfully inhibited biofilm formation in each of these strains as confirmed by the OD values of the treated bacteria which were all below the OD cutoff (OD_c) defining biofilm formation, thus revealing a strong anti-biofilm impact of 1018-K6 on the tested foodborne pathogens. Indeed, further investigations clearly suggested that a peptide concentration of at least 80 μ M was needed to completely prevent the biofilm formation by all the strains of interest (data not shown).

Minimum biofilm eradication concentration (MBEC) determination

An important goal in the treatment of biofilm is to explore the potential application of AMPs in the eradication of biofilms. Indeed, it is considered that sessile cells are usually more

resistant to antimicrobials with respect to their planktonic counterparts (Høiby, Bjarnsholt, Givskov, Molin, & Ciofu, 2010), because mature biofilms are surrounded and protected by the components of the extracellular matrix, such as DNA, polysaccharides, proteins, and others (Flemming & Wingender, 2010). In this context, the obtained results showed that a complete *S. aureus* ATCC 35556 biofilm eradication by 1018-K6 was reached when the peptide was used at a concentration of 80 μ M, even if a concentration equal to twice (40 μ M) its MIC resulted in a 1.7 Log₁₀ CFU/peg reduction of biofilm biomass. Similarly, also MRSA ATCC 33591 and SA1 biofilms were totally eradicated using the peptide at 80 μ M. Differently from the previous findings on the ability of 1018-K6 to inhibit *L. monocytogenes* biofilm formation (Palmieri et al., 2018), our study evaluated, for the first time, the eradication activity of this peptide against established biofilms. Therefore, 1018-K6 not only confirmed its capability to inhibit biofilm formation, but it also showed a strong eradicating activity against staphylococcal biofilms.

Kinetic of action of 1018-K6 against established biofilms of *S. aureus*

Changing in the amount of biomass during the peptide treatment were further examined. As reported in Fig. 2, *S. aureus* MSSA ATCC 35556, MRSA ATCC 33591, and SA1 cell densities in the biofilms were reduced already after 1 min of exposure. Specifically, a complete disruption in biofilm cell surfaces after 5 min was observed in the case of MSSA ATCC 35556 and SA1, indicating a rapid and substantial killing efficacy of 1018-K6 ($p < 0.0001$). On the other hand, although a significant reduction of live cells (almost 50%, $p = 0.0015$) in the MRSA ATCC 33591 biofilms was observed after 5 min, the complete biofilm eradication occurred after 15 min of peptide exposure ($p < 0.0001$). Finally, no viable cells were detected from 30 min to 48 h incubation in any conditions under investigation.

These results revealed that 1018-K6 was able to remove biofilm cells within 15 min, displaying a remarkable and rapid anti-biofilm activity against the tested biofilm producer strains. These findings are quite relevant as it has been found that staphylococci possess genetic information for the resistance to antimicrobial peptides (Joo & Otto, 2015), since they have developed different molecular mechanisms involved in the prevention of AMP action during both contamination and infection (Peschel & Sahl, 2006). Such mechanisms – that are controlled by specific sensor/regulator systems and that include surface charge alteration, extracellular proteases, exopolymers, and efflux pump proteins (Joo & Otto, 2015) – could also contribute to the different susceptibility of the tested strains in the response to the peptide.

The results achieved in this study are very impressive in terms of rate of action of the peptide on existing biofilms. Specifically, AMPs so far studied showed the ability to eradicate established biofilms after longer times of exposure (e.g., 6 h of treatment; Lavery, McCloskey, Gorman, & Gilmore, 2015). Therefore, to the best of our knowledge, this is the first report concerning the effects of an AMP such as 1018-K6 against established biofilms of pathogenic bacteria within few minutes, which pointed out a very rapid mechanism of action. For this reason, we hypothesized that 1018-K6 could kill bacteria in a way that not necessary involves an intracellular response messenger, as this strategy would require a time-period longer than minutes to work.

Structural characterization of 1018-K6

Previous studies have indicated that the interactions of AMPs with membrane components should result in conformational changes of the peptide (Palmieri et al., 2016; Pasupuleti, Walse, Svensson, Malmsten, & Schmidtchen, 2008; Yang et al., 2018; Zelezetsky & Tossi,

2006). Therefore, CD spectroscopic measurements as function of the peptide concentration, were applied to examine the secondary structure of 1018-K6 and evaluate the correlation between the 1018-K6 conformational changes and the antimicrobial/anti-biofilm activities of the peptide against *S. aureus*. The results clearly demonstrated that 1018-K6 adopted α -helix/ β -sheet mixed conformations in micellar buffer solution, which remained preserved in the concentration range tested up to 48 h (Fig. 3). Specifically, by using a recently developed web server called BeStSel, a more accurate estimation of the secondary structure composition of the 1018-K6 peptide, has been performed from CD spectra. Indeed, the prediction of β -sheet-rich or α/β -mixed structures has proven to be difficult and biased due to their spectral variety and lower spectral amplitudes (Greenfield, 2006) and this is assumed to be an intrinsic limitation of CD spectroscopy (Khrapunov, 2009). Therefore, BeStSel improves the accuracy and increases the information related to the secondary structure prediction better than any other previously published algorithms (Micsonai et al., 2018). As shown in Fig. 3, an improvement in the percentage content of β -helix conformation, which paralleled to a decrease of the random coil structures, was observed by increasing the peptide concentration. In Fig. 4, these structural data are better highlighted and the information obtained by CD spectroscopy at the extreme of concentrations used (40–80 μ M) and 48 h incubation time were compared. The CD spectra obtained at the two concentrations showed noticeable differences in the relative content of the secondary structures. In the table included in Fig. 4, the values of the eight components of secondary structure contents, as determined with the BeStSel server, were showed and the data were plotted in a pie chart graphic for an easier display. Thus, the variations in the far-UV CD signals were attributed to the structural rearrangements in the peptide molecule when analyzed at different concentrations, suggesting that 1018-K6 underwent to conformational changes with a high tendency to preserve a well-organized structure. Interestingly, the folded condition remained stable at increasing concentrations with the rate of α -elements substantially unchanged and a conversion of the total content of β -parallel to antiparallel elements. Results revealed (Supplementary Table 1) that 1018-K6 displayed a general α/β -mixed structure, which appeared unchangeable both as function of peptide concentration and incubation time. Therefore, BeStSel resulted to be more suitable to predict any conformational changes of peptides in the presence of α/β -mixed folding as for 1018-K6. Finally, the CD experiments could suggest that 1018-K6 at increasing concentrations undergoes intermolecular interactions assisted via a spontaneously self-organization, which arise by the strong tendency to assume β -sheet conformations (Gambaretto, Tonin, Di Bello, & Dettin, 2008). On this basis, it could be hypothesized that the strongest anti-biofilm effect exhibited by 1018-K6 against *S. aureus* at 80 μ M was correlated to a possibly self-assembly process, which can be critical to affect the *S. aureus* biofilm stability and its architecture.

Scanning electron microscopy analysis of 1018-K6 effects on *S. aureus* biofilms

Numerous antibacterial peptides kill bacteria predominantly via membrane permeabilization and subsequent structural disruption, due to their amphiphilic properties, which render them able to easily insert into the membranes of bacteria (Batoni, Maisetta, & Esin, 2016; Brogden, 2005). As shown in Fig. 5, control biofilms (in the absence of peptide) were uniform and firmly attached, with a continuous, extensive and interconnected network of cells and exopolymeric matrix materials. In addition, control pegs resulted covered by multilayered and three-dimensional structures of sessile cells. In contrast, 1018-K6 exposure induced a significant membrane damage within 16 h treatment. Indeed, detached chunks of floating matrix material and cells in discontinuous clumps were visible, together with small

aggregates of cells presenting blebbing on the membrane surface (Fig. 6), visibly indicating a significant destabilization and impairment of the cell membrane structure. Therefore, the modification of bacterial morphology induced by 1018-K6 suggested that the mode of action of the peptide can be directed to the cell-envelope, rather than to intracellular messengers involved in biofilm formation.

Conclusions

The present study aimed at investigating the bactericidal efficiency of a novel IDR-1018-derived peptide, named 1018-K6, against planktonic and biofilm-embedded *S. aureus* ATCC 35556 and MRSA ATCC 33591 cells, as well as against a food isolated enterotoxigenic strain (SA1). The results achieved demonstrated that 1018-K6 was able to cause a fast and complete killing of staphylococcal biofilms within the first 15 min, as well as to fully prevent biofilm formation, displaying also a potent bactericidal activity against planktonic cells. Interestingly, the antimicrobial and anti-biofilm action of the peptide was observed not only on the reference strains deriving from ATCC collection, but also on a wild strain isolated from a food product (i.e., cheese) that carried the genes encoding for different SEs, indicating efficacy and potential utility of this peptide in the control of food-related *S. aureus* strains.

In addition, after treatment of the reference strain MSSA ATCC 35556 with supra-MIC concentrations of 1018-K6, several distinct signs of damage to the cell envelope were evident in the SEM micrographs, such as membrane wrinkling and multiple blebbing. These results could support a direct cell membrane-affecting mode of action of 1018-K6, not involving the interaction and inhibition of intracellular messengers of biofilm. These features represent an advantage for several biotechnological applications, as the membrane-affecting antimicrobials exhibit a rapid and broad-spectrum activity and a low propensity to develop antibiotic-resistance.

Finally, the antimicrobial and anti-biofilm activities, as well as the reliable *modus operandi* together with the uncommon stability at different temperature (i.e. 15 and 90 °C) and pH conditions and the scarce tendency to precipitate in aqueous solutions, make 1018-K6 a good candidate for industrial uses such as the implementation of “green” packaging technologies and bio-sanitizing formulations. Further studies will be necessary to better evaluate 1018-K6 performances both in free- or bound-form against clinical and environmental isolates of pathogenic and spoiler bacteria.
