**GIM International**

GIM International, the global magazine for geomatics, is published each month by Geomares Publishing. The magazine and related e-newsletter provide topical overviews and accurately presents the latest news in geomatics, all around the world. GIM International is orientated towards a professional and managerial readership, those leading decision making, and has a worldwide circulation.

**PAID SUBSCRIPTIONS**

GIM International is available monthly on a subscription basis. The annual subscription rate for GIM International is €140 within the European Union, and €200 for non-European countries. Subscription can commence at any time, by arrangement via our website or by contacting Abonnementenland, a Dutch subscription administration company. Subscriptions are automatically renewed upon expiry, unless Abonnementenland receives written notification of cancellation at least 60 days before expiry date. Prices and conditions may be subject to change.

For multi-year subscription rates or information on current paid subscriptions, contact Abonnementenland, Postbus 20, 1910 AA Uitgeest, Netherlands +31 (0)251-257926 (09.00-17.00 hrs, UTC +1) paidsubscription@geomares.nl.

**ADVERTISEMENTS**

Information about advertising and deadlines are available in the Media Planner. For more information please contact our account manager: sybout.wijma@geomares.nl.

**EDITORIAL CONTRIBUTIONS**

All material submitted to Geomares Publishing and relating to GIM International will be treated as unconditionally assigned for publication under copyright subject to the editor’s unrestricted right to edit and offer editorial comment. Geomares Publishing assumes no responsibility for unsolicited material or for the accuracy of information thus received. Geomares Publishing assumes, in addition, no obligation to return material if not explicitly requested. Contributions must be sent for the attention of the editorial manager: wim.van.wegen@geomares.nl.

High-rise buildings affect the skyline of a city and thus the human perception of urban spaces. From which points can a building, or parts of the building, be seen? The answer requires viewshed analysis of raster or vector 3D city models. Visibility is not just a geometric exercise in which lines of sight are calculated using standard GIS tools. Visibility and perception of space are also determined by atmospheric conditions, contrast between foregrounds and backgrounds including the sky, visual acuity and psychological aspects. Here, the authors present a simple but accurate method for generating visibility maps based on the above criteria and demonstrate its effectiveness for a newly erected skyscraper in Turin, Italy.

A viewshed represents the visibility of a building or another object from a fixed vantage point and this can be computed from a digital surface model (DSM) using standard GIS functions. The result may be either 'yes' – the building is visible from the viewpoint – or 'no' – it is not visible. The results of n viewpoints within an area end up in a cumulative viewshed: n – m, with m being the number of points from which the building is not visible. This simple addition of the binary values 1 and 0 does not do justice to partial visibility and for this the visual magnitude has been introduced, resulting in a range of values between 0 and 1. This measure has been widely used in the analysis of rural and forest landscapes. Visual acuity is determined by the eye's visual angle and means that a building with a diameter of 20m can be seen from a maximum distance of 69km assuming crisp air, i.e. haze, dust or other diffusing particles are absent.

**METHOD**

However, diffusing particles will be often present in the atmosphere and they will obstruct a clear view of the building when observed from long distances. Perfectly clear air is the best-case scenario but leads to unrealistic values as atmospheric conditions affect visibility more than visual acuity. Visibility can be indicated from parameters that describe the atmospheric conditions, but it is more feasible to use sight distances registered over time by weather stations. The sight distances should preferably be collected hourly, and such high-frequency observations can be obtained from international databases.

**Visibility Maps of Turin**

Enrico Fabrizio is an architect and holds a PhD in energy technologies from the Polytechnic of Turin, Italy, and a PhD in civil engineering from INSA in Lyon, France. He is assistant professor at the University of Turin.

enrico.fabrizio@unito.it

Gabriele Garnero is a professor of geomatics at the University of Turin and of planning sciences at the Polytechnic of Turin, Italy. His research interests include applications of GNSS, photogrammetry and remote sensing, architectural surveys, digital cartography, GIS and cadastral applications.

gabriele.garnero@unito.it
Real-time weather observations can also be used. Depending on the frequency of sight changes, the sight distances can be averaged over a certain time span, e.g. a week, month or year. The city of Turin, which has a lot of heavy industry, has lowest visibility in September and October, and highest in August and January; the difference may be up to 7km. This method does not simply perform averaging but instead selects the most dominant visibility distance in a certain time span.

Perfectly clear air is the best-case scenario but atmospheric conditions affect visibility more than visual acuity.

DATA AND RESULTS
The test area lies in Turin, northwest Italy. The bare ground heights were derived from a recent digital elevation model (DEM) of the Piedmont region, captured by airborne Lidar with an average density of 1 point per 5m² and interpolated to a grid of 10 x 10m. A map, scaled at 1:1,000 and containing eave outlines of buildings and their heights above street level, was transferred into a raster layer with a resolution of 10 x 10m.
cell size of 0.5 x 0.5m using ArcGIS tools. Also the DEM was resampled to a grid size of 0.5 x 0.5m. Merging both datasets created a raster including the buildings and their heights, which are shown as simple blocks (Figure 1). The skyscraper has a square footprint of 45 x 45m. Its height is 210m, the foot lies at 234.50m above reference level and the top lies at 444.50m for all four corner points. If one of the four corner points is visible, then the building is indicated as visible. Using geometric computations and visual acuity, the length of the line of sight appeared to be 218km. Subsequently, visibility constraints were introduced based on atmospheric conditions. Figure 2 shows two maps, each computed within 30 minutes, using the visibility distances of 20km and 1.6km.

CONCLUDING REMARKS
The method allows it to be determined at design stage how the (psychological) perception of places in an urban landscape will change when new buildings are erected or existing buildings are demolished. This provides valuable information for architects and city planners. The use of colour contrast between a building and its surroundings allows refinement of the method.
