Abstract

New initiatives have been introduced in Europe and the USA to encourage more rapid development of antibiotics. The need to ensure these new antibiotics can be safely used in children, and especially neonates, is important owing to high antimicrobial resistance in these patient groups. This review aims to determine what lessons can be learnt from the recent regulatory processes to speed up access to new medicines for children, focusing on antibiotics licensed for adults by the EMA since 2000. For the 11 newly approved antibiotics, 31 clinical trials enrolling children in Europe were identified. However, many of these trials included both adults and children but did not provide a subset analysis for paediatrics, limiting the relevance of their findings. Some studies have been prematurely terminated and others are apparently active but are still not yet recruiting patients. Among paediatric-specific studies, 18 evaluate safety and efficacy of new compounds, 4 are pharmacokinetic studies, but only 2 focus on neonates. Nearly all studies with an agreed Paediatric Investigation Plan have just started or are not yet recruiting. For most antibiotics, despite adult phase 3 studies being completed, with specific concerns for particular drugs already noted, it will take another 3–5 years before adequate prescribing information becomes available for paediatricians. Evidence from this review suggests that we could do better. Lessons should be learnt from paediatric antiretroviral development, with neonatal and paediatric pharmacokinetic, clinical trial and pharmacovigilance drug development programmes being run directly in parallel with adult studies—not a decade behind.
1. Introduction

The development of novel antibiotics is a key priority of antibacterial therapy in the 21st century. The US Food and Drug Administration (FDA) in the USA and the European Medicines Agency (EMA) in Europe are responsible for the scientific evaluation of applications for marketing authorisation of medicinal products and for the approval of specific proposed clinical indications for each compound.

Appropriate use of antibiotic agents may minimise selective pressure on the emergence of drug-resistant strains [1] and [2]. The licensing and marketing of a drug occur at the end of a long development process, in which clinical trials represent the final critical stage [3].

In the paediatric setting, the number of clinical trials is very low compared with the adult population: both economic and ethical factors can discourage pharmaceutical companies in conducting trials on children [4]. The result is a potential delay in the authorisation of antibiotics for children and a consequent increase in off-label prescribing [5]. Moreover, given the paucity of information of new antibiotics in children, data on drug safety and tolerability are often extrapolated from adult studies, with the consequent risks of underestimating toxicity, inadequate dosages and clinical failures [6].

Important new initiatives have recently been introduced both in the USA and Europe to encourage earlier and more complete evaluation of new drug products in paediatrics. The ‘Paediatric Regulation’ is a new legislation governing the development and authorisation of medicines in children that was introduced in the European Union (EU) in 2007 [7]. It brought in the creation of a Paediatric Committee, within the EMA, that provides objective scientific opinions on required drug development plans submitted by pharmaceutical companies. Such Paediatric Investigation Plans (PIPs) are aimed at ensuring that the necessary data to support authorisation of the medicine for paediatric use are obtained through targeted studies [8]. Further initiatives are now proposed to enhance the more rapid development of antibiotics. This study therefore aimed to see what lessons can be learnt from the recent regulatory processes to speed up access to new medicines for children, focusing on antibiotics licensed for adults by the EMA since 2000.

2. Materials and methods

The Medline, EMBASE and Cochrane library databases were systematically searched from January 2000 to December 2012 to identify all published papers regarding prospective clinical trials on the use of new antibiotics in infants and children aged 0–17 years and involving European countries. Only new antibiotics that have been licensed in the EU for adult use were
considered. A cross-check on references of major articles reporting adult data was also performed. To identify ongoing trials or recently completed trials, a search of the World Health Organization (WHO), US National Institutes of Health and EU clinical trials registers was performed (last accessed 31 January 2013) [9], [10] and [11]. PIPs were systematically searched through the EMA database [8].

3. Results

Eleven antibiotics approved in the EU since 2000 were identified (Table 1). A total of 31 clinical trials were found. A brief summary of completed and ongoing trials, as well as PIPs, for each drug is given.

Table options

3.1. Aztreonam lysine

Aztreonam is a synthetic monobactam that has been available intravenously for many decades. It displays a mechanism of action similar to penicillin and has selective bactericidal activity against susceptible Gram-negative bacteria, including Pseudomonas aeruginosa and most clinically relevant Enterobacteriaceae. Aztreonam is inactivated by extended-spectrum β-lactamases (ESBLs) and has no activity against Gram-positive bacteria or anaerobes.

An inhaled formulation, aztreonam lysine (AZLI), administered using an ultrasonic nebuliser, was recently developed. It received conditional approval by the EMA in 2009 for the treatment of P. aeruginosa infections in adults with cystic fibrosis and was also approved by the FDA in 2010, although not in children [12] and [13]. Three clinical trials enrolling children with cystic fibrosis and lower respiratory tract infections with P. aeruginosa are registered in Europe (Table 2). AZLI demonstrated superiority in lung function and a reduction in acute pulmonary exacerbations compared with tobramycin inhalation solution in adult and paediatric patients with pulmonary P. aeruginosacolonisation. However, only a small number of children were enrolled (n = 58; 22%) and no separate analysis for the paediatric population was performed [14] and [15]. Two studies evaluating the safety and efficacy of AZLI are active but are not yet recruiting patients [16] and [17].

3.2. Ceftaroline fosamil

Ceftaroline fosamil is a novel broad-spectrum cephalosporin approved by the EMA in 2012 for the treatment of adults with complicated skin and soft-tissue infections (cSSTIs) and community-acquired pneumonia (CAP) [18].

Ceftaroline inhibits bacterial cell wall synthesis by binding penicillin-binding proteins (PBPs), including PBP2a produced by meticillin-resistant Staphylococcus aureus (MRSA). It has activity against a wide spectrum of Gram-negative and Gram-positive pathogens, such as MRSA (including vancomycin- and daptomycin-resistant strains), penicillin-resistant Streptococcus pneumoniae (PRSP), meticillin-resistant Staphylococcus epidermidis (MRSE) and Enterococcus faecalis. It is not active against P. aeruginosa and ESBL-producing strains [19].

Although clinical data are still limited, ceftaroline displays a good safety and tolerability profile. The paediatric dosage is yet to be determined. In addition to the approved indications, a potential promising role for ceftaroline is empirical monotherapy when an MRSA or MRSE infection is suspected.
Two randomised controlled trials (RCTs) are recruiting paediatric patients in Europe (Table 3): they will assess the safety, efficacy, tolerability and pharmacokinetics of ceftaroline versus comparators in children aged 2 months to 18 years with CAP and cSSTIs [20] and [21].

A PIP for treatment of cSSTI and CAP has been agreed [22].

3.3. Daptomycin

Daptomycin is a cyclic lipopeptide that was approved by the FDA in 2003 for the treatment of adults with SSTIs caused by Gram-positive bacteria as well as S. aureusbacteraemia or right-sided endocarditis. It is inactivated by pulmonary surfactants and therefore should not be used for non-haematogenous pneumonia [23] and [24].

Daptomycin binds to the bacterial cell membrane in a calcium-dependent manner, causing rapid membrane depolarisation and bacterial death. It has selective activity against Gram-positive bacteria, including glycopeptide-resistant enterococci, MRSA, MRSE, streptococci and corynebacteria. In adults, daptomycin is given intravenously at 4 mg/kg or 6 mg/kg once daily, respectively, for SSTIs and S. aureusbacteraemia/endocarditis. Safety and tolerability of higher dosages have been reported both in adults and children [25], [26] and [27]. Daptomycin is generally well tolerated. As its most relevant side effect is muscular toxicity, regular monitoring of creatine kinase levels is recommended [28]. A warning that daptomycin could cause life-threatening eosinophilic pneumonia has recently been issued [29].

The experience of daptomycin in children is very limited and the paediatric dosing regimen remains to be determined [30], [31], [32], [33], [34] and [35]. According to the latest Infectious Diseases Society of America (IDSA) guidelines on the management of MRSA infections, daptomycin should be administered at 6–10 mg/kg every 24 h in children with bacteraemia, osteomyelitis and septic arthritis [36].

The pharmacokinetic (PK) profile, efficacy and safety of daptomycin in infants and children are under evaluation in several trials. Among these, only two are recruiting children in the EU. One study aims at characterising the peak concentration of daptomycin in cerebrospinal fluid of children aged 3 months to 16 years with acute Gram-positive meningitis (Table 4); daptomycin will be given as single-dose add-on therapy [37]. The second study will describe the safety and efficacy of daptomycin versus standard of care in children aged 2–17 years with S. aureus bacteraemia [38].

Table options

At present, the lack of adequate safety data does not allow daptomycin to be routinely used in children. Potential uses in selected cases include right-sided endocarditis with or without bacteraemia, infection of intravascular devices, and osteoarticular infections caused by MRSA, MRSE and vancomycin-resistant enterococci (VRE) [39].

No PIP is currently agreed on daptomycin.

3.4. Doripenem monohydrate

Doripenem monohydrate is the most recently developed carbapenem [40] and [41]. It was approved by the EMA in 2008 for the treatment of nosocomial pneumonia (NP) [including ventilator-associated pneumonia (VAP)], complicated intra-abdominal infections (cIAIs) and complicated urinary tract infections (cUTIs) including pyelonephritis.

When compared with imipenem/cilastatin and meropenem, doripenem had enhanced in vitro activity against P. aeruginosa and Acinetobacter spp. It is also active against most β-lactam-susceptible Gram-positive bacteria, Gram-negative bacteria (including ESBL-producing strains) and anaerobes. As with other carbapenems, it inhibits synthesis of the bacterial
cell wall by attaching to PBPs and has no activity against Stenotrophomonas maltophilia. Adverse effects of doripenem are similar to those of other carba-penems [40], [41], [42], [43] and [44].

In phase 3 studies, doripenem was non-inferior to comparators in the treatment of NP and cIAIs [45], [46] and [47]. However, a recent trial evaluating its safety and efficacy in severely ill patients with VAP was terminated prematurely due to excess mortality and poorer clinical cure rates in the doripenem group [48]: in that study, doripenem was administered at a higher dose [1 g every 8 h (q8h)] and for a shorter treatment period (7 days) than currently authorised (500 mg q8h for 10–14 days) and was compared with 1 g q8h of imipenem/cilastatin for 10 days. Following these preliminary results, the EMA's Committee for Medicinal Products for Human Use (CHMP) recommended updating the prescribing information allowing higher doses (1 g q8h for 10–14 days) in patients with NP caused by non-fermenting Gram-negative bacteria [49].

PK and pharmacovigilance studies of doripenem in children have been started in Europe (Table 5).

Table options

The pharmacokinetics, safety and tolerability of single-dose doripenem have been studied in hospitalised neonates (both term and preterm) and in infants <12 weeks of age with, or at risk for, bacterial infections under treatment with other intravenous (i.v.) antibiotics [50] and [51]. In that study, doripenem was given as add-on therapy. The study was completed in April 2012 but results are not available at present. One study comparing the safety and tolerability of doripenem with cefepime in children with bacterial pneumonia was suspended following premature discontinuation of the adult VAP study [52] and [53]. Three randomised controlled paediatric studies are currently ongoing. Doripenem is compared with i.v. cefepime for safety and efficacy in the treatment of cUTIs in children aged 3 months to 18 years; sampling for PK investigation is scheduled in doripenem-treated subjects [54] and [55]. A second study is evaluating doripenem versus meropenem in hospitalised children with cIAIs; a PK subanalysis for the doripenem group is also planned [56] and [57]. Another study plans to assess the penetration of doripenem (given as add-on therapy) into the cerebrospinal fluid of hospitalised children aged <1 year with meningitis [58].
Following the limited data on the safety of doripenem and its limited potential advantages over older carbapenems, its role in paediatrics remains to be established. Given its broad spectrum of activity, it might be useful for treating children with nosocomial infections or with infections caused by enteric or non-fermentative Gram-negative bacteria [41].

A PIP for treatment of hospital-acquired pneumonia (HAP)/VAP, cIAIs and UTIs including complicated and uncomplicated pyelonephritis and cases with concurrent bacteraemia has been agreed [59].

3.5. Ertapenem sodium

Ertapenem is a carbapenem with broad-spectrum antibacterial activity against aerobic and anaerobic pathogens, including ESBL- and AmpC-producing Gram-negatives [60] and [61]. In contrast to other carbapenems, it is not active against P. aeruginosa and Acinetobacter baumannii. Ertapenem is approved in Europe for the treatment of adults and children aged ≥3 months with cIAIs, CAP, diabetic foot infections and acute pelvic infection. It is also licensed for surgical-site infection prophylaxis in elective colorectal surgery in adults. Further indications in the USA include cSSTIs and UTIs [62]. Paediatric dosing is 15 mg/kg i.v. every 12 h (q12h) in children aged 3 months to 12 years (maximum 1 g/daily) and 1 g once daily in older children [60]. The intramuscular route has been licensed in the USA but not in Europe. The safety profile in children was comparable with that found in adults [60]. Use of ertapenem was associated with neutropenia, diarrhoea and mild-to-moderate elevation of liver function tests; seizures were identified with comparable frequency to comparators [63].

Arguedas et al. investigated the safety, tolerability and efficacy of ertapenem versus ceftriaxone in children aged 3 months to 17 years with cUTIs, SSTIs or CAP (Table 6) [64] and [65]. The overall incidence of clinical adverse events (AEs) was comparable between the two groups. The most common drug-related AEs were diarrhoea, vomiting, infusion-site pain and erythema. In general, the clinical response to ertapenem was similar to that found in adults for similar infections.

In a separate RCT, ertapenem was the comparator drug to moxifloxacin in children aged 3 months to 17 years with cIAIs [66] and [67].

A potential advantage of ertapenem compared with other carbapenems is the spectrum of activity sparing *P. aeruginosa*: ertapenem does not adversely affect carbapenem resistance among these bacteria, and improved *P. aeruginosa* susceptibilities have been reported after years of its use [61] and [68]. Ertapenem's prolonged half-life with once-daily dosing facilitates its use in outpatient parenteral antibiotic therapy (OPAT) for children older than 12 years.

No PIP is currently available on ertapenem.

### 3.6. Fidaxomicin

Fidaxomicin is the first in a new class of narrow-spectrum 18-ring macrolide antibiotics. Produced by an actinomycete, it has selective bactericidal activity against pathogenic *Clostridium difficile*, with minimal effects on the normal intestinal microflora. Its mechanism of action consists in inhibition of bacterial RNA polymerase [69] and [70].

Fidaxomicin is approved in the EU and USA for the treatment of adults with *C. difficile*-associated diarrhoea (CDAD). In pre-marketing studies, fidaxomicin was non-inferior to oral vancomycin in achieving clinical cure of CDAD (92.1% vs. 89.8%) and was associated with fewer recurrences [71]. In the USA, a study on the safety, tolerability and pharmacokinetics of fidaxomicin in children (6 months to 18 years) with CDAD is currently in progress [72]. In the EU, a prospective observational study in children has recently started (Table 7), aiming to determine the incidence and clinical outcomes of *C. difficile* infection in 60 term neonates and to investigate the feasibility of a potential interventional study [73].

Table options

A PIP for treatment of CDAD in children has been agreed [74].

3.7. Linezolid

Linezolid is the first member of the oxazolidinones [75]. It exhibits a selective spectrum of activity against Gram-positive bacteria, including MRSA, MRSE, VRE and PRSP. Linezolid inhibits bacterial protein synthesis through blocking the initiation process.

In Europe, approved indications for its use in adults are CAP, HAP and cSSTIs caused by Gram-positive bacteria. The FDA labelled linezolid for paediatric use in 2002 at doses of 10 mg/kg q8h in children aged 0–11 years and 10 mg/kg q12h (maximum 600 mg q12h) in older children. Conversely, in most European countries it remains off-label in the paediatric setting, although recent reports note that it is occasionally prescribed in children [76] and [77]. Neonatal dosing of linezolid has been poorly studied. PK data suggest that linezolid clearance is decreased in preterm and in term neonates <7 days of age; therefore, all neonates should be treated with 10 mg/kg q12h during their first week of life [78]. The main side effects in
children are gastrointestinal disturbances. Peripheral and optic neuropathy and myelotoxicity seem less frequent than in adults, however the risk of these severe complications should be considered and careful monitoring is recommended [77]. Linezolid has several advantages over glycopeptides. The high and rapid tissue penetration supports its use for central nervous system or osteoarticular infections. The oral formulation, with excellent bioavailability, can be useful in step-down therapy and in outpatients. Its activity against mycobacteria justifies its potential role in treating drug-resistant tuberculosis [79].

Five clinical trials enrolling adults and children (aged 13–17 years) treated with linezolid have been completed in the EU (Table 8). In three trials, linezolid was administered to treat CAP caused by PRSP, cSSTIs and catheter-related bloodstream infections due to Gram-positive organisms, or febrile neutropenia in oncological patients [80], [81], [82], [83] and [84]. In all these studies the number of enrolled children was limited and a stratified analysis for the paediatric population was not given. Therefore, no definite conclusions can be drawn. For the remaining two trials, evaluating children aged 0–17 years with haemato-oncological disease or undergoing haematopoietic stem cell transplantation, results are not yet available. The first study evaluated the efficacy and safety of rescue therapy with antibiotic-lock technique with either linezolid, vancomycin or amikacin for the treatment of indwelling central venous catheter (CVC)-related bacteraemia in retained CVC [85]. The second study evaluated continuous infusion with either linezolid, vancomycin, ceftazidime or meropenem as salvage therapy of tunnel/pocket infections of an indwelling CVC [86].

In two previously cited RCTs, linezolid is one of the comparators for ceftaroline [20] and [21].

No PIP is currently available on linezolid.

### 3.8. Moxifloxacin

Moxifloxacin is a fourth-generation fluoroquinolone with a rapid bactericidal effect [87]. It acts by interfering with topoisomerase II and IV, which are essential enzymes for the replication, transcription and repair of bacterial DNA. Its spectrum of activity covers Gram-positive bacteria (including *S. pneumoniae* and *S. aureus*), Gram-negative bacteria, some
anaerobes and atypical strains. Moxifloxacin has high oral availability and rapidly distributes to extravascular spaces, with a strong affinity for alveolar tissue.

Although moxifloxacin displayed a favourable safety profile in clinical trials, the EMA-approved indications have been recently restricted due to the increased risk of adverse hepatic reactions [88]. They include second-line therapy of acute bacterial sinusitis, acute exacerbations of chronic bronchitis (AECB) and CAP. Warnings have also been raised for spontaneous tendon ruptures, worsening of myasthenia gravis symptoms and severe skin reactions. Other serious adverse effects include irreversible peripheral neuropathy and QTc prolongation [89].

The main advantages of moxifloxacin are once-daily administration, fast bactericidal action, good tissue penetration and broad spectrum of activity, including mycobacteria.

Moxifloxacin is not licensed for paediatric use, with the exception of the topical formulation, and its dosage in children is still to be determined. The WHO guidelines on the treatment of drug-resistant tuberculosis recommend a moxifloxacin dose of 7.5–10 mg/kg/day (maximum 400 mg) in children [90]. In the USA, a trial is currently investigating the pharmacokinetics of single-dose moxifloxacin in children aged 3 months to 14 years [91].

Four trials on the systemic use of moxifloxacin (hydrochloride) in children are being conducted in the EU (Table 9).

Table options

A RCT is evaluating the safety and efficacy of moxifloxacin versus ertapenem in hospitalised children with cIAIs. The study is still recruiting participants. The safety endpoints focus on cardiac and musculoskeletal AEs [66] and [67].

The remaining three studies are observational phase 4 trials, but their paediatric relevance is limited as the number of enrolled children is not reported and no paediatric subanalysis is available. The first study enrolled outpatients aged ≥12 years under daily treatment with oral moxifloxacin for AECB. It aimed to determine the impact of AECB on the patient and the community and to evaluate the safety and efficacy of moxifloxacin in daily practice [92] and [93]. The second study evaluated patients aged ≥10 years with cSSTIs: moxifloxacin under daily-life treatment conditions appeared effective and the incidence of AEs was low [94]. The third study evaluated the potential benefits, tolerability and safety of moxifloxacin in patients with acute bacterial sinusitis [95].

Finally, a European trial is currently evaluating the safety and efficacy of topical moxifloxacin otic solution in children with acute otitis media with otorrhoea and tympanostomy tubes [96].
PIPs for treatment of pelvic inflammatory disease in female adolescents aged from 12 years to <18 years and cIAIs aged from 3 months to <18 years have been agreed on moxifloxacin [97], [98], [99] and [100].

3.9. Retapamulin

Retapamulin is a topical antibiotic belonging to the new class of pleuromutilins. It is approved by the EMA for bacterial superficial skin infections, such as impetigo due to meticillin-susceptible S. aureus or Streptococcus pyogenes, in patients ≥9 months of age. Retapamulin inhibits bacterial protein synthesis by interacting at a site on the 50S subunit of the bacterial ribosome through a unique mechanism. Systemic exposure following topical application through intact skin is low. The most common adverse reaction is irritation at the application site [101] and [102].

Retapamulin ointment was superior to placebo in adults and children with primary impetigo (Table 10). Pruritus at the application site was the most common AE (6%) [103] and [104]. Retapamulin and sodium fusidate had comparable clinical and bacteriological efficacy in the treatment of impetigo in adults and children aged ≥9 months; both drugs were well tolerated [105], [106] and [107]. The pharmacokinetics of retapamulin has been evaluated in 86 children (2–24 months) with secondarily infected traumatic lesions, dermatoses or impetigo. The study has been completed but the results have not been published [108] and [109]. A pharmacovigilance study will monitor the prescriptions of retapamulin across the EU in infants <9 months of age [110].

No PIP is available on retapamulin.

3.10. Telithromycin

Telithromycin is a semisynthetic erythromycin derivative and the first member of the ketolides. It was approved in Europe in 2001 and in the USA in 2004. It acts through inhibition of bacterial protein synthesis through binding to the bacterial ribosome with higher affinity than erythromycin [111] and [112]. Following oral administration, telithromycin is rapidly absorbed and diffused into tissues and phagocytes. Telithromycin is used to treat respiratory infections as it is effective against macrolide-resistant *S. pneumoniae* [113]. In Europe it is marketed for the treatment of adults with mild-to-moderate CAP, AECB, acute sinusitis and tonsillitis/pharyngitis caused by Group A β-haemolytic streptococci (GAS). It is also licensed at 25 mg/kg once daily in children aged 12–18 years with GAS tonsillitis/pharyngitis when β-lactams are not appropriate [114].

The most common side effects are gastrointestinal symptoms. Prolonged QTc intervals may also be observed. Recently, serious safety concerns have been raised regarding risks for severe liver toxicity, visual disturbances, transient loss of consciousness and exacerbations of myasthenia gravis: indeed, part of the telithromycin molecule acts as an antagonist of cholinergic receptors of muscles, eye and liver. For safety reasons, in 2007 the FDA revised the labelling removing two indications (acute bacterial sinusitis and AECB), whilst the EMA has recommended to restrict the use of telithromycin to the treatment of bronchitis, sinusitis and tonsillitis/pharyngitis caused by bacterial strains that are resistant to or cannot be treated with β-lactams or macrolides [115] and [116]. Following the benefit/risk evaluation by the CHMP, the marketing authorisation holder decided to stop the paediatric development programme [117]. Therefore, three studies investigating infants and children with acute otitis media were terminated in Europe (Table 11) and no PIP has been issued [118], [119] and [120].

Table options

3.11. Tigecycline
Tigecycline is the first member of the glycylcyclines. It is structurally similar to tetracyclines and acts as a protein synthesis inhibitor by binding to the 30S ribosomal subunit of bacteria [121] and [122]. Its bacteriostatic activity is maintained in the presence of several resistance mechanisms that affect other antibiotics and it covers a variety of Gram-positive and Gram-negative bacteria (including MRSA, S. maltophilia, A. baumannii and multidrug-resistant Enterobacteriaceae), anaerobes and atypical bacteria. It is not active against P. aeruginosa, Morganella or Providencia spp.[121] and [122].

Tigecycline was given a fast-track approval by the FDA for the treatment of cSSTIs, cIAIs and CAP. It was authorised in the EU in 2006 for adults with cSSTIs (excluding diabetic foot infections) and cIAIs; a variation application to include CAP in licensed indications was withdrawn in 2008.

Tigecycline has similar side effects to the tetracyclines, such as diarrhoea, nausea and vomiting. It may also cause photosensitivity, pseudotumour cerebri and pancreatitis [121], [122] and [123]. Its use is to be avoided in young children and during pregnancy owing to its effects on teeth and bone. Recently, a warning regarding increased mortality risk associated with tigecycline use has been issued [124] and [125]. A recent meta-analysis of RCTs of tigecycline documented that septic shock and superinfections were significantly more frequent in patients treated with tigecycline than with comparators. The CHMP has recommended to restrict tigecycline use to only when other suitable alternatives are not available and to include new warnings to inform prescribers of the higher mortality recorded in tigecycline trials [126].

Two paediatric studies on tigecycline have been conducted in Europe (Table 12). A multicentre study investigated emergency use of the drug in adults and children aged ≥8 years infected by resistant bacteria where other treatments had not been successful. The study has been completed but results for the paediatric cohort are not available [127]. A phase 2 study evaluated the PK profile of multiple doses of tigecycline in children aged 8–11 years with cIAIs, cSSTIs or CAP to identify an appropriate dose regimen (0.75, 1 or 1.25 mg/kg q12h) and to assess the safety profile and efficacy of tigecycline [128] and [129]. The ca. 1.2 mg/kg q12h dosage appeared the most appropriate, to be tested in phase 3 clinical trials. In this cohort, nausea was the most frequent AE and the overall clinical cure rate was 94%.

pts, patients; OL, open label; i.v., intravenous; q12h, every 12 h; q24h, every 24 h; NA, not available; cIAI, complicated intra-abdominal infection; cSSTI, complicated skin and soft-tissue infection; CAP, community-acquired pneumonia; PK, pharmacokinetic; Cmax, peak concentration of drug; Tmax, time at which Cmax is observed; AUC, area under the
concentration–time curve; Vd,ss, volume of distribution at steady state; TOC, test of cure; PD, pharmacodynamic; MIC, minimum inhibitory concentration.

Table options

A PIP has been agreed for treatment of cSSTIs and cIAIs in children aged 8–18 years [130].

4. Discussion

The increasing problem of multidrug-resistant bacteria will encourage the development and hopefully subsequent approval of new antibiotics [2]. The need for targeted studies on antibiotics in children has been recognised as a matter of concern by the regulatory authorities. However, despite the recent efforts in implementing paediatric trials, the number of studies that have been or are being conducted in children in this area still remains strikingly low, especially in Europe. For all the different possible indications for the 11 antibiotics newly approved by the EMA (of which only 2 have paediatric labelling), 31 clinical trials enrolling children in Europe were identified. However, many of these trials were mainly focused on adults and did not provide a subset analysis for the older children recruited, limiting the relevance of their findings. Some studies have been prematurely terminated and others are active but are still not yet recruiting patients. Among paediatric-targeted studies, 18 evaluate the safety and efficacy of new compounds, 4 are PK studies, but only 2 focus on neonates, the population in which dosing is likely most different from adults or older children. We could identify only one paediatric pharmacovigilance study on antibiotics in Europe. Nearly all studies with an agreed PIP have just started or are not yet recruiting. To our knowledge, this is the first comprehensive review on clinical trials conducted in the EU on antibiotics in children. Previous reports in the USA have documented an increase in the quantity and quality of paediatric controlled trials, demonstrating a success of the FDA paediatric exclusivity programme. However, it also emerged that dissemination of trial results in the literature is limited, as barely one-half of studies were published and determined labelling changes [131], [132] and [133]. A possible bias should also be taken into account in our study: unregistered trials, as well as unpublished data retained by pharmaceutical companies, may have led to an underestimation of available results. The new interventions and legislation introduced both in the USA and Europe should further promote drug evaluation in paediatrics, but the efficacy of these processes is under review. There are a number of steps that would improve the design of new antibiotic trials in children in Europe. These include an adequate knowledge of the basic epidemiology of key clinical syndromes in children (CAP, SSTI, IAI, etc.) through prospective observational studies. Second, a closer collaboration between clinicians and the pharmaceutical industry is necessary, particularly in early study design. The EMA has created a European paediatric network of research networks, investigators and
centres with expertise in paediatric clinical studies [European Network of Paediatric Research at the European Medicines Agency (Enpr-EMA)], that supports high-quality studies in children and helps with fostering closer links between industry, the regulators, patient representatives and academic clinical trial networks [134].

The EU and the European Federation of Pharmaceutical Industries and Associations (EFPIA) have launched a public–private partnership called the Innovative Medicines Initiative (IMI), aimed at improving and speeding up the drug development process. Combating and treatment of infectious diseases is a key research priority of the IMI programme: in May 2012, the IMI launched its 6th Call on the theme ‘Combating Antibiotic Resistance’ that includes ‘innovative trial design & clinical drug development’ [135]. It was perhaps slightly disappointing that the call did not include any specific development programme for children, with the call being only on clinical trials for adults. One potential model could be based on the Paediatric European Network for Treatment of AIDS (PENTA), established in 1991 as a collaboration between paediatric human immunodeficiency virus (HIV) centres in Europe, working closely with industry and the regulator to rapidly develop appropriate studies in children in parallel with adult HIV drug development programmes [136]. These studies are often a combination of PK, safety and strategic trials, rather than expensive and often not appropriate large phase 3 efficacy studies. PENTA has now become PENTA-ID, and can work with Pharma to develop new antimicrobials in Europe. This structured approach may actually speed drug development within the current regulatory framework. This level of collaboration with baseline observational studies, linked to planned interventional studies, is now required for antibiotics under early development.

Funding: IL was partly supported by the European Union through the European Regional Development Fund, the Estonian Science Foundation and target financing of the Estonian Ministry of Education and Research (SF0180004s12).

Competing interests: None declared.

Ethical approval: Not required.
