ABSTRACT

Functional variants rs7270101 and rs1127354 of inosine triphosphatase (*ITPA*) were recently found to protect against ribavirin (RBV)-induced hemolytic anemia. However, no definitive data are yet available on the role of no functional rs6051702 polymorphism. Since a simultaneous evaluation of the three *ITPA* SNPs for hemolytic anemia has not yet been investigated, we aimed to understand the contribution of each SNPs and its potential clinical use to predict anemia in HCV treated patients.

A retrospective analysis included 379 HCV treated patients. The *ITPA* variants rs6051702, rs7270101 and rs1127354 were genotyped and tested for association with achieving anemia at week 4. We also investigated, using multivariate logistic regression, the impact of each single and paired associated polymorphisms on anemia onset.

All SNPs were associated with Hb decrease. The carrier of at least one variant allele in the functional *ITPA* SNPs was associated with a lower decrement of Hb, as compared to patients without a variant allele. In multivariate logistic regression analyses the carrier of a variant allele in the rs6051702/rs1127354 association (OR=0.11, p=1.75x10^{-5}) and Hb at baseline (OR=1.51, p=1.21x10^{-4}) were independently associated with protection against clinically significant anemia at week 4.

All *ITPA* polymorphisms considered were shown to be significantly associated with anemia onset. A multivariate regression model based on *ITPA* genetic polymorphisms was developed for predicting the risk of anemia. Considering the characterization of pre-therapy anemia predictors, rs6051702 SNP in association to rs1127354 is more informative in order to avoid this relevant adverse event.

Keywords: (Anemia; HCV; ITPA; Ribavirin; Single Nucleotide Polymorphism; Adverse Event).
INTRODUCTION.

Hepatitis C virus (HCV) is one of the major causes of liver cirrhosis and hepatocellular carcinoma (Barrera et al., 1995). Sustained viral response (SVR), defined as undetectable plasma HCV RNA 24 weeks after the end of treatment, is achieved in less than 50% of patients with genotype-1 infection using the dual regimen consisting of pegylated-interferon (PEG/IFN) and ribavirin (Hadziyannis et al., 2004).

Although two new antiviral drugs are being introduced into clinical use, the combination of pegylated-interferon-alfa (pegIFN-alfa) and ribavirin (RBV) still remain the backbone of anti-HCV therapy.

Anemia is a major untoward effect of anti-HCV chronic therapy. Both PEG/IFN and RBV play a role in haemoglobin (Hb) decrease, although most of the responsibility is by far attributable to the latter. Moreover, with the forthcoming introduction of the new HCV protease inhibitors, telaprevir and boceprevir, the incidence of anemia is likely to increase, as shown by the results of recent clinical trials (Hezode et al., 2009; Kwo et al.; Suzuki et al.).

Repeatedly, individual RBV dose and pharmacokinetic (Pk) exposure have been found to be consistent determinants of treatment-associated anemia, and recommendations on dose reduction have been released in order to mitigate the impact of RBV on the severity of anemia (Aguilar Marucco et al., 2008; D'Avolio et al., 2012a; Kubota et al.; Lindahl et al., 2004; Mac Nicholas and Norris; McHutchison et al., 2006).

Among the non-modifiable individual factors also contributing to anemia development in recipients of anti-HCV therapy, there are single nucleotide polymorphisms (SNPs) in the human DNA region coding for inosine triphosphatase (ITPA). These were identified recently as the most significant variables influencing the risk of anemia (Fellay et al., 2010; Suzuki et al., 2011;
Thompson et al., 2010a). In these studies, by using a genome-wide association approach, two functional variants of ITPA, including one coding and one intronic variant, were found to be associated with treatment-induced anemia in HCV-infected patients (Caviglia et al., 2012; D'Avolio et al., 2012a; Fellay et al.; Ochi et al.; Suzuki et al.), as defined by the magnitude of Hb reduction after 4 weeks of treatment. This genetically determined vulnerability was subsequently confirmed in several ethnically heterogeneous clinical cohorts. The association signal was accounted for by two functional variants in the ITPA gene on chromosome 20: a missense variant in exon 2 (rs1127354, P32T) and a splice-altering single nucleotide polymorphism in intron 2 (rs7270101). Both polymorphisms had previously been well characterized and validated as functional variants in studies of patients with ITPase deficiency, a benign inherited enzymopathy in which inosine triphosphate (ITP, the substrate for ITPase) accumulates in red blood cells (Shipkova et al., 2006; Sumi et al., 2002).

A recent study established that intraerythrocytic accumulation of ITP, as seen in carriers of such anemia-protecting mutants, provides an alternative source of nucleoside-triphosphates that eventually compensates for RBV-induced ATP reduction (Hitomi et al.).

The introduction of the ITPA rs1127354 and rs7270101 genetic polymorphisms substantially improves our ability to predict the individual risk of treatment-induced anemia (D'Avolio et al., 2012a), but it is not clear how the non-functional rs6051702 ITPA polymorphism should be considered in this scenario.

Similarly to rs12979860 and rs8099917 polymorphisms that are localized in the region upstream of the gene encoding for IL28B (Ge et al., 2009; Tanaka et al., 2009), rs6051702 polymorphism on chromosome 20 (20p13 region) (Fellay et al., 2010) is localized in a no coding region adjacent to ITPA gene (Fellay et al., 2010).
As a simultaneous evaluation of the three *ITPA* SNPs for hemolytic anemia has not yet been investigated, we aimed to understand the contribution of each SNP and its potential clinical use to predict anemia in HCV treated patients at 1 month, date before which clinicians generally evaluate readjustments of ribavirin doses and the use of growth factors such as erythropoietin.
2 MATERIALS AND METHODS.

2.1 Patients

In this retrospective study, 379 patients with chronic HCV infection, treated in two university hospitals (Amedeo di Savoia and S. Giovanni Battista) of the city of Turin, Italy, between March 2005 and November 2012 were enrolled.

Patients were treated with PEG/IFN-α-2b (1.5 µg/kg s.c. once a week; sub dermal injection) or PEG/IFN-α-2a (180 µg once a week; sub dermal injection) plus RBV (600–1400 mg daily depending on bodyweight; orally). Sampling was performed after obtaining written informed consent in accordance with local ethics committee guidelines; patients were asked for an additional authorization for the genetic screening of their stored samples. Main inclusion criteria were: above 18 years old, no concomitant interacting drugs, self-reported adherence > 95%, no RBV and/or PEG/IFN dose modification up to week 4 of treatment and no treatment with growth factor before week 4. Patients with other forms of liver disease, active hepatitis A, hepatitis B infection, HIV infection, decompensated liver disease, hepatocellular carcinoma, severe depression or other psychiatric diseases, significant cardiac or renal disease, seizure disorders or pregnancy were excluded from this study. Data collected included: age, gender, weight, previous IFN therapy, concomitant drugs, baseline and week 2 and 4 biochemical parameters, such as white blood cells, Hb, alanine transaminase (ALT) level, serum HCV RNA level (logIU/mL).

2.2 Genotyping

Patients from whom DNA samples were available and who agreed to undergo genetic analyses were genotyped at polymorphic sites rs1127354, rs7270101 and rs6051702 on chromosome 20 using the ABI TaqMan allelic discrimination kit by real time PCR using standard methodology.
All primers, probes, and PCR conditions are available on request. The possible genotypes for each biallelic polymorphism are as follows: rs1127354: C/C, A/C, A/A (minor allele = A); rs7270101: A/A, A/C, C/C (minor allele = C); rs6051702: A/A, A/C, C/C (minor allele = C).

2.3 Definition of Clinical End Points

According to outcome definition in clinical trials for HCV chronic hepatitis treatment, Hb decline at week 4 on-therapy, was taken as the clinical endpoint. Patients were classified according to two clinical cut-off: (a) absolute Hb value lower than 10 g/dL, and (b) Hb reduction >3 g/dL at week 4.

The anemia grade was defined according to WHO (Groopman and Itri, 1999) as following: grade 0 (≥ 11g/dL), grade 1 (< 11-9.5g/dL), grade 2 (<9.5-8g/dL), grade 3 (<8-6.5g/dL), grade 4 (<6.5g/dL).

2.4 Statistical Analysis

For descriptive statistics, continuous variables were summarized as median (25th to 75th percentiles). Categorical variables were described as frequency and percentage. All data were assessed for normality using a Shapiro-Wilk test and categorical data were compared using a Mann Whitney or Kruskal-Wallis statistical test. To investigate continuous data, a Spearman Rank correlation was utilized. The association between individual ITPA SNP and the incidence of significant Hb decline was tested by a basic allelic test and calculated using the $\chi^2$-test. Multivariate logistic regression analysis with stepwise forward selection was performed with $P$-values of less than 0.05 as the criteria for model inclusion. Statistical analyses were conducted by
using SPSS software package ver. 20.0 (Chicago, IL, USA). Linkage disequilibrium analysis was conducted considering $r^2$ and using Haploview 4.2.
3 RESULTS.

Twenty-nine out of 408 initial patients were excluded due to the lack of demographic and clinical information. Of the 379 patients included in the analysis, 231 patients (60.9%) were male, the median age was 46 years (IQR, 40–57 years) and the median Body Mass Index (BMI) was 24.3 kg/m² (IQR, 22.0–26.6 kg). 360 patients (94.9%) were Caucasian and 19 (5.1%) were African. 233 patients (61.5%) were treated with PEG/IFN-α-2a (180 µg/ once a week) and 146 (38.5%) were treated with PEG/IFN-α-2b (1.5 µg/kg s.c. once a week). The median dose of RBV was 13.88 mg/kg (12.70-15.33). The majority of patients were treated with 800 mg (n=108) or 1000 mg (n=201) of RBV; three patients received 600 mg, three received 400 mg, sixty 1200 mg and four 1400 mg. The baseline patients characteristics were summarized in Table 1.

The median Hb reduction was -2.3 g/dL (-3.4 to -1.3) at week 4. 129 patients (34%) had anemia (Hb reduction>3g/dL or Hb<10g/dL) after one month of therapy; moreover 64 (16.9%) and 10 (2.6%) patients developed WHO anemia grade 1 and 2, respectively, and none grade 3 or 4. Baseline Hb was correlated with Hb reduction (r=0.350 p=2.47x10⁻¹²).

The variant allele frequencies for rs1127354 C/A, rs7270101 A/C and rs6051702 A/C were 5.5%, 10.0%, and 14.5%, respectively; Specifically: 42 (11.1%) patients were CA and none AA for rs1127354 SNP; 64 (16.9%) patients were AC and 6 (1.6%) were CC for rs7270101 SNP; 84 (22.2%) patients were AC and 13 (3.4%) were CC for rs6051702 SNP. All SNPs were in Hardy-Weinberg equilibrium. The three SNPs in analysis result in low Linkage Disequilibrium (D'=0.65 for rs6051702/rs7270101 and D'=0.53 for rs6051702/rs1127354) in our population. No differences concerning demographic, racial, physical characteristics and biochemical parameters, (Hb, platelet count, alanine transaminase -ALT- level, serum HCV RNA level) were observed among genetically defined groups.
The two functional *ITPA* SNPs responsible for inosine triphosphatase deficiency (rs1127354 and rs7270101) and the co-segregate SNP (rs6051702) were associated with the magnitude of hemoglobin decrease after one month of therapy. Patients with rs1127354CC (n=337) had the greater hemoglobin decrement (-2.4 g/dL, IQR -3.5 to -1.5), compared to patients with CA/AA genotypes (-0.9 g/dL, IQR -1.6 to -0.2, p=1.28x10^{-11}) (Figure 1B). Similarly patients with genotype rs7270101AA (n=309) had a greater hemoglobin decrement (-2.4 g/dL, IQR -3.6 to -1.3), compared to patients with AC/CC (-1.7 g/dL, IQR -2.5 to -0.9, p=0.001) (Figure 1C) and patients with rs6051702AA (n=282) had a greater hemoglobin decrement (-2.5 g/dL, IQR -3.6 to -1.6) compared to patients with AC/CC (-1.4 g/dL, IQR -2.3 to -0.7, p=2.35x10^{-10}) (Figure 1A).

As shown in Table 2, the factors related to anemia after 1 month of therapy are the baseline hemoglobin and *ITPA* genetic polymorphisms.

The associations in pair of mutation carriers of the three polymorphisms were evaluated on their ability to predict anemia with a logistic regression analysis. As shown in Table 3 only the carrier of variant allele in the association in pair of rs6051702 AC/CC and rs1127354 CA/AA is able to predict anemia (p<0.001) in multivariate logistic analysis.

Many factors previously linked to anemia were also included in multivariate logistic regression analysis and only the rs6051702/rs1127354 genetic association has been considered on the basis of the results in table 3. In the evaluation of the factors in the logistic regression analysis, hemoglobin at baseline (OR=1.51, p=1.21x10^{-4}) and the carrier of at least one variant allele of SNPs association (OR=0.11, p=1.75x10^{-5}) in *ITPA* gene (Table 4) were independently associated with achievement of significant anemia.
Finally, the positive and negative likelihood ratios (LR+ and LR-) between the presence of at least one protective variant allele of rs6051702/rs1127354 SNPs and absence of anemia showed to be 1.44 and 0.30 respectively, with 88.4% of sensibility and 38.8% of specificity.
4 DISCUSSION.

Recently several genetic variants associated with substantial effects on both efficacy and toxicity of PEG/IFN and ribavirin therapy have been identified. SNPs in the IL28B gene were found to be strongly associated with response to therapy of chronic genotype 1 HCV infection (D'Avolio et al., 2011; D'Avolio et al., 2012b; Ge et al., 2009; Suppiah et al., 2009; Tanaka et al., 2009; Thompson et al.) and SNPs in the ITPA gene were identified as predictors of RBV treatment-associated anemia in the European-American and Japanese populations (Caviglia et al., 2012; D'Avolio et al., 2012a; Fellay et al., 2010; Kurosaki et al., 2013; Naggie et al., 2012; Ochi et al.; Rau et al., 2012; Sakamoto et al., 2010; Suzuki et al., 2011; Thompson et al., 2010a). The anemia experienced as a consequence of PEG/IFN and RBV combination therapy is primarily caused by a RBV-induced hemolysis and secondarily by interferon-induced bone marrow toxicity. Ribavirin toxicity can be explained by the accumulation of RBV phosphate metabolites in erythrocytes, oxidative damage and consequent cell lysis (De Franceschi et al., 2000). The impact of anemia on the outcome of anti-HCV infection therapy is substantial, since RBV dose-reduction or early treatment interruption due to anemia often leads to suboptimal drug intake and a higher chance of treatment failure (Fried et al., 2002). The possibility of identifying those patients who are more likely to undergo significant Hb loss while on treatment might be helpful in order to implement those measures which might limit the impact of anemia on treatment outcome.

In this study the newly identified genetic polymorphisms of ITPA confirmed their value as predictors of treatment-induced anemia, as established by HB reduction after 4 weeks of PEG/IFN-RBV treatment. Furthermore, we observed that baseline Hb was correlated with Hb reduction and, strikingly, RBV dose was not significantly correlated to anemia by a statistical
point of view, but shows a borderline statistical significance (p=0.056) respect to other paper
(Sulkowski et al., 2010), confirming, however, that anemia is even a pharmacodynamic marker
of RBV exposure.

However having a higher baseline HB concentration is a biologically benign condition, which
testifies to a higher functional reserve as compared to the other patients. For pure numerical
reasons such condition is more vulnerable to a HB loss, since HB loss is here measured in terms
of absolute values rather than percentage HB loss from baseline.

Beside ITPA polymorphisms, a series of individual features such as RBV concentration, age,
platelet count, haemoglobin concentration and haptoglobin phenotype were found to have some
degree of association with the risk of anemia (Caviglia et al., 2012; D'Avolio et al., 2012a;
Lindahl et al., 2004; Nomura et al., 2004; Rendon et al., 2005; van Vlerken et al., 2011; Van
Vlierbergh et al., 2001). Among these, the only modifiable feature is RBV pharmacokinetic
exposure, which shows a remarkable variability among HCV-infected patients (Tsubota et al.,
2003). In fact, early assessment of RBV concentration is suggested by some studies (Caviglia et
al., 2012; D'Avolio et al., 2012a; Loustaud-Ratti et al., 2008; Morello et al., 2008; Rendon et al.,
2005) in order to adjust individual RBV dose.

Following the identification of ITPA polymorphism as the strongest predictor of anemia in
PEG/IFN-RBV recipients, the question arises as to how to integrate this newly identified genetic
marker in order to predict and manage the individual risk of anemia. The three SNPs analyzed in
this study, two functional and one no-functional ITPA polymorphisms, retain their independent
predictive values and display limited overlap in terms of predictive value (Table 2 and Figure 1).
As shown in Table 3, the pairwise associations of the three studied polymorphisms showed that the combination rs6051702/rs1127354 is the most significant in predicting anemia at 1 month after initiation of therapy.

These data are partially unexpected because between the two polymorphisms considered in the combination only the rs1127354 SNP is functional, while rs6051702 SNP is in the non-coding region of the \textit{ITPA} gene. This finding is similar to what has been found for the two non-coding polymorphisms rs1297860 and rs8099917 \textit{IL28B} gene identified as the most powerful genetic factors influencing IFN therapy response.

The polymorphism rs7072101, which is functional and often it is studied in association with the rs1127354 (Caviglia et al., 2012; D'Avolio et al., 2012a; Fellay et al., 2010; Naggie et al., 2012; Rau et al., 2012; Thompson et al., 2010a; Thompson et al., 2010c) seems to have minor clinical significance, compared to the other.

Therefore, considering the importance of pre-therapy anemia prognostic factors rs6051702 SNP should be considered in place of rs7270101 in association to rs1127354. According to our LR-results, for a patient carrier of at least one mutation for rs6051702/ rs1127354 SNPs, the probability to not develop anemia is nearly 3 times higher respect to the probability to develop anemia.

The clinical use of \textit{ITPA} genetic polymorphisms substantially improves our ability to predict the individual risk of treatment-induced anemia, particularly including the non-coding polymorphism rs6051702. The main implication of our results suggests that the carriage of \textit{ITPA} variants is associated with a rather limited median Hb loss on-therapy, independently of RBV concentration (D'Avolio et al., 2012a).
Otherwise, it has been demonstrated that anemia is related to the intra-erythrocytic and plasma concentrations of RBV (Caviglia et al., 2012; D'Avolio et al., 2012a; D'Avolio et al., 2013; D'Avolio et al., 2012c; De Franceschi et al., 2000; De Nicolò et al., 2013; Kubota et al., 2010; Loustaud-Ratti et al., 2008; Loustaud-Ratti et al., 2011; Morello et al., 2008; Rendon et al., 2005), moreover RBV plasma and intra-erythrocytic concentrations are correlated with the RBV doses taken by patients. Otherwise, RBV concentration is not only dependent on the administered dose, but also on body weight, absorption (nucleoside transporters and food effect) and excretion. Then the integration of the early therapeutic drug monitoring of RBV (after 1-4 weeks of therapy) (D'Avolio et al., 2012a; De Nicolò et al., 2013; Loustaud-Ratti et al., 2008; Loustaud-Ratti et al., 2011) and RBV dose selection by clinicians on the basis of ITPA genetic profile could improve the management of anemia.

Genetic testing is widespread and as short turnaround time compared to therapeutic drug monitoring (TDM) for ribavirin. The characterization of the most significant ITPA SNPs pairs at the baseline may to able the estimation of the individual risk of treatment-induced anemia. Ribavirin TDM might maintain a role in the management of the prevailing proportion of wild type ITPA genotype patients, whose RBV concentration may be fruitfully modified by dose adjustment. Since RBV pharmacokinetic exposure is also associated with the rate of SVR (Aguilar Marucco et al., 2008; Breilh et al., 2009; D'Avolio et al., 2011; Maynard et al., 2008; Pedersen et al.; van Vlerken et al.), TDM might also apply to carriers of ITPA variants with suboptimal RBV concentration, in whom RBV dose may be increased with a smaller risk of anemia.
5 CONCLUSION

In conclusion, this retrospective study confirms the high impact of *ITPA* SNPs on hemolytic anemia and suggest that rs6051702/rs1127354, and not rs7270101/rs1127354 combination, is the best genetic predictor able to predict anemia after 1 month of therapy. Although more studies are needed to clarify and confirm the relationship between anemia, *ITPA* polymorphism and RBV pharmacokinetics, these results show that estimating the risk of anemia by genotyping these two SNPs is more accurate than genotyping for the two functional SNPs. Moreover, these data might suggest the development of an individual screening algorithm, based on *ITPA* genetic profiles, able to reduce the impact of anemia on the rate of response to anti-HCV treatment, maybe limiting the need of TDM RBV plasma concentrations in this setting.
