Introduction The practice of Badminton has expanded during the last decade in our country due to the easiness of adaptation of spaces and the low cost of materials for its practice. However, the benefits of this sport have been poorly studied in the Brazilian literature. The purpose of this research was to evaluate the differences in levels of attention, concentration, reasoning and speed of processing in Badminton practitioners, comparing initial and final results and also comparing with a Control Group. Methods This study was performed with 21 subjects: 12 in the experimental group (EG) and 9 in the control group (CG). In the EG, tests were applied in the beginning and after four weeks of Badminton lessons, twice a week, about 60min. The GC also had tests but did not attend classes. The cognitive skills included: 1. Reasoning - BPR-5: consists in five subtests - Abstract, Verbal, Numerical, Mechanical and Spatial Reasoning, which are evaluated according to the responses (higher score, better ability of reasoning). 2. Attention and concentration - subtest of WAIS: assesses attention, concentration and the ability to differentiate essential from nonessential details in 25 figures. 3. Processing speed: subtest codes of WAIS: assesses selective attention and processing speed, throughout a series of numbers and symbols, which must be reproduced in 2 minutes (maximum score 133). Results The results showed differences in cognitive abilities measured in GE before and after training: speed of processing: pre-test = 85.42, post-test = 91.67 (paired  $t = 3.59$ ,  $df = 11$ ;  $p < 0.001$ ), attention and concentration: pre-test = 20.25, post-test = 22.67 (paired  $t = 5.56$ ,  $df = 11$ ,  $p < 0.001$ ), verbal reasoning: pre-test = 83.42, post-test = 87.33 (paired  $t = 1.02$ ,  $df = 11$ ,  $p = 0.33$ ), abstract reasoning: pre-test = 70.17, post-test = 85.67 (paired  $t = 3.05$ ,  $df = 11$ ,  $p = 0.01$ ), mechanical reasoning: pre-test = 79.00, post-test = 77.17 (paired  $t = 0.51$ ,  $df = 11$ ,  $p = 0.62$ ), spatial reasoning: pre-test = 77.50, post-test = 89.17 (paired  $t = 2.89$ ,  $df = 11$ ,  $p = 0.01$ ), numerical reasoning: pre-test = 67.83, post-test = 76.42 (paired  $t = 1.95$ ,  $df = 11$ ,  $p = 0.08$ ); general reasoning: pre-test = 79.83, post-test = 87.08 (paired  $t = 3.02$ ,  $df = 11$ ,  $p = 0.01$ ). In the GC there was little difference in the evaluation in two stages: although most cognitive abilities (with the exception of processing speed and abstract reasoning) showed some improvement in the two periods evaluated, only the attention / concentration was statistically different. Discussion Thus, we conclude that the practice of Badminton, proposed in this study, was effective in improving cognitive skills, since the changes occurred not only for the simple passage of time or the knowledge of the tests in a second time.

### GAME LOCATION AND TEAMS' ENTITATIVITY

Guraj, K., Kofta, M.

*University of Warsaw*

Introduction: Home advantage has been an issue in team sports since a long time. Studies examined multiple factors that may contribute to the phenomenon, yet no definite answer has been found (p.e. Nevill, Holder, 1999; Bray et al., 2002). However, most of them didn't put much attention to possible effects of intergroup context. The aim of this study is therefore to examine inter- and intragroup processes in relation to game location. Methods: A questionnaire study was conducted in a repeated measures design with 3 conditions included – control (at practice) and 2 experimental (home and away). We examined responses from 31 male elite volleyball players from Polish first division. They assessed following variables: both competing teams' entitativity, own team's cohesion, inclusion of foreigners into the team, perceived consensus within team-members, liking of own team and anxiety level before the competition. Results: Territory had a strong influence on the variables related with social functioning within the group. Competing on the opponents' territory increased perceived level of opponents' entitativity without significantly changing the perception of the own team. Nevertheless, high own team entitativity proved itself to be a strong determinant of general positive attitude towards the team, especially of social cohesion and perceived consensus. There was no significant effect of stress level (measured by CSAI 2-R). Conclusion/Discussion: The study has proven that game location has a significant effect on athletes' perception of others. Observed changes may be the reason why athletes differ in the way they perceive threat. The increase in opponents' perceived entitativity level while playing away suggests that group processes and group perception may play a significant role in sports competition. Therefore, further research explaining whether discovered phenomenon leads to an increase in mobilization and a better performance or the opposite – to threat being perceived as bigger and a poorer performance – is a must. **DOES NUMBER OF QUALITY THROW ATTEMPTS AFFECT THE COMBAT OUTCOME IN TOP WORLD JUDO COMPETITIONS?**

Courel, J.1, Stankovic, N.2, Escobar-Molina, R.1

1: UGR (Granada, Spain), 2: UN (Nis, Serbia).

Introduction Judo is an Olympic sport in which it is extremely hard to predict winners of the most important competitions. Neither one Olympic champion from Beijing defended his title in London four years later. In addition to this fact, 45 from 56 medal winners in London won their first medal on the Olympics. Research was conducted in order to find out if there are differences between winners and losers in number of quality attacks in finals and semi-finals of the most important championships, depending on the combat period. Methods Applying observational methodology, a total of 273 combats from males and females finals and semi-finals of 12 Top World Tournament were analyzed by 13 trained judo observers. Inter and intra-observer reliability were assessed, by calculating Randolph's free-marginal multirater kappa (Randolph, 2008) and Cohen's Kappa. An ad hoc instrument was developed using Lince software (Gabin et al., 2012), including the variables a) quality throw attempts - analysis includes throw attempts that referee declares valid and ineffective actions in which a contestant clearly threw his opponent out of balance b) combat outcome and c) combat period - first two minutes and last three minutes of the fight. Statistical analysis included cross-tabulations analysis with Chi-square testing. Results Male winners perform a 26.8% more of quality throw attempts than losers during the last three minutes of the combat (ASRs= 2.7; p= .008). No significant differences were found in female fighters and between weight categories. Discussion The most important finding was that in the second part of the fight, male winners increase number of quality throw attempts while losers decrease the number. As coaching advice we recommend that constant activity is needed through the fight, but most important is to rapidly increase number of quality attempts during last three minutes. For doing this judokas need developed system of lactic anaerobic endurance (Lech et al., 2010) in order to get to those final moments of combat in good condition. No differences found in female competitors led us to conclusion that physical preparedness is not a crucial factor for success in decisive matches. Our suggestion is that in female competitors more attention should be given to psychological and tactical preparation, which according to results of Sterkowicz et al. 2007, are 2nd and 3rd factor most important for the sport result. **COMPARISON OF MONO- AND MULTIFREQUENCY BIA DEVICES IN THE ASSESSMENT OF HYDRATION STATUS IN ELITE ATHLETES**

Zubero, J.1,2, Iruñia, A.1, Chaverri, D.1, Barrero, A.1, Nebot, V.3, Štrumbel, B.4, Qiu, J.5, Iglesias, X.1, Rodríguez, F.A.1

1:GRCE, INEFC-Barcelona, UB/Barcelona, Spain)2:Nursing Dep. II, UPV/EHU (Donostia, Spain)3:UCV "San Vicente Màrtir" (Valencia, Spain)4:U. of Ljubljana (Slovenia)5:Shanghai Institute of Sport Science

Introduction Hydration status assessment can be a useful tool for monitoring training, nutrition and environmental health-related factors. Bioelectrical impedance analysis (BIA) is an easy non-invasive method for clinical and field studies (Armstrong, 2007). BIA device comparisons typically conclude that they are accurate (Wang et al., 2013), but it seems to fail in some studies on athletic and non-athletic populations (Moon, 2013). We compared two (mono- and multi-frequency) BIA devices for assessing total body water content (TBW) in a selected group of elite swimmers with the purpose of determining its crossed validity for field studies in athletes. Methods 48 elite swimmers (23 M, 25 F; age 22.0±3.8 y; body mass (BM), M 79.3±6.6, F 62.5±4.8 kg; height, M 186.3±5.6, F 173.0±5.6 cm) were assessed at the same occasion using two BIA devices: a foot-to-foot mono-frequency (50 Hz) BIA device (Tanita BC-420MA, Japan) and a multi-frequency wrist-to-ankle device (Z-Metrix®, BioparHom Co, France) (MONO and MULTI, respectively). TBW estimates were compared and inter-method agreement was assessed by two-tailed paired t-test, Pearson correlation (r), and Bland-Altman analysis. Results In males, TBW (l) by MULTI were greater (53.5±7.9, TEM 1.6) than by MONO (50.3±3.8, TEM 0.8) (18% diff., p<0.001). In females, TBW by MULTI were also greater (41.8±5.4, TEM 1.1) than by MONO (35.4±2.8, TEM 0.6) (6.4% diff., p=0.006). TBW estimates by both methods were highly correlated in males (r=0.86, p<0.001) but moderately in females (r=0.61, p=0.001). Discussion Both BIA methods were not in good agreement in estimating TBW content. The multi-frequency impedanciometer systematically measured greater TBW values, particularly in males. More important, measured values were highly correlated in males but not so in females. Even if none of the two devices can be considered a 'gold standard', it seems reasonable to assume that the multi-frequency device would provide more valid estimations of TBW content because of its more advanced technical design and fewer sources of error (e.g. electrode vs. foot plant). Adequate validation studies are warranted before BIA can be considered a valid tool in monitoring athletes' hydration status. References Armstrong LE (2007). *J Am Coll Nutr*, 25(5 suppl.), 575-584S. **SUCCESSFUL TEAMS' TACTICAL BEHAVIOR WITHOUT BALL IN THE U17 WORLD CUP MEXICO 2011**

Fritzier, W.

University of Football

Introduction Tactical behavior in soccer is often unpredictable as it depends on the interactions between offense and defense (Lames, 2006). However, it can be assumed that successful teams present tactical patterns with certain consistency that explain their positive results (Lames & McGarry, 2007). Tactical behaviors that characterize successful teams should become tactical training aims (Garganta, 2009). In this study, the actions of players without the ball were categorized and assessed by online-observation during the U-17 World Cup Mexico 2011; the ball-actions were analyzed in a second study using video-analysis. Methods The actions of 149 players (excluding goalkeepers) were observed in 8 matches; these actions were categorized according to different variables of tactical behavior: 12 actions

were assessed qualitatively (graded on a Likert scale of 5 levels) and 17 assessed quantitatively (frequency and outcome of the actions). The qualitative and quantitative variables were selected from a list of scouting criteria for talented players of Club Pachuca. The actions of each player were assessed by a trained observer. Afterwards, they were compared in order to identify those tactical variables that characterized successful teams. Score averages and frequencies (both absolute and relative) of actions between winning and losing teams were compared using Student's T-test. Results For qualitative variables, the defenders and midfielders of the winning teams: repeated efforts, made themselves available for a pass more often, guided their teammates, marked closely and pressed the opponent more than losing teams. Attackers showed no significant differences in any variable. The quantitative evaluation showed that the players of winning teams won more running duels and offered themselves more often in the center stripe. The midfielders and defenders of the winning teams showed a tendency to join the attack more often after winning the ball and to let the opposition's attackers get to their back less frequently. Discussion Significant differences between winning and losing teams focused on defenders' and midfielders' tactical behavior, while attackers showed no significant differences. This could lead to the conclusion that, at U-17 level, the training concentrates more on attacking play. According to these conclusions, the tactical training should aim on vertical play, on quick counterattack after recovering ball possession, and on tactical behaviors related with physical efforts, such as constant pressing upon the opponent, repeating efforts throughout the game and marking closely. ## CHARACTERISTICS OF SKI MOTIONS FOR BEGINNERS ON SHORT STAY SKI PROGRAM OF ELEMENTARY SCHOOL

Tatsumi, J., Kokudo, S.

*kobe university*

Introduction There are various difficulties to master ski skills even if child is beginner. It is important to elucidate the methods to estimate objectively ski motion for making sure of the current state of ski ability. The purposes of this study were to examine characteristics of ski motions for beginners, to elucidate procedure for mastering ski skills and the construct the simplified check points for evaluate beginners' ski ability. Methods The school children in Kobe city participate of the 3 days ski program. The samples of the study were 6th grade children, 6 boys and 5 girls. Their ski motions were recorded 6 times during the ski program. They were analyzed based on 28 observational motion points, which have multi rating categories. The graded response model of item response theory (IRT) was applied in order to estimate the ski ability of the children and item characteristics such as item difficulty (ID) and discrimination power (DP). Repeated-measure ANOVA and multiple comparisons were applied in order to examine the proficiency of ski skill through the activity. Results and discussion The 2 motions were 'looking down (ID=0.476)' and 'mistakes (ID=0.523)', had high ID. These motions were much difficult for beginners. Item was 'Bad waist position (ID=-0.841)' showed the highest ID at low-level category. It was suggested that beginners feeling to fear of ski or fall lost their postures. There were 4 motions, 'speed control and stopping (DP=3.092)', 'motion with center of gravity (DP=2.613)', 'looking ahead (DP=2.575)', and 'turning smoothly (DP=2.683)' which had high DP. It was suggested that edging skills like Pflugfahren (a double stem) and Pflugbogen (a double stem turn) were closely related to beginners' proficiency of ski skills. 'Bad waist position (DP=1.886)' also showed high DP. It was suggested that conquest of the fear was related to beginners' proficiency. The ski skills were improved significantly between beginning and end of the 1st day program, morning and afternoon of 2nd day programs repeating. It was suggested that beginners improve steadily through 2-hour programs. Their ski skills improved significantly through programs of two days and the average of ability scores after all programs ( $\theta=0.760$ ) was higher than IDs of items related to Pflugbogen skill. It was suggested that beginners' Pflugfahren skill and Pflugbogen skill was mastered through programs of two days. References Suzuki H. (1997). *Bulletin of Hokkaido University of Education*, 25, 21-30, (in Japanese). Sato M. (2002). *Bulletin of Komazawa University*, 18, 7-20, (in Japanese).

## OCCURANCE OF CHOKING IN ATP TENNIS

Kondo, E., Schembri, A.J., Bedford, A.

*RMIT University*

Introduction Choking under pressure is a common occurrence in professional sports. The aim of this paper was to investigate the nature and prevalence of choking in ATP tennis, and determine whether choking is more prevalent among certain athletes or stages within tournaments. Methods A database of matches played between 2007 and 2011 was developed on ATP matches and a total of 13,059 matches were included. Matches had to meet certain criteria to be considered potential choking. Best-of-three set matches were required to be played to three sets, and in terms of the best of five matches, all five sets of a match had to be played. The deciding set(s) of the match must have also had a final score of 7-6 or 7-5. These criteria were congruent with Wang's (2002) operationalisation in that the player could have won the match if they had not choked. Of the initial sample, 3,559 matches were played to three sets, whilst 656 finished to 7-6 or 7-5 in the second and/or third sets; 181 matches from the best-of-five met the criteria. Results Players were found to have choked in 236 matches. Players won the first set and choked in the second or third sets in 168 matches, whilst in 68 matches, the player lost the first set, won the second set, and choked in the third and final set. The most common choking comprised players serving for the match in the second or third sets, yet went on to lose the match. In over 15% of these matches, the player had match points on serve yet went on to lose the match. It was found that 2.8% of all matches played involved choking. Given that the majority of three set tournaments contain 64 players and 63 matches, this equates to approximately one choking incident per tournament. Quite a high proportion of matches (37) incorporated a player choking in both the second and third sets of a match and only 1 match for both 4th & 5th sets. Discussion Choking occurred in 2.2% of best-of-three set ATP matches and 1.43% for the best-of-five matches. The most common type of choking was the circumstance where a player had at least one opportunity to serve for the match, yet went on to lose their service game and subsequently, the match. On 23 occasions a player had a single match point and lost on serve, however there were 57 occasions when a player had at least one match point when receiving serve yet went on to lose the match. This finding provides evidence for the likelihood of winning points when on serve, but also the difficulty players have closing out a match when receiving, even if their general play has been superior to their opponent for the duration of the match. References Wang (2002). *Developing and Testing an Integrated Model of choking in sport*. PhD Thesis. Victoria University.

## MULTIVARIATE STATISTICAL APPROACHES TO TALENT IDENTIFICATION

Heazlewood, I.

*Charles Darwin University*

Do not insert authors here Introduction Talent identification (ID) is a major focus of many national sports associations. Sport promotes national pride, such as World Championships, Olympic and Commonwealth Games Paralympic Games. The foci of talent ID is to identify talent for World Championships, Olympic, Commonwealth and Paralympic Games; identify human talent for professional sports due to high turnover of athletes; enhance the use of limited resources by targeting the appropriate athletes and identify the next generation of high performance athletes. Many programs in Australia and overseas are directed towards target populations, such as children, adolescents and adults athletes. Predictive problems with univariate statistical approaches to talent ID include analysis of variables in isolation and they do not describe complex interactions that often occur between many tests that are conducted in talent ID. A significant level of redundancy within test variable sets may exist and this redundancy is difficult to evaluate using the univariate approaches. Multivariate prediction models permit a more holistic analysis of factors (Arbuckle, 2009; Hair et al., 2010) that explain and predict high performance athletes. Multivariate methods exist that can explain complex interactions that predict competition performance (Vaeyens, 2008). Methods A number of sports were analysed using multivariate statistical methods, such as multiple linear regression using kinanthropometric, exercise physiological, biomechanical and sports psychological factors to predict high performance triathlete times, factor analysis to examine the more complex relationship between torque, power, work, fatigue and acceleration, path analysis and structural equation modeling to predict performance outcomes in the decathlon and heptathlon, kinanthropometric, exercise physiological, biomechanical factors predicting BMX competition performance and neural network analysis to classify karate ability based on general motor and specific motor fitness tests. Results The multivariate methods were capable of developing hierarchies of importance for the predictor variable sets that explain and predict competitive performance. The explained variance utilising multivariate statistical methods was more substantive and enabled redundancy analysis and the identification of critical predictive subsets of factors predicting performance. Discussion Multivariate statistical approaches to talent identification provide both more meaningful and more complex explanations in predicting performance and as a more complete method of talent identification. ## THE EFFECT OF RULE MODIFICATIONS ON TECHNICAL DEMANDS AND DECISION MAKING IN JUNIOR RUGBY LEAGUE GAMES

O Connor, D., Cotton, W.

*University of Sydney*

Introduction Currently the Australian Rugby League is examining the junior game in relation to recruitment, retention and the skill development of 6-12 yr old players (ARLC, 2012). Preliminary findings from stakeholder forums indicated there were concerns that the game in its current form 'discouraged players from developing game awareness and tactical skills' (ARLC, 2012, p.5). The aim of this study was to investigate the influence of three proposed rule modifications (introduction of arm bands for the dummy-half and first receiver allowing these players to run the ball without fear of losing possession for their team if tackled, narrower field and kicking allowed on any tackle) on player involvement, decision making and skill development. Methods Participants were from 36 teams competing in Australian domestic Under 11 competitions. Thirty three games were filmed (17 played under traditional rules and 16 played under the new rules) and systemically analysed using the developed RL coding sheet (inter and intra tester reliability was  $r > 0.85$ ). Results Initial results indicated there was no significant difference ( $p > 0.05$ ) in the total number of plays or average number of sets of tackles performed in each game format. Furthermore, there was no significant difference in the technical skills (passes, catches, kicks and tackles) performed, effective plays such as line breaks and offloads, errors made (e.g. missed tackles, ball lost, penalties), or tries scored. However under the new rules players gained more metres on each play ( $p < 0.001$ ) and the dummy-halves decided to run more, were tackled more ( $p < 0.001$ ), kicked more, and gained more metres when they ran ( $p < 0.05$ ). Under the new rules the first receiver also ran on more occasions compared to standing and passing ( $p = .01$ ). Discussion The main aim of this study was to determine whether the introduction of three rule changes would provide greater opportunities for the development of technical skills and tactical awareness as these are considered paramount to the enjoyment and retention of players. Preliminary results revealed limited differences in overall game performance particularly in relation to the similar number of opportunities for executing technical skills and effective plays such as line breaks. However the introduction of the arm bands may have provided more decision making opportunities for the play makers and assist in developing their game sense and tactical awareness. These preliminary findings support the need for further research incorporating a larger sample before administrators can make an informed decision on the impact of these rule modifications on the development of junior rugby league players. References Australian Rugby League Commission (2012) Rugby League Participation Pathways Review, 1-16.

## THE TEMPORAL CHARACTERISTICS OF BASKETBALL OFFENSIVE PERFORMANCE

Chiang, H.Y., Tseng, K.T., Liu, Y.T.

*National Experimental High School at Hsinchu Science Park, National Longtan Agricultural and Industrial Vocational High School, National Taiwan Normal University*

Introduction The play-by-play records of the basketball game provide records of players' performance associated with time during the game, therefore it is possible to reconstruct the game based on these records and analyze the performance with respect to time. The purpose of the study was to examine the temporal characteristics of the offensive performance in 2012 FIBA Asia Cup, specifically the distributions of the ball possession time and shooting performance. Methods The analyses were based on the FIBA official records of 32 games of 2012 Asia Cup, and the cluster analysis on the game score difference (Csataljay et al., 2009) was used to group the 32 games into Closed Games (12 and under, CG), Balanced Games (13-35, BG), and Unbalanced Games (36 and above, UG). Ball possession time was calculated from the play-by-play records and the number of shots taken was also calculated for ball possession time of 5 s and under, 5-8 s, 8-14 s, and 14 s and above (Chen et al., 2005). In addition, the situation of how the ball possession was initiated was categorized into offensive rebound (OR), defensive rebound (DR), steal (S), and boundary (B). ANOVAs on the ball possession time and the distribution of shots made were used to examine the differences between winning (W) and losing (L) teams and among different ball possession time categories. Results The W teams of the UG group show a significantly shorter ball possession time than the L teams. The CG and BG groups show a general trend of shorter ball possession time for the hit than missed shooting results, and shorter 2-pt than 3-

pt shot attempts. The W teams of both BG and UG show significantly higher shooting percentage than the L teams in the 5 s and under category, the CG group shows a significantly higher shooting percentage for the 5 s and under category than the 8-14 s and 14 s and above categories. The analyses of the distribution of shots made from different ball possession time categories and ball possession initiation situations show that shots made from DR dominates the 5-8 s category and the W teams had significantly more shots than the L teams for all 3 groups. Discussion Fast pace has always been considered as a characteristic of basketball game. The analyses of offensive performance in different ball possession periods provide evidence to support the fast pace nature of basketball games. The official play-by-play records of basketball game offer the opportunity to analyze the players' performance dynamically. Future studies should take advantage of these dynamic data and examine time-related performance in basketball games. References Csataljaj G, O'Donoghue P, Hughes M, Dancs H. (2009). *Int J Perform Anal Sports*, 9(1), 60-66. Chen K-W, Zhu T-Q, Xu Y-L, Liu J-Q. (2005). *J Wuhan Inst Phys Educ*, 39(2), 91-93.

### **SUBJECTIVE EVALUATION OF BATTING FORM IN YOUNG JAPANESE CHILDREN USING ITEM RESPONSE THEORY**

Osamu, A.

*Fukuoka University*

Purpose Children's motor performance should be evaluated in terms of whether their form is proper or reasonable, but not using measurements such as time, distance, or force. The method which classifies various motor forms into two or more typical motor patterns and investigates changes in these motor patterns by individual cannot discriminate the short-term development of motor form. This study aimed to propose a new evaluation method for assessing batting form that can discriminate development over a short time span. The new evaluation method used a subjective rating by body part and item response theory to build a ratio scale. Methods One hundred and thirty-four Japanese young children aged 5 to 6 years volunteered to be measured while batting a ball. Two different sized rubber balls were rolled toward them on the ground and they were asked to hit the balls strongly and straight ahead. We evaluated how strongly and accurately they hit a ball using a 3-grade-scale: "strong/accurate," "medium," and "weak/inaccurate". At the same time, we videotaped their hitting performance and subjectively rated their form afterwards using 19 subjective rating items such as "Was the child's head stable before hitting?" "Did the child swing his/her arm smoothly?" and "Did the child hold the bat with one hand or two hands?" In addition, we also evaluated the child's form using a 3-grade-scale: "yes," "not discernible" and "no". Results and discussion A one-dimensional individual ability parameter, theta, and a step difficulty parameter, indicating the difficulty on the 3-point-scale subjective rating scale, were derived using the Partial Credit Model, a type of item response theory. Correlation coefficients of individual ability parameters with the speed of the big and small ball and the accuracy with the big and small ball were 0.442, 0.004, 0.294, and 0.050, respectively, showing that the correlation coefficient of the big ball had a significant relationship with individual ability parameters at the 1% significance level. Correlation coefficients of individual ability parameters with age, standing height, and body weight were 0.465, 0.336, and 0.219, respectively. These significant relationships indicated that estimated individual ability parameters reflected the maturity of subjects. The total item information function was 9.0, which corresponded to a reliability coefficient of 0.90, covered a value of theta from -1.0 to 0.7, indicating that this test was reliable in the middle to slightly inferior sample group. The objectivity coefficient between two groups of individual ability parameters computed from two raters was 0.684. Finally we proposed a practical method of computing individual ability parameters by a score that summed up the subjectively rated form score as 2 as "yes", 1 as "not discernible" and 0 as "no".

### **THE ROLE OF PREVIOUS ACTION IN THE ACCURACY OF THE JUMP SHOT IN MEN AND WOMEN BASKETBALL PLAYERS**

Rousanoglou, E.1, Argyriou, M.2, Bolatoglou, T.2

*1Sports Biomechanics Lab - Department of Sports Medicine & Biology of Exercise, 2Department of Sport Games,*

Introduction The jump shot (JS) is the most common type of shot in a basketball game (Ibanez et al., 2007). The accuracy of the JS (JSA) is determined by kinematic factors (Bartlett et al., 2007) and by factors of visual control (Vickers et al., 2009). The previous action (PrAc) (technical skill and tactical cooperation) aims to create the kinematic and visual conditions most favorable for an accurate JS execution; however there is lack of data on its role in the JSA. The purpose of this study was to investigate the role of the PrAc in the JSA in men and women basketball players. Methods A notational analysis (Hughes and Franks, 2004) was used in 30 men's and 27 women's games (A1 league championship - first 6 ranking teams, respectively). The PrAc examined were those of technical skills (way of receiving the ball, way of stopping, number of dribbles, hand of last dribble, receiver's movement) and tactical cooperation (use of screen, area and side where the pass came from). To test the significance of the relationship between PrAc and JSA the technique of cross-classification was applied (Chi-Square index,  $p \leq 0.05$ ) with gender as a control variable, separately for each PrAc. Results The significant correlations between the JSA and PrAc had a different gender pattern. For the technical skills, the JSA was significantly related to the way of receiving the ball and the receiver's movement in the women ( $p \leq 0.05$ ) while in men no significant correlations were found ( $p > 0.05$ ). For the tactical cooperation, the JSA was significantly related with the area where the pass came from for both genders, while, it was significantly related to the use of screen for receiving the pass and the side where the pass came from only in men ( $p \leq 0.05$ ). Discussion The different gender pattern of the significance of the correlations between the JSA and the previous technical and tactical action indicates the need for a gender specific training design. For improving the JSA coaches should take into consideration the particular needs of the men and the women basketball players as well as the gender differences in cooperation and competition (Van Vugt et al., 2007). Introduction Game's study and analysis are essential to achieve the highest levels of performance. It is therefore important to access information in order to increase game's knowledge. This study objective was to build an handball winning teams profile, using efficacy values derived from the combination of simple game indices, and therefore establishing what level of relationship in their application is necessary to obtain relevant information. Methods Sample for this study was composed by a total of 192 games of the Handball 1st division Portuguese Championship. Independent variables were the condition of game winner and loser and dependent variable the

efficacy coefficient. A descriptive statistical analysis of proposed rates was applied, T-tests for the two independent samples with normal requirements (KSL) and equal variance (Levene), non-parametric tests (Man-Withney U) and also Spearman bivariate correlations. Results indicate that the attack efficacy rate, the missed shots rate in the attack, the shot efficacy rate, the efficacy and inefficiency shot rate and the goalkeeper efficacy rate are the most relevant when doing associations with final standings. It appears to exist a relationship between the shot efficacy and the final standings and a strong relationship between goalkeeper's efficacy and final standings. Discussion Proposed efficacy coefficients are valid to determine the winner or loser condition in a handball match, namely the attack efficacy rates, the missed shots in the attack, the efficacy and inefficiency shot rate, and the goalkeeper's efficacy rate are the only ones who seem to have significant differences between the winner and loser teams. Goalkeeper's efficacy rate was the main coefficient when relating to the final standings. There was a very marked difference in the comparison between the first and the last ranked, reinforcing the importance of the handball goalkeeper's and their teams end results. (Pascual, 2008; Sá, 2012). It was possible to identify a considerable number of factors that can contribute to an improvement in the performance of handball teams. Thus, it is important to transfer the competition data to training, preparing in a more careful, adjusted and focused way teams for a better performance. References Pascual, X. (2008). ### ANALYSIS OF SEQUENCE OF PASS, SHOTS ON GOAL AND GOALS CONVERTED IN THE HANDBALL FEMALE IN THE 2008 OLYMPIC GAMES

Leonardo, L., Krahenbühl, T.

*University of Campinas (UNICAMP)*

**Introduction** The handball is a sport in which the pass is a technical element of great importance in the construction of sequences offensive and which determines the actions prior to submission attempt on goal. Thus, studying the use of this technique for shot the goal is characterized as an index of relevance for understanding the logic of the game of handball. The literature review presents studies related to the analysis of sequence of passes in moments that precede the loss of possession, however, there is no agreement among studies, which warrants further investigations on this subject. The aim of this study is to compare the data obtained on the sequence of passes (SP) on the basis of the shots on goal and situations where there is not a goal, seeking information that may help in studies on the topic. **Methods** The method is the systematic observational indirect and not participant (ANGUERA et al, 1978) in 12 female handball matches of the 2008 Olympics Games. Was considered sequence of passes (SP) the period beginning with the conquest of possession until the interruption of the sequence of passes or loss of possession. The categories analyzed were: FS= shot on goal without converted; FG= goal converted, and N = loss of possession in other situations. Results Compared SP with FG, FS and N, was observed that for SP=0: (FG=56,7%, FS=28,9% e N= 14,4%) and to SP=1: (FG =35,5%, FS=33,1% e N=31,5%), with p-value <2.2e-16, which is inversely proportional relation between SP and FG, with better of FG between SP = 0 and 1 and occurrence of a directly proportional relationship between SP and N. For FS + FG (total shot on goal) it was found that have an inverse relationship between SP and FG + FS, with better use of FG + FS between SP=0 (FG + FS=85.6% and N=14.4%), SP=4 (FG + FS = 52.6%) and SP=7 (FG + FS = 52.6%), and occurrence of a directly proportional relationship between SP and N (p-value = 3.985e-16). **Discussion** The present study is the first to make a relationship between sequence of passes and the different situations of loss of possession (FG, FS and N) of female national teams in the 2008 Olympics Games, that is to our knowledge. Regarding the literature, these present data agree with Tavares and Moreira (2004) and Garcia et al (2008) studies who analyzed only male teams. This study demonstrates that for handball games analyzed, the lower number of passes is more objective (creation of some passages) and is the best decision-making to create situations more effective as demonstrated in an inverse relationship between the sequence of passes and the criteria FG and FS. ### OBSERVATIONAL TOOL TO EVALUATE DECISION MAKING IN BASKETBALL PLAYERS

Serna, J., Lavega, P., Hileno, R., March, J., Sáez de Ocáriz, U.

*INEFC(Lleida, Spain)*

**Introduction** According to motor praxiology, basketball is a cooperation-oposition game (Parlebas, 2001). In this kind of games, decision making is a key factor for the performance. All players must use its motor intelligence in order to interpret the internal logic of sport and motor behaviors of teammates and opponents (Lagardera and Lavega, 2004). Observational methodology allows great opportunities to study player's motor intelligence. The aim of this study was to create an observational tool to evaluate decision making within coach's game plan. **Methods** Nine Spanish male players participated in this study (age 23.0 ±2.4 years). Following observational methodology (Castellano et al., 2008), we built a tool with 48 categories organized in 7 criteria. Four trained and expert observers were divided in two groups so as to analyze one EBA Spanish League game. Each group of observers analyzed 1539 units of observation. Afterwards, the optimization of observational system included a strict control of the quality of data based on ANOVA and Generalizability Theory (Cronbach et al., 1963). The EduG (Cardinet et al., 2010) was used to design two facets for making random infinite calculations in order to determine the reliability between the observers (Gorospe et al., 2005). **Results** The statistical analysis of inter-observer reliability revealed that most variability (99.9%) corresponded to the categories, and was zero for the observers and very low in the categories-observers interaction (0.1%). The overall analysis generalizability coefficients showed that the accuracy reliability generalization of the results was excellent (1.00). In addition, we observed highly significant goodness categories through the generalizability coefficient (0.00). **Discussion** Observational tool built adhoc allowed us to identify decision making of basketball players depending on team's strategy. According to background (Lagardera and Lavega, 2004; Parlebas, 2001), we identify different levels of motor intelligence when we study decision making within game coach's strategy. Players with the ball and their defenders can be studied with a high reliability using this tool. **References** Cardinet J, Johnson S, Pini, G (2010). Applying Generalizability Theory using EduG. **16:20 - 17:50****Invited symposia****IS-PM09 The brain at work \*****EXERCISE IN THE HEAT**

Nybo, L.

*University of Copenhagen*

This presentation focus on central fatigue provoked by prolonged exercise in the heat and evaluates the possible associations between hyperthermia-induced fatigue and changes in the cerebral perfusion, metabolism, thermodynamic and neurohumoral responses. Exercise-induced hyperthermia is associated with an impaired ability to maintain voluntary activation of the alpha-motor neurons during sustained maximal muscle contractions. An elevated brain temperature as consequence of heat accumulation in the brain appears to be a main factor influencing the ability and will to continue exercising, but neurotransmitter activity of the dopaminergic system and inhibitory signals from thermoreceptors arising secondary to the elevated core and skin temperature and augmented afferent feedback from the exercising muscles and the cardiorespiratory system are also of importance. Hyperventilation-induced reductions in cerebral blood flow and the associated lowering of the cerebral oxygenation is also considered in the integrated model that is presented to describe the interplay among peripheral and central factors influencing fatigue during exercise in the heat.

**EFFECT OF ORTHOSTASIS ON CEREBRAL BLOOD FLOW AND OXYGENATION**

Van Lieshout, J.

*Dpt Internal Medicine & Laboratory for Clinical Cardiovascular Physiology*

Upon either passive or active assumption of the upright body position, the first circulatory event is a gravitational displacement of blood away from the thorax to dependent regions of the body with a fall in venous return. Depending on the type of orthostatic stress (i.e. active standing vs. passive head-up tilt or simulated orthostatic stress by lower body negative pressure) approximately one half to one litre of blood is transferred to the regions below the diaphragm. Orthostatic pooling of venous blood begins immediately and the total transfer is almost complete within 3-5 min depending on the investigated body region. In addition to this transfer of thoracic blood, the central blood volume is affected by transcapillary filtration of fluid into the interstitial spaces in the dependent parts of the body. The circulatory adjustment to active standing up includes an initial ~30 s lasting fluctuation in mean arterial pressure (MAP) followed in 1-2 min by a phase of relative stability. Initially, MAP drops some 25 mmHg as total peripheral resistance falls ~40% for 6 to 8 s unrelated to orthostasis or straining and attributed to the instantaneous increase in vascular conductance of the active leg muscles. This transient and rapid fall in MAP is likely to explain the feelings of light-headedness that even healthy humans sometimes experience shortly after standing up, and may even cause recurrent transient loss of consciousness (TLOC). When standing, both the position of the cerebral circulation and the reductions in MAP and cardiac output challenge cerebrovascular autoregulatory mechanisms and cerebral perfusion and oxygenation decrease. The mechanisms underlying the postural reduction in cerebral perfusion are as yet incompletely understood. The role of systemic pressure/flow control, static and dynamic cerebrovascular autoregulation and the carbon dioxide (CO<sub>2</sub>) responsiveness of the brain vasculature will be discussed. With exercise the initial increase in cerebral blood flow is blunted at higher exercise intensities by a hyperventilation-induced lowering of the arterial CO<sub>2</sub> partial pressure and subsequent cerebral vasoconstriction. For exercise-related fainting the key question is whether TLOC developed during or after stopping exercise.

**CEREBRAL BLOOD FLOW AND METABOLISM DURING EXERCISE**

Secher, N.

*University of Copenhagen*

Regulation of cerebral blood flow (CBF) is markedly different from control of flow to skeletal muscles. While flow to skeletal muscles is inadequate to maintain muscle oxygenation during exercise, cerebral activation is associated with a marked increase in (regional) CBF and the activated regions of the brain may be identified by their enhanced oxygenation. Yet, for the brain as a whole, small muscle exercise (e.g. with one forearm) does not affect CBF. On the other hand, whole body exercise is associated with an approximately 20% increase in CBF, at least as long as the work rate is moderate. During intense exercise, CBF approaches the resting level and may become even smaller than the resting level because of the associated marked increase in ventilation and therefore decrease in the arterial carbon dioxide tension. However, the cerebral metabolic rate for oxygen (CMRO<sub>2</sub>) increases with work rate and, accordingly cerebral oxygenation becomes affected during intense exercise, may be to the extent that cerebral oxygenation limits cerebral activation and induces (central) fatigue. Also, the brain releases lactate during exercise and, as demonstrated in the rat, its glycogen deposit is used. Thus, brain glycogen depletion may represent another avenue for developing central fatigue and during exercise in the heat; brain temperature may reach a critical level. Taken together, exercise affects both cerebral blood flow and metabolism and that seems to implicate slow rather than rapid muscle contractions, providing a framework for insight into motor control when exercise becomes challenging.

#### NEUROMUSCULAR FUNCTION, HORMONAL AND REDOX STATUS AND MUSCLE DAMAGE OF PROFESSIONAL SOCCER PLAYERS AFTER A HIGH-LEVEL COMPETITIVE MATCH

Silva, J.R.1, Rebelo, A.1, Marques, F.2, Pereira, L.2, Seabra, A.1, Ascensão, A.3, Magalhães, J.3

*Faculty of Sport, University of Porto*

**Introduction** Professional players should be able to successfully compete during a 10–11 months congested competitive schedule. Match competition, in particular, seems to represent a major source of physical stress and physiological demands during the competitive season. The purpose of the present study was to examine the impact of an official match on biochemical and neuromuscular parameters of professional players. **Methods** Seven professional players from the same team performed an official match being data collected 72-h before, 24-h, 48-h and 72-h post-match. Plasma testosterone/cortisol ratio (T/C), creatine kinase (CK), superoxide dismutase (SOD), glutathione peroxidase (GPX) and reductase (GR) activities, myoglobin (Mb), C-reactive protein (CRP), uric acid (UA), protein sulfhydryls (-SH), malondialdehyde (MDA) concentrations and total antioxidant status (TAS) were measured. Sprint, jump and change of direction performance, and maximal isokinetic knee extension and flexion were obtained. Results Cortisol increased and T/C decreased until 48-h recovery ( $P < 0.05$ ). Mb, CRP and -SH ( $P < 0.05$ ) increased at 24-h and CK, TAS, SOD and MDA ( $P < 0.05$ ) increased up to 48-h recovery. GR increased and GPX decreased at 24-h recovery ( $P < 0.05$ ). Jump performance decreased 24-h post-match ( $P < 0.05$ ). **Discussion** Data demonstrate that an official soccer match of male professional players induces a hormonal catabolic environment during the recovery period. Also, increased levels of oxidative stress and muscle damage throughout 48-h of the recovery period were observed (Fatouros et al., 2010; Magalhães et al., 2010; Rampinini et al., 2011). Although match induced certain biochemical alterations, data from the present study suggest that professional players present small performance impairments and biochemical responses than those described in semi-professional players after a soccer official match (72-h; Magalhães et al., 2011; Fatouros et al., 2010). **References** Fatouros IG, Chatziniakolaou A, Douroudos, II, Nikolaidis MG, Kyparos A, Margonis K, Michailidis Y, Vantarakis A, Taxildaris K, Katrabasas I, Mandalidis D, Kouretas D, Jamurtas AZ. #### BICYCLE COMMUTING AND PHYSICAL ACTIVITY LEVELS

Donaire-Gonzalez, D., Jerrett, M., Rodriguez, D., Cole-Hunter, T., de Nazelle, A., Mendez, M., Garcia-Aymerich, J., Basagaña, X., Curto, A., Nieuwenhuijsen, M.

*Center for Research in Environmental Epidemiology (CREAL)*

**Background:** Physical inactivity has emerged as a major public health problem The World Health Organization's recent assessments rank physical inactivity as the 10th leading cause of premature death globally. Active transportation such as bicycling has been proposed as a method to increase physical activity levels, reduce air and noise pollution, and therefore improve public health. As present, however, it is uncertain whether a transport mode shift to bicycling from other less active commuting modes will increase physical activity or only a replace other physical activity regularly performed by individuals. **Objective:** We sought to assess whether bicycle travelling duration creates a difference in individual level of physical activity as an addition or as a replacement to other physical activity. **Methods:** Given the low prevalence of cyclists in Barcelona, a case-control sampling scheme was used, in which adult cyclists and non-cyclists (car drivers, motor drivers and public transport users) were recruited in the street, at forty random points in the city. The questionnaire, answered by participants, includes physical activity from the international physical activity questionnaire short form, common use of bicycle and walk modes of transport, commuter travel behaviour, health condition and socio-demographic questions. **Statistical analyses** included: (i) multivariate linear regression analysis and (ii) multivariate non-linear regression analysis. **Results:** Participants ( $n = 752$ : 49% female; mean (standard deviation) age = 37 (10) years, body mass index = 24 (3)  $\text{kg}/\text{m}^2$ ). Fifty-six percent of participants ( $n = 422/752$ ) bicycle travelled within the previous reported week for a total duration of 3.1 (2.5) h/week. The main determinants of lower levels of physical activity were female gender, older age, higher number of children and lower social class, while the main confounder of the relationship between commute mode and physical activity level was vigorous activity level. Active travel (including bicycle commuting and walking) was found to result in positive statistically significant differences in physical activity level across participants ( $p < 0.05$ ) and represented 2.8, 0.9, 1.1 and 1.8 h/week of physical activity levels for bicycle commuters, private motorized (car and motorcycle) commuters and public transport commuters, respectively. There was no relation between bike travel duration and physical activity level for those with low ( $< 29$  min/week) or high ( $> 9.5$  h/week) bike use. In those with intermediate levels of bike use, bike travel duration was positively and significantly associated with physical activity duration. **Conclusions:** Bicycle commuters exhibited higher level of physical activity than users of other commute transport modes, which was attributable to, and increased with, bicycle travel duration. Physical activity from bicycle travelling did not replace the performance of other physical activity in this sample.

#### VALIDITY OF THREE COMMONLY USED ACTIVITY MONITORS FOR ESTIMATING SEDENTARY TIME IN SCHOOL CHILDREN

Staalesen, J., Vik, F.N., Berntsen, S.

*University of Agder, Norway*

**Introduction** Sedentary behaviors, defined as sitting and lying down and activities of low levels of energy expenditure, is gaining more attention regarding health aspects, especially in western societies. It is important to focus on the health aspect and prevention of extensive sedentary behaviors in children. The major challenge today is to find a cost-affordable way to measure sedentary behavior in which both are applicable and valid so that it is possible to get an overview of the behavior and extent. The aim of the present study was to compare and assess the validity of the three monitors, ActivPAL™ (PAL Technologies Ltd., Glasgow, UK), ActiGraph GT3X+ (GT3X+;

Pensacola, FL, USA) and Sensewear Armband Pro3 (SWA; Bodymedia, Pittsburgh, PA, USA), used for estimating sedentary behavioral time (SB), compared to indirect calorimetry. Method Thirty-five boys and 32 girls (10-12 years) wore the GT3X+, SWA and ActivPAL when performing 6 different activities: 3 play-exercises and 3 screen-based activities (6 min each, 36 min in total). A sub-sample also wore a portable oxygen analyzer (MetaMax II or MetaMax 3B, Cortex Biophysic, Leipzig, Germany). Exercises 1: Ball-toss, standing, 2: Ball-toss, sitting, 3: "Musical chairs" (walking in circles around chairs using a whistle as signal), 4: TV viewing, 5: Playing videogames when sitting, and 6: Playing videogames standing with movement-based games (Playstation Move™). Counts per minute (CPM) <100 were used for GT3X+ to define SB. For ActivPAL sitting posture was defined as SB. The VO<sub>2</sub> data from the portable oxygen analyzers were calculated and categorized accordingly into categories of sedentary time (>1.50 times Basal metabolic rate BMR). BMR were found using predicted BMR for children (WHO/FAO/UNU 1985). Results During standing and walking activities indirect calorimetry calculated 0 minutes of sedentary time while ActivPAL estimated 47%, GT3X+ estimated 14%, and SWA estimated 2% sitting time in this period. During sitting activities we found, using indirect calorimetry, that 10% was sedentary time, while SWA estimated sedentary time to be 46% of the time, GT3X+ estimated 52% and ActivPAL estimated 60% sedentary time. Compared to only each other, during walking activities SWA estimated sedentary time 3% of the time, GT3X+ estimated 9% and ActivPAL estimated 78% sedentary time. Discussion Compared to indirect calorimetry, and compared to SWA and GT3X+, ActivPAL seems to overestimate sedentary time and may not be accurate when assessing sedentary behaviors. SWA can be recommended in estimating sedentary time in walking and standing activities, but may not be accurate when assessing sedentary time in sitting activities or activities that include extensive arm-movements. The GT3X+ may be a more cost-affordable way to measure sedentary time, but it does not appear to be as accurate as SWA.

### THE CONTRIBUTION OF YOUTH SPORT TOWARDS WEEKEND AND WEEKLY PHYSICAL ACTIVITY AND RELATIONSHIPS WITH INDICATORS OF ADIPOSITY AND CARDIOVASCULAR RISK

Fenton, S., Duda, J.L., Barrett, T.G.

*University of Birmingham*

Introduction As indicated via heightened BMI and body fat % (BF%) values and due to associated cardiovascular risk (e.g., waist circumference, WC), attention is being paid to the increasing incidence of childhood overweight and obesity. Participation in Organised Youth Sport (OYS) contributes around 23% towards daily weekday moderate to vigorous physical activity (MVPA) and has been advocated as a vehicle for obesity treatment and prevention in young people. The weekend offers greater opportunity for engagement in OYS and therefore MVPA and vigorous physical activity (VPA). Thus, the contribution of OYS towards daily physical activity (PA) and its utility as a tool for obesity prevention/treatment might have been previously underestimated. Aims 1) Determine the contribution of weekend OYS towards total weekend and weekly levels of MVPA and VPA. 2) Identify whether a) MVPA and VPA from OYS, b) Average weekend (AW) MVPA and VPA, and c) Average daily (AD = weekend + weekday) MVPA and VPA predict BMI, BF% and WC in OYS participants. Methods Anthropometric and PA data were collected from 164, OYS participants (Female, N = 47; Male, N = 117). Participants wore a GT3X accelerometer for 7 days and measures of height (SECA), weight, BF% (Tanita, SC331S) and WC were taken. Weekend OYS data was available from a sub-sample of 90 male grassroots football participants. Results OYS (min/day) were MVPA, M = 39.62 ± 17.26 and VPA, M = 21.13 ± 11.86. OYS contributed on average 49.59% and 60.54% towards total weekend MVPA and VPA respectively. For total weekly activity, the contribution was less (M = 15.84% (MVPA) and M = 23.29% (VPA)). Hierarchical linear regression demonstrated weekend OYS MVPA and VPA (min/day) did not predict BMI, BF% or WC. Both AW and AD MVPA and VPA (min/day) significantly and negatively predicted BMI (AW = MVPA,  $\beta = -.18$ , VPA,  $\beta = -.22$ ; AD = MVPA,  $\beta = -.21$ , VPA,  $\beta = -.27$ ) and BF% (AW = MVPA,  $\beta = -.20$ , VPA,  $\beta = -.24$ ; AD = MVPA,  $\beta = -.25$ , VPA,  $\beta = -.28$ ). Only AD VPA significantly and negatively predicted WC ( $\beta = -.18$ ). Conclusion Participation in OYS makes a substantial contribution towards weekend and weekly levels of MVPA and VPA. Whilst PA from OYS did not predict indicators of adiposity, weekend and daily MVPA and VPA were negatively related to BMI and BF%. Daily VPA was also negatively associated with a cardiovascular risk factor (WC). Results point towards OYS being a vehicle through which we can increase levels of MVPA and VPA to levels required to maintain a healthy body composition in youth. In addition, relationships were stronger for VPA than MVPA. Given that OYS appears to make a greater contribution towards VPA than MVPA, OYS may serve as an important source of VPA and thus contribute to associated health benefits.

### INFLUENCE OF 30-HOURS OF EXERCISE AND SLEEP DEPRIVATION ON LACTATE METABOLISM DURING GRADED TEST TO EXHAUSTION

Ziemba, A.1, Mikulski, T.1, Dabrowski, J.1, Kozacz, A.1, Bogdan, A.2

*1 Mossakowski Medical Research Centre PAS, Warsaw, Poland. 2 Central Institute for Labour Protection – National Research Institute, Warsaw, Poland.*

Introduction Popularity of ultra-endurance events is increasing. Although the exercise intensity is moderate during most of the event it often ends with a sprint finish. Thus, the aim of the present study was to evaluate the lactate metabolism during graded maximal effort performed by subjects submitted to prolonged exercise combined with complete sleep deprivation beforehand. Methods Graded maximal test (50 W every 3 min) to volitional exhaustion was performed on cycloergometer by 11 endurance trained men before (trial B) and immediately after (trial A) 30 hours of prolonged exercise (simulated adventure race) combined with complete sleep deprivation. Heart rate (HR), oxygen consumption (VO<sub>2</sub>), carbon dioxide secretion (VCO<sub>2</sub>) were recorded continuously and blood lactate (LA) concentration was measured at the end of each completed workload. Lactate threshold (LAT) was calculated according to the log-log transformation method. Results Subjects completed exercise test at the similar workload in both trials B and A (336±12 W vs. 331±14 W, respectively) and VO<sub>2</sub>max (58±3 ml/kg/min vs. 52±3 ml/kg/min). Both maximal HR and LA were significantly lower in trial A than B (179.5±4.0 bpm vs. 184.5±3.2 bpm, p<0.05 and 5.8±0.6 mmol/l vs. 8.6±0.7 mmol/l, p<0.01). Lactate concentration at LAT was also significantly lower in trial A than B (1.5±0.1 mmol/l vs. 1.9±0.1 mmol/l, p<0.05), whereas workload corresponding to LAT was similar 182±8 W and 191±8 W). Discussion Prolonged physical activity promotes mobilization of fat energy substrates from adipose tissue and increases its contribution in energy metabolism during exercise. On the other hand, carbohydrate stores are decreased, what altogether limits the availability of substrates for lactate formation during anaerobic exercise but did not limit performance. Additionally, lactate utilization for gluconeogenesis is enhanced by prolonged exercise.

**INFLUENCE OF REGULAR BREATH-HOLDS ON HEART RATE AND ARYTHMIA IN ELITE BREATH-HOLD DIVERS.**

Narycheva, I.I, Chomahidze, P.I, Achkasov, E.I

*1: MSMU (Moscow, Russia).*

Introduction In breath-hold divers cardiac arrhythmias have been reported during deep breath hold dives (Muth et al. 2005) and in static apnea (Lemaître et al. 2005). Prolonged breath-holding may trigger abnormal automaticity, mechanical–electrical feedback mechanisms (Lin 1984) and re-entry signaling. Aim of the present study was to investigate cardiac status in elite breath-hold divers with long-term training experience. Methods Thirty volunteers: 15 healthy untrained males (C-group) and 15 male breath-hold divers (D-group) from 27 to 32 years ( $32.4 \pm 2.1$  years) participated in the study. The mean height of the subjects was (C-group  $181 \pm 1.9$  cm, D-group  $179.9 \pm 2.6$  cm), and the mean weight was (C-group  $76.8 \pm 3.7$  kg, D-group  $72.7 \pm 1.6$  kg). Training experience in D-group was from 2.5 to 7 years ( $3.6 \pm 0.6$  years). Athletes trained at least three times a week, duration of training was not less than 1.5 hours. Trainings included static and dynamic breath-holds. The study was carried out during competitive season. The measurement was carried out at least 48 hours later after the last training. Holter monitoring of ECG was conducted during 24 hours (SCHILLER MT-200 Halter-ECG V 2.51, Switzerland). ECG was evaluated for heart rate, cardiac arrhythmias, cardiac conduction, dynamics of the T wave and segment ST were evaluated. Results The mean heart rate was: C-group  $58 \pm 3.7$  beats/min, D-group  $66.1 \pm 3.2$  beats/min. Minimum heart rate was: C-group  $50 \pm 3.3$  beats/min, D-group  $41.6 \pm 2.1$  beats/min and the maximum heart rate C-group  $118 \pm 9.6$  beats/min, D-group  $126.4 \pm 7.3$  beats/min. The main difference between the groups was the presence of cardiac changes in D-group (in 6 of 15). Isolates supraventricular arrhythmias and couplets were found in three cases (27%), AV-blocks in three cases (20%) and both were found in one case (7%). AV blocks were registered only in highly trained athletes, members of Russian freediving team. None of those changes were observed in C-group. Discussion Highly trained breath-hold divers may be exposed to higher risk of AV blocks than general population. The changes found in cardiac status may be associated with changes of metabolism due to regular breath-holds. References 1. **16:20 – 17:50****Invited symposia****IS-BN09 Biomechanics in disability sport: Challenges and solutions \*****MODELING AND OPTIMAL CONTROL OF DOUBLE AMPUTEE RUNNING**

Mombaur, K.

*University of Heidelberg*

Introduction Running motions of double transtibial amputees on special carbon fiber running prostheses, such as the Össur Cheetah, can lead to remarkable performance, as Oscar Pistorius has demonstrated in recent years. This has raised the question if the springy running prostheses which are lighter than lower legs and produce high passive torques might provide an advantage over able-bodied sprinters [2], and what the ethical consequences of admitting such devices are [3]. The goal of our research is to address this question using mathematical models and optimal control techniques to better understand the underlying mechanics and control of sprinting on prostheses. Methods We perform numerical optimal control computations based on dynamic models of the sprinters. We have established rigid multibody system models with 9 segments and 11 degrees of freedom for able bodied as well as double amputee sprinters in the sagittal plane. In the able bodied case, there are torque actuators in all 8 internal joints; in the double amputee case, the actuators at the ankles are replaced by linear spring damper elements, but the other 6 actuators remain. Running motions for these models are generated by solving hybrid multiphase optimal control problems with periodicity constraints, using a direct multiple shooting approach. Results In a first study we have generated optimal running motions for an imposed average speed of 9 m/s minimizing weighted joint torques squared for both models (able bodied as well as double amputee), thus selecting the most efficient out of many redundant motions. It could be shown that indeed the double amputee running motions require much less effort than the able-bodied motions in terms of different measures linked to mechanical work and joint torques. It could also be shown that the double amputee model exhibits a different type of running motion with a reduced knee flexion, compensated by a significant compression of the ankle spring [1]. Discussion From the above results it can NOT yet be concluded that prostheses provide an unfair advantage due to various reasons: - efficiency is not the only criterion for superiority in sprinting; also other criteria such as max. power have to be considered - in addition to constant speed running, also acceleration and deceleration phases would have to be taken into account - the models should include more details, e.g. the reduced strength of joints next to the amputation, or the coupling between leg and prosthesis. More computations in this sense are currently performed. References 1. K. Mombaur: A mathematical study of Sprinting on Artificial Legs, acc. for Proc. of HPSC 2012, LNSC, Springer 2. G.-P. **PROSTHESES FOR RECREATIONAL AND ELITE SPORTS: BIOMECHANICAL REQUIREMENTS AND TECHNICAL FULFILMENTS**

Brüggemann, G.

*German Sport University Cologne*

In the past the focus of technical improvements of artificial limbs was on performance enhancement mainly in running or sprinting. Little attention was given to technical aids and devices for recreational sports and other activities than straight running. A more comprehensive

understanding of the biomechanics and the energetic contribution under different prosthetic conditions and in different sports activities is essential for the development of technical aids and protection devices. In running of double amputees the role of artificial limbs has been intensively analyzed and revealed evident mechanical differences between double transtibial amputee sprinting and sprinting of able-bodied athletes. The energy contribution to the joints of the lower extremities in the symmetric runners is inverted in single amputee runners. When running at about 7 m/s the sound ankle does about two to three times more mechanical work than the sound knee or the sound hip joint. (Buckley, 2000). These biomechanical differences will lead to different requirements of the prostheses. Unilateral and bilateral transtibial or transfemoral amputees especially in recreational sports will not reduce their activities to straight running. Posture control and body balance in standing, walking, running and hiking, cutting or even pivoting maneuvers increase the requirement of sport prostheses. The technical requirements can be directly derived from the biomechanical demands of these activities. However, a critical review of recent technical fulfillments finds mainly solutions for straight running and related track and field disciplines. The most recent technical solutions allow a differentiation of beginners and advanced athletes through modification of the alignment of the knee rotation axis or the anterior-posterior placement of the prosthetic foot to the artificial knee. Different stiffness of the foot gives the opportunity to adapt the prosthesis to different body weights and different biomechanical requirements of running or jumping at different intensity. Recent swing phase control mechanisms are focused on running and gives free knee movement up to 60° knee flexion and a progressive hydraulic deceleration to a maximum flexion angle of 135°. The prosthetic feet or carbon blades are equipped with running surface related outer soles or even spikes. In summary the technical fulfillments of lower leg prostheses for recreational and elite sports partly meet the biomechanical requirement but have a great potential of further enhancement allowing the amputee to participate in sports and physical activity. ## BIOMECHANICS OF SPRINTING ON NATURAL LIMBS AND SPRINTING ON ONE OR TWO PROSTHESES

Potthast, W.

*German Sport University Cologne*

The role of artificial limbs in running biomechanics has been intensively discussed (Bruggemann et al., 2008; Weyand et al., 2009). The movement analysis of the double amputee Oscar Pistorius revealed evident mechanical differences between double transtibial amputee sprinting and sprinting of able-bodied athletes (Bruggemann et al., 2008; Weyand et al., 2009). In double amputee sprinting the loading of the lower extremity and the energetic contributions of the joints of the lower extremity show entirely different distributions. In the limb with prosthetic supply about 80-90% of the mechanical work is done in the artificial ankle (prosthesis). Knee and hip joints contribute hardly. In the sound athletes the energetic contribution of ankle, knee and hip joint is much more evenly distributed. However, this relationship of energy contribution in the symmetric runners (double amputee & sound athlete) is inverted in single amputee runners (asymmetric): When running at about 7 m/s the sound ankle does about two to three times more mechanical work than the sound knee or the sound hip joint. At the prosthetic side about 80% of the mechanical work is done at the hip joint while knee and (artificial) ankle contribute less (Buckley, 2000). A more comprehensive understanding of the energetic contribution under different prosthetic condition is essential for the adjustment for rules and regulations as well as for the development of technical aids and protection devices. #### USING THE ACTIVE WORKSTATION: CAN WE BE ACTIVE AT WORK AND STILL BE PRODUCTIVE?

Walsh, M., Funk, R., Ohlinger, C., Cox, R.

*Miami University*

**INTRODUCTION:** Integrating low-intensity physical activity into work environments by using the active workstation (treadmill with desk attached), could provide health benefits to many adults. Although use of the active workstation may increase health benefits, concerns have been raised about the ability to walk and perform tasks simultaneously. **PURPOSE:** To assess the effects of walking and typing practice on rectifying typing speed (WPM) decrements and improving walking mechanics. **METHOD:** Nineteen adults aged 43± 11, who could type at least 50 adjusted words per minute (AWPM) participated. All subjects completed a typing test while seated and while walking at 1.6 km/h. Subjects were randomly assigned to a massed practice session (3 consecutive 15 min blocks) or to distributed practice (daily sessions of 15 min each). During the pre and posttests, reflective markers were fixed placed to the right ankle, knee and hip and subjects were filmed while walking and walking and typing. Walking mechanics were assessed through a digitized analysis of this film. A series of 2 X 2 (Practice Condition by Time) Mixed Model ANOVAs with repeated measures on the second factor were conducted to assess the effects of the two practice conditions on subjects' typing performance and gait parameters. Paired samples t-tests were performed to compare postural conditions. **RESULTS:** A significant difference in participants' typing performance (WPM), was found between baseline sitting (67±9.5) and walking measurements (57±8.3)  $p < .00$ , as well as, significant changes in knee height between walking and walking & typing,  $p < .03$ ; and stride length between walking and walking & typing,  $p < .00$ . There was no significant improvement in typing performance in the massed practice group, but a significant improvement in the distributed practice group ( $p < .00$ ), while both groups exhibited significant increases in stride length. The initial result of walking while typing elicited a negative effect on typing performance and changed the gait pattern of the user, yet with distributed practice these variables reverted to baseline measure-

ments. CONCLUSION: Distributed practice was effective in the recovery of typing speed and may be associated with a return of normal walking mechanics.

### PHYSICAL FITNESS AND HEART RATE VARIABILITY IN PEOPLE WITH SCHIZOPHRENIA

Blasco-Lafarga, C.1, Tortosa-Marfínez, J.2, Caus Pertegaz, N.2, Marfínez-Navarro, I.1

*University of Valencia, Spain*

INTRODUCTION: People with schizophrenia have a reduced life-expectancy of 10 to 20 years, with cardiovascular diseases being responsible for two thirds of deaths (Brown et al. 2000). Cardiac autonomic dysfunction has been observed in schizophrenics being a major cause of cardiac events (Henry et al. 2010), but Physical Activity (PA) has been proved to promote autonomic nervous system integrity increasing Heart Rate Variability (HRV) in many clinical populations (Routledge et al, 2010). Since this remains to be elucidated in schizophrenics, the study aims to examine the relationship between physical fitness and HRV in schizophrenia. METHODS: 54 hospitalized patients diagnosed with schizophrenia (DSM-IV criteria) were recruited from a public mental health institution, Spain. Participants were assessed for HR dynamics and the Six-Minute Walk Test (6MWT). RR intervals were continuously recorded during 10 min with a Polar RS800 HR tachometer (Polar Electro, Oy, Finland), with subjects lying on bed, on fasting conditions. 5 min central data were analyzed by means of Kubios HRV 2.0 software, considering linear and non linear HRV analyses. RESULTS: Significant positive correlations were found between the 6MWT and DFA1 ( $p<0.05$ ); and SD2( $p<0.05$ ). A negative correlation was found for the SD1/SD2 ratio ( $p<0.01$ ). After controlling for confounding variables (RRi, age, illness duration, gender, nicotine intake, and Body Mass Index), the significance and the power of the correlation increased for SD2 and DFA1, and remained stable for SD1/SD2 ratio. DISCUSSION: Our results suggest that people with schizophrenia who can walk further distances in the 6MWT have better cardiovascular health as measured by non linear HRV indices, thus suggesting that non-linear methods could be more appropriate for controlling the effects of PA on HRV. However, longer periods must be registered since the time-series in the study is not long enough to ensure adequate confidence in SD2 (Rakobowchuk et al. 2012). There is a need for randomized controlled trials to better understand the effects of PA programs in HRV in schizophrenics. REFERENCES: Brown S, Inskip H, Barraclough B (2000). ### PSYCHO-PHYSIOLOGICAL RESPONSES TO A STANDARDIZED EXERCISE PROGRAM INDOORS VS. NATURAL ENVIRONMENT: PRELIMINARY RESULTS FROM A PILOT STUDY. PART IV: CORTISOL PROFILE

Mikkila, S.1, Calogiuri, G.2, Weydahl, A.1, Patil, G.2

*1: Finnmark University College, Alta, Norway, 2: Norwegian University of Life Science, Aas, Norway*

Introduction Previous studies indicate that exposure to nature elicits faster recovery from psycho-physiological stress. It has been suggested that 'green exercise' may elicit wellbeing and enhanced health beyond exercising elsewhere, but its evidence of indicators of physical health is still scarce (Thompson Coon et al. 2011). Assessment of cortisol release has been used to investigate stress-related disorders. This assessment, however, presents challenges due to the circadian fluctuation of the cortisol. Lower cortisol concentration and a rapid reduction of the cortisol levels after awakening are considered as indicators of a healthy allostatic load status (Golden, Wand, Malhotra, Kamel, & Horton 2011). As a pilot study, we have studied the impact of standardized exercise program indoors (gym hall) vs. outdoors in a natural setting on the cortisol release. Methods Healthy adults, 7 females and 7 males (age 48.5+/-7.3 years; BMI 25.4+/-2.4; VO2 39.8+/-7.7 ml/min/kg), undertook two exercise sessions within 1-week, each consisting in 25-min biking (60.1+/-7.9 %HRR) followed by 20-min of circuit-strength training with rubber bands (49.7+/-9.6 %HRR). The subjects exercised at 15:30, randomized to the indoor or the outdoor exercise group. Cortisol was measured in baseline conditions (no exercise for at least 48-hours) and after each exercise session. Sample collection included 15-hour urine collection (18:00-09:00), a blood test (08:00), a 7-time point saliva collection determining PRE/POST-exercise values, POST-exercise recovery, amplitude of rhythm (AMP) and the cortisol awakening response (CAR) slope. Results When adjusted for individuals' baseline values, only a marginally significant difference across groups was found for the overnight urinary levels ( $p=0.057$ ), with more extensive reduction for the outdoor group compared to the indoor group. Moreover, the CAR showed improved profiles for the outdoor group ( $p=0.037$ ). No significant difference across groups was found for PRE/POST-exercise, POST-exercise recovery, AMP or serum morning values. Discussion These results provide further support for the positive effects on stress responses after exercising in natural environment, which may in the long term have a positive impact on health. The data also shows the importance of considering the cortisol release in its circadian complexity, rather than adopting simple measurements such as the PRE/POST changes or the morning serum release. ### WALK@WORKSPAIN: EFFECTIVENESS ON INCREASING PHYSICAL ACTIVITY LEVELS IN OFFICE EMPLOYEES.

Bort-Roig, J.1, Puig-Ribera, A.1, González-Suárez, A.M.2, Martínez-Lemos, I.3, Giné-Garriga, M.4, Fortuño, J.4, Gilson, N.D.5

*1. Universitat de Vic, 2. Universidad del País Vasco, 3. Universidad de Vigo, 4. Universitat Ramon Llull-Blanquerna, (Spain) 5. The University of Queensland (Australia)*

Introduction: Physical inactivity is the fourth leading risk factor for global mortality (WHO, 2010). However, 50% of the Spanish population does not achieve physical activity (PA) recommendations for health. As most adults spend half of their waking day at work (Tudor-Locke et al., 2011), the workplace has become a convenient setting for delivering PA promotion interventions. This study investigated the impact of a web-based "sit less and move more at work" program had on employee's PA levels. Methods: Office employees from four Spanish universities engaged in the program over 19 weeks ( $n=264$ ; age  $42\pm 10$  years; 171 women). The intervention group (IG,  $n=129$ ) used a pedometer, a diary and a website which provided strategies, motivational materials and interactive features to increase step counts and reduce sitting time at work. Following baseline measures, the intervention consisted of a (i) ramping phase to progressively increase baseline step counts to 10,000 by integrating active working tasks, short and long walking routes at work, (ii) a maintenance phase to sustain the increased volume of step counts through researcher support. An additional campus in each university acted as a control

group (CG, n=135). Employees completed a PA questionnaire (IPAQ short version) at baseline, post-intervention, and two months follow-up. PA status changes (MET-h-wk-1) were analysed using ANOVA between and within groups. Results: The IG significantly increased PA levels at post-intervention (+205MET-h-wk-1;  $p < .05$ ), and two months follow-up (+590MET-h-wk-1;  $p < .05$ ). No statistically significant differences between groups were observed. When data from the IG were analysed relative to baseline activity status, inactive employees (n=17, 13%; <600MET-h-wk-1) increased PA levels the most at post-intervention(+1,330MET-h-wk-1;  $p < .05$ ) and follow-up (+1,366MET-h-wk-1;  $p < .001$ ). Active employees (n=70, 54%; 600-3,000 MET-h-wk-1) also showed significant increases at post-intervention (+991MET-h-wk-1;  $p < .001$ ) and at follow up (+1,237MET-h-wk-1;  $p < .001$ ), whereas highly active employees (n=42, 32%; >3,000MET-h-wk-1) decreased their PA levels (-809MET-h-wk-1;  $p > .05$ ). Discussion: Office employees that engaged the program increased their overall PA levels. Increases were most evident for the least active. Walk@WorkSpain may be effective to achieve PA recommendations for health in Spanish population. References: World Health Organization. (2010). Tudor-Locke C, Leonardi C, Johnson WD, Katzmarzyk PT. ## RUNNING OUT OF TIME? STRATEGIES AND PERCEPTIONS IN CONNECTION TO PHYSICAL ACTIVITY

Book, K.

*Malmö University*

RUNNING OUT OF TIME? STRATEGIES AND PERCEPTIONS IN CONNECTION TO PHYSICAL ACTIVITY Introduction Although most people are aware of the health benefits of physical activity, it is not easy to fit it into the busy schedule of everyday life. The knowledge about how adults in the middle of their careers reason about physical activity and develop strategies to be active is surprisingly limited. Therefore, this study aims at increasing the knowledge by answering the following research questions: How, when and where do employed people (in Sweden), age 30-50, find time and space for physical activities? How do these people reason about physical activity and time in everyday life? At an early stage of the study, running stood out as a popular activity among the target population: How could the running trend be explained? Theoretical Departures and Methods The theoretical framework of the project concerns perspectives on time use and perception and strategies for physical activity (see for instance Robinson & Godbey, 2000; Zuzanek, 2004). Physical activity refers to the whole scale from light to intense activities. Methods for gathering empirical material: 550 surveys at three major work places in Malmö, interviews with gym owners regarding training trends, field studies and in-depth interviews with six persons within the target population. Finally, the running trend has been problematized. Results - The majority of full-time employees within knowledge-based sectors has an ambition to be physically active (and a majority is). A high preoccupation with the importance of exercising also results in feelings of pressure and guilt. - Difficulties in finding time for physical activity make individuals develop different strategies to cope with physical activity, such as: preferences for time-efficient and flexible activities, using lunch breaks for gym-session or for walks, exercising early mornings on the way to work, active transports, creating challenges in order to push themselves, etc. - Flexible work hours are considered favourable for being physically active, but also stressful as leisure and work time blend together. - Organizational rather than economic incentives for training by the employer are preferred. - The running trend could be understood in different ways: running as a flexible, accessible and efficient activity, as back to basics, a lifestyle, as pressure and inspiration from social media, as a demand for being challenged, as part of commodification and a product of the event industry, etc. References Robinson, J. & Godbey, G. #### SHORT-TERM KINEMATIC ADAPTATION TO UNANTICIPATED SPRINT RUNNING CONDITIONS IN FIELD SPORT

Wdowski, M.M.1, Gittoes, M.J.R.1, Irwin, G.1, Nokes, L.2

*Cardiff Metropolitan University.1. & Cardiff University.2.*

SHORT-TERM KINEMATIC ADAPTATION TO UNANTICIPATED SPRINT RUNNING CONDITIONS IN FIELD SPORT Wdowski, MM.1, Gittoes, MJR.1, Irwin, G.1, & Nokes, L.2. 1: Cardiff Metropolitan University, Cardiff, UK 2: Cardiff University, Cardiff, UK. Introduction An important characteristic of skilled behaviour in unanticipated conditions, such as sprinting in field sports, concerns the functional relationship between adaptive movement variability and performance outcome. The process of improving a skilled behaviour involves developing a stable performance under different conditions with a consistent performance reflecting mastery in a given task (Preatoni et al., 2012). The aim of this study was to extend insight into lower limb kinematic adaptation to unanticipated sprint running conditions in field sport. Methods An automatic marker tracking system (200 Hz) was used to track three-dimensional, bilaterally (lower limb) located active markers during the initial 20 m of sprint run acceleration trials performed by twenty university footballers. The performers were made aware of the final sprint distance prior to initiating the sprint in the anticipated 20 m (A20) condition. In the unanticipated 20 m (U20) and 40 m (U40) conditions, the performers were informed of the final sprint distance immediately after initiating the sprint. The groups mean step velocity was determined as the primary performance measure with its mechanical step determinants e.g. step frequency, being the kinematic measures of adaptation. Results No difference in performance outcome or individual variability of performance outcome between conditions was observed (mean step velocity m.s<sup>-1</sup>; A20: 6.71±0.20; U20: 6.69±0.19; U40: 6.71±0.20). Determinants of step velocity and their variability were significantly different ( $p < .05$ ) between conditions (e.g. mean step frequency Hz; U20: 4.34±0.24; U40: 4.37±0.24). Discussion A stable performance outcome was maintained by the performers between all conditions, which suggested mastery in carrying out the specific task (Preatoni et al., 2012). The combination of a maintained step velocity and adapted determinants are in direct contrast to Hunter et al.'s (2004) mechanical model of sprinting, which may be an example of kinematic adaptations that are specific to the task (Wdowski & Gittoes, 2012). Differences observed in step determinant variability between conditions may allude to the functionality of movement variability in adapting to variable external conditions (Bartlett et al. 2007). Anticipated sprint protocols may subsequently not entirely facilitate skill specific adaptations for unanticipated field sport match conditions. References Bartlett R, Wheat J, Robins M. ### EFFECTS OF RESISTED SLED TOWING ON ACCELERATION SPRINT KINEMATICS IN SPRINTERS

Alcaraz, P.E.1, Jiménez-García, A.3, Elvira, J.L.L.4, García-Roca, J.A.1, Cánovas, J.F., Angulo, R.3

1: UCAM (Murcia, Spain), 2: UCLM (Toledo, Spain), 3: INEFC (Barcelona, Spain), 4: UMH (Elche, Spain)

**Introduction** Sled-towing exercise is a common method to improve power output in sprinting. Usually, many coaches set the weight of the sled to a percentage of athlete's body mass (Bm), but resisted sprint training has shown changes on sprint kinematics depending of the load used (1, 2). In this sense, the aim of this study was to define the effects of increasing of load on the sprint kinematics in national level sprinters. **Methods** Eleven active competitive athletes specialized in sprinting with previously sled-towing training experience (9 men and 2 women) were recruited to the study ( $18.8 \pm 3.3$  years;  $1.84 \pm 0.08$  m;  $72.0 \pm 13.1$  Kg). Subjects performed four 20-m sprints (unloaded, 10, 15 and 20% of Bm) from a crouched start. The athletes were placed 1-m behind the starting line and trials' order was randomized for each participant, and an unlimited rest period was given between trials. Sprint trials were performed using a weighed sled attached to each athlete by a 3.6-m cord and waist harness. Sprint trials were recorded with a digital video camera operating at 210 Hz. The camera's placement was at 90° angle to the direction of the sprinting, a distance of 20 m from the middle of the athlete's lane and it was mounted on a rigid tripod. Kwon3D biomechanical analysis software was used to analyse the video images of the trials. Twenty-two body landmarks that defined a 14-segment model of the athlete were digitized. The kinematic variables were measured at the instant of touchdown and take-off. To the analysis of stride length (SL), stride frequency (SF), and ground contact time (GCT) were considered at first, second and third step. One-way ANOVA with Tukey's post hoc was used to compare the four running conditions. Results SL decreased significantly with 20% Bm, while changes in GCT and SF were not relevant when sled weight increased. Minor changes in joint and segment angles were observed in lower limbs and trunk. There were no significant changes in angular velocities, neither hip nor knee during ground contact or take-off phase. COM velocity decreased significantly in ground contact and take-off phase with 20% Bm, while only COM velocity in stance phase changed significantly with 15% Bm. Body lean only changed significantly in take-off phase in all resisted conditions, while no effect was observed in ground contact phase. **Discussion** The aim of the present study was to show the effects on the athletes' sprint kinematics in order to set the load in an attempt to avoid negative changes on sprint technique. The results suggest that several important kinematic variables might appear when loads above to 15% Bm were used in the first steps of the acceleration phase in national sprinters. Therefore, caution must be used when sprinters use high loads resisted sprint training. **References** 1. Alcaraz et al. (2008) J Strength Cond Res 22,890-7 2. Cronin et al. ### STANCE LIMB KINEMATIC VARIABILITY IN MAXIMUM VELOCITY PHASE SPRINT RUNNING

Gittoes, M.J.R.1, Bezodis, I.N.1, Exell, T.A.2

1: Cardiff Metropolitan University, 2: University of Southampton

**Introduction** The stance leg action has been considered a major determining factor of sprint running performance (Hunter et al., 2004). Individuals may self-organise and vary their movement pattern (kinematics) to facilitate an optimal solution in athletic performance. A recent preference for individual athlete analyses (Salo et al., 2011; Exell et al., 2012) may be warranted to facilitate knowledge of the self-organising processes used to develop sprint running performance. The aim of this study was to enhance insight into the stance limb kinematic contributions to maximum velocity phase sprint running performance using individual athlete variability analyses. **Methods** Sagittal plane, joint centre coordinate data of the stance limb were obtained from automatic marker tracking (200 Hz) of maximum velocity phase sprint running trials performed by six well-trained athletes. Step velocities were subsequently derived and used to rank order the performance of individual athletes. The coefficients of variation (CV%) of stance limb joint (ankle, knee and hip) angular kinematic parameters were also derived for individual athletes. Results The most highly ranked athlete (mean step velocity:  $8.84 \pm 0.25$  m.s<sup>-1</sup>) produced a larger CV% in the knee joint configurations (e.g. touchdown: 1.9%, peak flexion: 2.3%) than their slowest (mean step velocity:  $7.87 \pm 0.13$  m.s<sup>-1</sup>) counterpart (e.g. touchdown: 0.9%, peak flexion: 0.8%). Higher ranking athletes typically demonstrated a larger CV% in the peak hip joint angular velocity (fastest athlete: 7.6%) when compared to slower athletes (slowest athlete: 4.2%). **Discussion** A larger CV% in the knee joint angular displacements and peak hip extensor angular velocity of the highly ranked athletes indicated greater kinematic variability in the respective joints than the slower athletes. Inconsistency in the joint actions of elite athletes across multiple sprint runs has been considered reflective of a compensatory joint function (Bezodis et al., 2008). The extent to which knee and hip joint stance kinematics are perturbed may indicate an individual athlete's ability to self-organise kinematic responses to achieve superior sprint performances. **References** Bezodis, I.N., Kerwin, D.G, Salo, A.I.T. ### EFFECT OF MASAI BAREFOOT TECHNOLOGY SHOES ON KNEE JOINT MOMENTS IN SUBJECTS WITH KNEE OSTEOARTHRITIS

Tateuchi, H., Taniguchi, M., Takagi, Y., Goto, Y., Otsuka, N., Kobayashi, M., Ichihashi, N.

Kyoto University

**Introduction** Footwear modifications have been investigated as conservative ways to manage osteoarthritis of the knee (Knee OA). Although mobility shoes and variable-stiffness shoes can reduce external knee moment, high-heeled shoes and stability shoes result in an increase in knee load while walking (Radzimski et al., 2012). The purpose of this study was to evaluate the effect of Masai barefoot technology (MBT) shoes on knee joint moments during walking in subjects with knee OA; these shoes are characterized by a rounded sole in the anterior-posterior direction with a soft pad underneath the rear foot. **Methods** This study was performed in 17 women diagnosed with knee OA (age,  $63.6 \pm 7.9$  years). The protocol was approved by the local Ethics Committee. Participants were asked to walk at 2 speeds, a self-selected speed and a slow speed with control shoes. The shoes widely used in rehabilitation facilities (Ayumi; Tokutake Sangyo Co., Ltd.) were used as control shoes. The control shoes were flexible with a flat sole. Participants were given instructions on how to walk properly while wearing MBT shoes and then were asked to practice walking for approximately 20 min. After subjects became accustomed to walking with MBT shoes, they were asked to walk at self-selected speed. Kinematic and kinetic measurements were recorded using a 7-camera Vicon motion system and 4 force plates. The following dependent measures were analysed: walking speed; stride length; peak of knee flexion moment in early stance (KFM1) and in late stance (KFM2), knee extension moment in mid-stance (KEM), knee

adduction moment in early stance (KAM1) and in late stance (KAM2); peak of knee adduction moment (KAMp); and impulse of knee adduction moment (KAMimp). Joint moments were expressed as external joint moments and were normalized according to body weight and height. Three successful trials for control shoes and 5 trials for MBT shoes were used for subsequent analysis. Paired t-test was used to compare gait variables while walking with the 2 shoes. If the self-selected speeds while wearing the control and MBT shoes were significantly different, the walking speed, from among the self-selected speed and slow speed, that was closest to the speed while wearing the MBT shoes was chosen for comparison of joint moments. Results The self-selected speeds while wearing the 2 shoes were significantly different. After the adjustment for walking speed, there was no significant difference in the walking speed and stride length. KAM1, KAM2, KAMp, and KAMimp did not differ statistically while wearing the 2 shoes. Meanwhile, KFM1 was significantly lower while wearing MBT shoes (control shoes:  $0.30 \pm 0.19$  Nm/kgm vs MBT shoes:  $0.25 \pm 0.14$  Nm/kgm). Discussion The results suggest that MBT shoes is effective especially for patients with knee OA coexisting with patellofemoral osteoarthritis because these patients are required to reduce overload due to knee flexion moment. ## HEIGHT OF THE COUNTERMOVEMENT JUMP – A PREDICTOR OF THE PEAK MECHANICAL POWER OUTPUT

Gajewski, J., Busko, K., Michalski, R., Mazur-Rozycka, J.

*Institute of Sport*

Introduction Countermovement jump (CMJ) is frequently used to assess jumping abilities of athletes. Many researchers demonstrated that jump height was related to peak power output at the take-off (Johnson and Bahamonde, 1996). Regression approach, used to assess peak power output usually involves jump height and body mass (Canavan and Vescovi, 2004). The aim of this study was to formulate non-linear prediction equation for the peak power taking into consideration also the countermovement depth. Methods One hundred young male sportsmen practicing various sports served as subjects in the study. Their mean ( $\pm$ SD) age, body mass and body height were  $16.8 \pm 1.9$  years,  $80.0 \pm 9.1$  kg and  $186.5 \pm 8.5$  cm, respectively. Every subject performed three CMJs on the force plate, the highest jump being taken for further analysis. The course of vertical displacement of the body mass center (take-off position adopted as zero) as well as power course were computed based on vertical ground reaction course. Body mass (m), height of jump (H) and countermovement depth (D; lowest position of the body mass center) were taken as possible peak power (PP) predictors. The variables were transformed to logarithms. A stepwise backward regression procedure was applied. Results The mean ( $\pm$ SD) peak power, jump height and countermovement depth were  $2641 \pm 620$  W,  $45.6 \pm 4.8$  cm and  $41.6 \pm 5.9$  cm, respectively. The multiple regression equation ( $R^2=0.897$ ) was retransformed to:  $PP=3.685 \cdot m^{0.974} \cdot H^{1.304} / D^{0.879}$ , where PP – peak power, H – height of jump, D – countermovement depth. Standard error of this prediction was 185 W (CV=7%). Since exponent value of body mass was nearly 1, the regression procedure was done also for the relative peak power ( $pp=PP/m$ ). The following equation was obtained:  $pp = 3.369 \cdot H^{1.455} / D^{0.883}$ . That prediction proved quite satisfactory ( $R^2=0.869$ ), its standard error amounting to 2.29 W/kg (CV=7%). Residuals from both predictions were not correlated either with body mass or body height. Discussion A relatively big sample size enabled concluding that peak power can be assessed accurately based on jump height, body mass and countermovement depth. If all subjects performed their jumps with the same countermovement depth (normalized technique), the jump height would exactly reflect the relative peak power. Thus, maximum jump height can be used as an indicator of subject's attainable peak power output. The peak power developed at single jump is affected by the technique applied and it cannot be treated as a trait. Acknowledgments The study was partly supported by Ministry of Science and Higher Education. References Johnson, DL, and Bahamonde, R. (1996). *J Strength Cond Res*, 10(3), 161-166. ## BIOMECHANICAL ANALYSIS OF LONG JUMP IN ATHLETES AMPUTEES

Padullés, J.M.1, Torralba, M.A.2, Olsson, H.2, López, J.L.3, Padullés, X.1, García, A.1, De Fuentes, M.L.2, Theodorou, A.4

1: INEFC, UB (Barcelona, Spain), 2: UB (Barcelona, Spain), 3: GREAF, UV (Vic, Spain), 4: UA (Athens, Greece)

Introduction The incorporation of disability sport in society requires a thorough knowledge of the techniques of each of the specialties. Using biomechanical tools allows to study and objectively assess the parameters that determine the performance improvement, facilitating their social inclusion. Methods Purpose: to analyze the running approach and duration of the take-off phase in the long jump F42-F44 men's final of the Paralympic Games London 2012. The results obtained were compared with the results of the able-bodied men's long jump final at the IAAF World Championships Berlin 2009 (Mendoza and Nixdorf, 2011). We have studied 11 male athletes participating in the categories F44 (6) and F42 (5), transtibial/transfemoral amputee. Data collection was performed using 4 high-speed cameras Casio Exilim F1 at a frequency of 300 Hz. The variables analyzed in the last three strides (3L, 2L, 1L) of the approach run were: Stride velocity, SV (m/s); Stride frequency, SF (Hz); Stride length, SL (m); Contact time, CT (s); Flight time, FT (s) and duration of the take-off (s). The image analysis was performed with Dartfish Pro Suite 2010 software. The statistical analysis of the data was performed using PASW V.18.0.0 software. Results 3 to last / 2 to last / 1 to last stride: F44: SV=  $8.38 \pm 0.52$  /  $8.56 \pm 0.71$  /  $10.12 \pm 0.24$ ; SF=  $4.54 \pm 0.53$  /  $4.07 \pm 0.45$  /  $5.40 \pm 0.23$ ; SL=  $1.86 \pm 0.13$  /  $2.10 \pm 0.12$  /  $1.88 \pm 0.04$ ; CT=  $0.106 \pm 0.01$  /  $0.107 \pm 0.01$  /  $0.104 \pm 0.01$ ; FT=  $0.117 \pm 0.02$  /  $0.141 \pm 0.02$  /  $0.081 \pm 0.01$ . F42: SV=  $7.78 \pm 0.95$  /  $7.45 \pm 0.80$  /  $8.88 \pm 0.96$ ; SF=  $4.52 \pm 0.96$  /  $3.70 \pm 0.82$  /  $5.04 \pm 0.76$ ; SL=  $1.75 \pm 0.16$  /  $2.07 \pm 0.36$  /  $1.79 \pm 0.27$ ; CT=  $0.113 \pm 0.03$  /  $0.119 \pm 0.02$  /  $0.115 \pm 0.01$ ; FT=  $0.116 \pm 0.03$  /  $0.161 \pm 0.04$  /  $0.087 \pm 0.03$ . Take-off duration: F44:  $0.123 \pm 0.01$ . F42:  $0.133 \pm 0.02$ . Discussion The F44 athletes can achieve further jumping distances ( $6.30$  m  $\pm 0.58$ ), than F42 ( $5.28$  m  $\pm 1.03$ ), and they recorded faster SV, SF and SL, and less CT, FT and duration of the take-off. For the London group, the average SV in the last three strides is 8.11, 8.05, 9.56 m/s respectively. This differs from results obtained in previous research with able-bodied athletes, where there is a loss of velocity in the last stride. Velocity at take-off is a key value both in the official jumping distance and the effective jumping distance. In the London group, a high correlation between take-off duration and both the official distance ( $r=0.797$ ,  $p=0.003$ ) and the effective distance ( $r=0.843$ ,  $p=0.001$ ) was found. Among 9 athletes within the London group that use prosthesis, 7 perform take-off with their prosthetic leg ( $6.03$  m  $\pm 0.91$ ) and 2 with the other leg ( $5.50$  m  $\pm 1.00$ ). ## IS-BN08 Biomechanics of sport equipment: Triad of performance, comfort and injury prevention \*

**METHODOLOGICAL CHALLENGES AND BEST PRACTICE EXAMPLES IN SPORTS TECHNOLOGY RESEARCH AND DEVELOPMENT**

Senner, V.

*TUM Technische Universität München*

Most sportsmen have probably made the same experience: among the multitude of sport equipment, apparel, footwear in use, there a few which seem to stand above all the rest: The soft shell, which always finds the way into the backpack, the running shoe we would like to use for ever, the beloved tennis- or golf racket. This raises the question: What is it that makes these favourites so appealing? One major issue of sports technology research is to answer this difficult question. This not only includes the definition of "attractiveness" in the context of sports, but also the search for appropriate methods to quantify related items. Extending this to sports technology it involves the definition of "functionality" and consequently the establishment of science based product tests. After a brief introduction which gives possible definitions for the above three terminologies, the presentation will then describe four relevant research fields with a special focus on subjective product testing. Examples from ski tests and golf club fitting will be used to illustrate practical application. Returning to the given categorization of sports technology the second part of the presentation will then offer a selection of best practise examples in order to illustrate the variety of different approaches in sports technology and the results hereof. An outlook into the future of sports technology with some concluding remarks will complete the presentation.

**PERFORMANCE, COMFORT AND INJURY PREVENTION IN TENNIS EQUIPMENT**

Miller, S.

*International Tennis Federation*

Introduction Tennis equipment plays an important role in the outcome of a match. The manufacture and marketing of tennis equipment is based (in part) on performance, comfort and injury prevention, all of which are intertwined and not mutually exclusive. This paper assesses each factor as it relates to tennis equipment. Discussion The main characteristics of a tennis racket in the context of this paper are: frame and string bed stiffness, string type, and damping. Racket performance (power) is generated by virtue of an impact with the ball. For a non-spinning shot, the post-impact ball speed is determined by the energy losses during impact. These losses arise from deformation of the racket frame, strings and ball, with lower total energy losses being associated with higher post-impact ball speed. The commonest injury risk due to rackets is 'tennis elbow' (lateral epicondylitis). It is generally accepted that this is due to rapid extension of the wrist extensor muscles, while playing a backhand, particularly while with a flexed wrist (e.g. Pluim, 2004). All other things being equal, increases in stiffness will increase the magnitude of the force generating this extension. It has also been postulated that the impact vibrations of the racket influences tennis elbow (Kotze et al., 2003), and that effective damping reduces that influence. Modern rackets, due to their high stiffness, have a lower damping ratio than wooden rackets, and so are less effective in that regard. There appears to be little, if any, published research on racket 'comfort'. It is hypothesised, however, that ball and string stiffness are influential factors. That is, an increased dwell time of the ball on the strings will be associated with greater comfort. By implication, therefore, stiffer strings would be perceived as less comfortable. However, modern string materials tend to be stiffer than their predecessors. In addition to using less stiff string materials, reduction of string tension will lead to lower string bed stiffness, which will be perceived as more comfortable. This has the knock-on effect of increasing post-impact ball speed, as a greater amount of the energy generated during impact will be stored in the strings, which return that energy much more efficiently than the ball. Haake et al. (2003) demonstrated that players prefer stiffer tennis balls, which tend to suffer less hysteresis energy loss. However, this decreases dwell time, which suggests that comfort is not the most important characteristic in determining ball preference. Discussion With the exception of the relationship between stringbed stiffness and post-impact ball velocity, it appears that there are limited opportunities for equipment manufacturers to increase equipment performance (as defined by post-impact ball speed), while maintaining or increasing comfort and/or reducing the risk of injury.

**ALPINE SKI RACING EQUIPMENT – THE CHALLENGE OF BALANCING PERFORMANCE AND SAFETY ASPECTS**

Spörri, J., Kröll, J., Schwameder, H., Müller, E.

*University of Salzburg*

A main challenge for sports equipment design is balancing performance and safety aspects. On the one hand a certain equipment modification may improve safety, but on the other hand it may negatively affect performance and vice versa. Furthermore, this compromise is not only influenced by equipment design itself, but also by the athletes' adaptations on modified equipment. These are two of the main reasons why injury prevention by equipment rules is very challenging, as the following example of alpine ski racing illustrates. Recent data by the International Ski Federation (FIS) Injury Surveillance System showed an alarmingly high incidence of severe injuries (Florenes et al., 2009). In most of the knee injuries the athletes initially lost balance inward and/or backward; then, while trying to regain the grip on the outer ski the inner edge of either the inner or the outer ski abruptly caught the snow, forcing the knee into valgus and internal rotation (Bere et al., 2011). A main contributor for this sudden catch of the edge seems to be the system "ski, binding, plate and boot", in particular its self-steering behaviour (Spörri et al., 2012a). Based on these findings, different ski prototypes (varying in length, width and side-cut) have been constructed and have undergone a rigorous testing process (Kröll et al., 2012). Finally, FIS introduced new equipment rules for the competition season 2012/2013. In a recent study we investigated the influence of this rule change on biomechanical variables related to performance. For the new regimented skis, it was found that, by tendency, turns were initiated and terminated lower regarding the vertical position on the slope plane and centre of mass showed a longer substantial change of direction; two factors known to be related to lower performance (Spörri et al., 2012c). While the athletes tried to compensate the reduced self-steering behaviour of the skis by increasing their hip angulation at the beginning of the turn (positive trend with respect to safety), some of the equipment suppliers started to adapt their equipment components within the regimentation boundaries and/or lacks. These adaptations in equip-

ment design, however, might result in new safety problems and start a next round in the circle of sufficiently balancing performance and safety aspects. ### BIOMECHANICS OF SPORT EQUIPMENT: TRIAD OF PERFORMANCE, COMFORT AND INJURY PREVENTION

Schwameder, H.

*University of Salzburg*

Motor activities are always executed with an interaction between at least one contact area of the human body and its environment. Sport related activities are mainly performed using specific sport equipment, which has to be used in a very wide sense and does not only cover typical sport equipment, but also surfaces and clothes. In the context of 'human-movement' interaction 'sport equipment' builds an important interface. 'Sport equipment' shows both biological and mechanical effects on the human body and on human movement. It is well documented in the literature that the type of equipment used in sport or daily life can have substantial effects on the coordination and the loading of joints and biological. In some cases even fairly small changes of the equipment lead to extensive biomechanical responses. From the goal-oriented perspective the equipment interventions can follow the aspects regarding the triad of performance and/or comfort and/or injury prevention with partly diverging issues. While it would be eligible to follow all three goals at once, often contradictory circumstances impede to aim that. Elite athletes definitively focus on equipment interventions related to performance, while aspects of comfort or injury prevention only play a minor role. In recreational sports, however, the main focus is given to comfort and injury prevention. Furthermore it has to be considered that the use and handling of high end sport equipment requires a certain amount of physical condition and coordinative skills. Otherwise the probability of discomfort or even pain, disorders and injuries might occur. There are evidences in the literature that performance, comfort and injury prevention are interrelated to a certain extent, due to the high complexity of the human-equipment-interaction, the high amount of influencing factors and the methodological challenge to proof pain or injury causing factors, the named relationships are still not well understood. The high complexity of the 'human-equipment interaction' requires to observe and to study these interactions with respect to various aspects. First to mention are the issues of stability (consistency of movement and loading of a person during a set of repeated cycles), sensitivity (intensity of an individuals' reaction regarding movement pattern and loading on changes of the sport equipment or environment) and laterality (difference between the left and the right limb regarding performance, movement pattern or loading; this issue is specifically important in cases of unilateral overloading or for laterality-based tuning of sport equipment). Another aspect to look at is if changes of sport equipment show general effects (similar for everyone), group effects (specific for groups, e.g. gender, age, sports relation, skill level) or individual effects (subject-specific reaction on equipment). Furthermore, it is important to look at time related effects including issues of adaptation, fatigue and learning.

#### NEUROMUSCULAR INTERACTION DURING RUNNING FOR ELITE LONG-DISTANCE RUNNERS

Ishikawa, M., Kunimasa, Y., Sano, K., Oda, T., Nicol, C., Komi, P.V., Locatelli, E., Ito, A.

*Osaka University of Health and Sport Sciences*

The recent years have demonstrated the great success of the East-African middle- and long-distance runners. Their high running economy could not be explained by any of the physiological, histochemical and/or biomechanical parameters (Saltin et al 2003). Consequently, the question can be asked whether the East-African runners possess particular advantages of mechanical and functional muscle-tendon complex, which could favor efficient storage and reutilization of elastic energy in Achilles tendon during locomotion. The purpose of the present study was to examine the muscle-tendon architectures and the muscle-tendon interaction during stretch-shortening cycle (SSC) exercises for international level East-African runners. Musculoskeletal ultrasonography, EMG and kinematics were measured together with ground reaction forces during SSC exercises. The present report will emphasize how the muscles of these athletes function efficiently during SSC exercises. Furthermore, our results suggest that the neuromuscular interaction of the East-African runners can be behaved differently as compared to Japanese distance runners during SSC exercises (Sano et al 2013) due to the differences of mechanical properties. These differences between East-African and Japanese middle- and long-distance runners could be crucial effects for running economy. References Sano K et al. (2013) *Eur J Appl Physiol*. In Press. Saltin B. (2003) *New Studies in Athletics*. 18:15-24.

#### MESSING WITH EVOLUTION: EXAMPLES FROM HUMAN WALKING

Cronin, N., Lichtwark, G.

*University of Jyväskylä*

In the human lower limb, muscles and tendons interact efficiently during level walking. During the stance phase, a large proportion of the muscle-tendon unit (MTU) stretch is taken up by the relatively compliant Achilles tendon, whilst muscles perform minimal work and shorten slowly relative to their maximal shortening velocity during the pushoff phase (1, 2). This pattern of interaction exploits the force-length and force-velocity relationships of muscle, whilst enabling tendons to act as springs that store elastic energy during the contact phase, and return a large proportion of that energy in the pushoff phase. However, this 'natural' pattern of muscle-tendon interaction may be disrupted in certain conditions, such as when walking in high heeled shoes. In women who wear high heels (> 5cm) regularly, the gastrocnemius muscle fascicles are shorter than in controls subjects. During walking, the heel wearers walk less efficiently with or without heels. The Achilles tendon is also stiffer in long-term high-heel wearers (3), and the muscle fascicles consequently undergo higher strains and higher strain rates during the stance phase of walking (4). To date, studies of the effects of high heels on gait parameters have been

limited to small sample sizes, and although long-term adaptations in neuromechanical parameters due to high heel use have been identified, the parameters responsible for such adaptations are not known. For example, heel height and duration of use seem likely to influence whether adaptations occur, and the extent of these adaptations. This in turn will influence how much the normal pattern of muscle-tendon interaction is disturbed. In this session I will present data from an ongoing study of muscle fascicle behaviour and ground reaction forces in a group of approximately 50 women aged 18 - 70. This group exhibit a wide range of shoe wearing habits, thus allowing us to examine the effects of various parameters on long-term neuromuscular adaptations to disruption of the natural foot position during gait. ## CORTICAL ADAPTATIONS FOR HUMAN WALKING

Grey, M.J.

*University of Birmingham*

The demands of bipedal locomotion have led to significant evolutionary pressure on the mechanisms by which it is controlled. It is commonly accepted that the supraspinal control mechanisms have a more predominant role in human walking than quadruped walking. This talk will review evidence for the involvement of the primary motor cortex and corticospinal tract during normal and perturbed walking and during gait adaptation. It will be argued that such knowledge is critical for an understanding of the basic motor control of walking and for rehabilitation of gait in patients with lesions of the brain and spinal cord.

## Oral presentations

### OP-PM52 Training and Testing [TT] 6

#### DIFFERENCES IN SWIMMING FORCE METRICS INDUCED BY GENDER

Amaro, N., Marinho, D.A., Batalha, N., Morouço, P.

*Polytechnic Institute of Leiria*

**Introduction** Swimming performance differences are notorious among male and female post-puberty swimmers. Previous studies point that, in adolescence, boys are taller and heavier than girls; taking advantage in swimming performance with that anthropometric difference (Morouço et al., 2012). Therefore, the aim of this study was to identify possible differences between performance (personal best at 50m freestyle) and parameters obtained in tethered swimming tests (force and impulse), between genders. **Methods** One group of 14 male adolescent swimmers (age: 14.6±1.2years of age, body mass: 53.1±9.0kg, height: 1.66±0.1m, arm span: 1.69±0.1m) and other of 8 female adolescent swimmers (age: 13.9±2.1years of age, body mass: 46.3±9.2kg, height: 1.57±0.1m, arm span: 1.59±0.1m) took part in the study. Each participant performed a 30 s maximal front crawl tethered swimming test (described in detail by Morouço et al, 2011) and a 50m in-water maximal bout. After normality assumption checked, speed in 50m in-water maximal bout (s50) and force metrics (average force – Favg; maximum force – Fmax; and impulse of force – Fimp) were assessed for each group. Results 50m swimming speed was significantly higher for the males group comparing with females cohort (1.69±0.11 vs. 1.52±0.13 m/s, p=0.004; respectively). The same superiority was observed in tethered swimming metrics (Favg: 78.1±17.1 vs. 56.0±14.5 N, p=0.006; Fmax: 200.8±51.4 vs. 141.4±35.48 N, p=0.009; Fimp: 74.7±15.6 vs. 52.8±16.3 N.s, p=0.006; respectively). No differences were found in body mass, height and arm span (p>0.05). **Discussion** It is assumed that body mass and height differences among males and females intensively increase after puberty (Kraemer et al., 1989). Thus, it is pointed that at these ages males are capable to produce more strength (Schneider & Meyer, 2005). However, in the present study no anthropometrical differences were noticed, and still performance and force exertion in-water were higher for the males group. These results suggest that other variables, rather than body constitution, should be considered when evaluating adolescent swimmers. The higher values in tethered swimming metrics may imply that male swimmers had higher muscle strength levels and/or a greater capacity to apply propulsive force to water. **References** Bencke J, Damsgaard R, Saekmose A, Jorgensen P, Jorgensen K, & Klausen K, (2002). *Scand J Med Sci Sport*. ; 12:171-178. #### REPRODUCIBILITY OF SELECTED PHYSIOLOGICAL PARAMETERS IN SWIMMING

Götz, J.K., Klug, A., Sperling, W., Hartmann, U.

*Universität Leipzig, Faculty of Sport Science*

**Introduction** There are numerous studies that deal with the energy cost and the measurement of respiratory gas parameters in swimming (e.g. Karpovich et al., 1944). But these investigations do not consider the reproducibility of the physiological parameters. Alberty et al. 2006 examined the repeatability of the performance of swimmers during training but did not consider the reproducibility of physiological parameters. **Aim** The aim of this study was to determine the reproducibility of the parameters oxygen uptake (VO<sub>2</sub>), carbon dioxide output, ventilation, breathing frequency, lactate (Lac) and movement frequency (MF). **Methods** In the study took part three trained male (VO<sub>2</sub>peak 4.55 ± 0.45 l/min) and four female (VO<sub>2</sub>peak 3.11 ± 0.83 l/min) swimmers and triathletes. Each of them swam on two different days 2x400 m front crawl with a passive break of 20 min in a swimming flume. The first 400 m of each testing day they performed their individual velocity at an aerobic training zone (aZ) and the second in a higher velocity, representing the individual aerobic-anaerobic (aanZ) training zone. At the two testing days, the swimming speeds of the 2x400 m were exactly the same. **Results** For the respiratory parameters and MF no significant differences between the two days were found. The correlation coefficient (CV) for VO<sub>2</sub> was calculated

for aZ with 5.56 % and for aanZ with 4.68 %. The lowest CV was calculated for MF with 2.21 % and 2.81 % and the highest for Lac with 12.96 % for aZ and 21.39 % for aanZ. Discussion The CV for VO<sub>2</sub> of our study was comparable with the results from Becque et al., 1993. Brisswalter et al., 1994 reported the lowest variability for the MF, like we did. A high variability for Lac was also already found by Batschelet et al., 2004, with a CV of 10 %. We concluded that the selected respiratory gas parameters and the MF were highly reproducible. The lactate concentration, in contrast, showed a higher variability. References Alberty, M.; Sidney, M.; Huot-Marchand, F.; Dekerle, J.; Bosquet, L.; Gorce, P., and Lensele, G. ## TRAINING VOLUME OF TRIATHLETES OF DIFFERENT AGE CATEGORIES: A NATIONAL INVESTIGATION

Comotto, S.1, Concari, R.1, Guerci, M.1, Bottoni, A.2, Piacentini, M.F.1

1: *University of Rome*

**Introduction** As a result of the interactions in the performance of three different disciplines (swim, cycle and run), triathlon is a complex sport in terms of training load control and quantification [2]. Training related triathlon studies are mainly focused on the amount of training elite athletes perform [4] while the knowledge of training for children and adolescents is currently based on limited scientific evidence [3]. Knowledge of training characteristics may help on the promotion and the selection of talent. So, the aim of this study is to describe the volume of training of young triathletes of different age categories. **Methods** A questionnaire specifically designed in collaboration with FITRI, was submitted to all the clubs in Italy that train the age categories between 8 and 19yrs. The questionnaire consists of 3 different parts: 1)club and coach data, 2)training volume (V) data of athletes between 8 and 13 yrs of age (Kids,K) and 3)training V data of athletes between 14 and 19 yrs of age (Youth,Y). Only 11 clubs out of a total of 63 contacted, answered the questionnaire. V data were analyzed as descriptive statistic, whereas ANOVA was used to verify difference in number of sessions and time spent for training between groups ( $P<0.05$ ). **Results** The 11 responders are the most representative clubs in Italy. K athletes swim 2-3 sessions per week (SW), cycle and run 1-2SW with a volume ranged from 2 to 5, from 20 to 40 and from 5 to 10km, respectively. Y athletes swim 3-6SW and cycle and run 2-3SW with a volume ranged from 10 to 20, from 50 to 170, and from 15 to 30km, respectively. All clubs train at least two disciplines during the same training session. Y have a significant higher number of SW ( $P<0.001$ ). The same aspect is evident analyzing each discipline except for cycling that showed the same number of SW for all age categories. Time spent for training per week increasing from K to Y ( $P<0.001$ ). Same results are evident analyzing each discipline separately ( $P<0.03$ ). **Discussion** Selection and promotion of talent is based not only on the performance of the athletes but also on their past training history. Therefore, these data may help the FITRI understand if there are differences in training modalities between different clubs in order to create specific guidelines based on the age category and to design the best strategy to achieve top level sporting results. In fact, cut-off model to select talent seems to be inadequate [1], but the selection should also take into account mental ability, rate of abilities' development, load and stress tolerance. References [1]Bottoni et al JHSE, 2011 [2]Cejuela Anta & Esteve-Lanao JHSE, 2011 [3]Millet et al IJSP, 2007 [4]Vleck et al JSCR, 2010

## A MODIFIED METHOD OF TRIMP CALCULATION TO QUANTIFY TRAINING LOAD IN ELITE SWIMMERS

García-Ramos, A., Feriche, B., Iglesias, X., Calderón, C., Chaverri, D., Barrero, A., Nebot, V., Schuller, T., Hynynen, E., Rodríguez, F.A.

FCADF, *University of Granada (Granada, Spain)*

**INTRODUCTION** The training impulse (TRIMP) method (Banister & Hamilton, 1985), based on heart rate (HR) monitoring and exercise duration, is an objective procedure for quantifying internal training load. It requires steady state HR measurements, thus limiting the accuracy with which interval exercise can be quantified (Borresen & Lambert, 2009). Moreover, the classical method does not discriminate between work and rest periods, which are merged into a single intensity parameter (HRmean). Here we propose a modified method to calculate TRIMP based on the addition of partial impulse units within a session (TRIMPa), and compare experimental results computed with the classical procedure. **METHODS** 17 elite swimmers' pool sessions were monitored for four consecutive weeks. HR was measured from RR intervals, and 50-m swimming and recovery intervals were timed using an integrated system with portable beacon transmitters placed by the pool (CardioSwim, TX H2O, Freemap, Fleurier, Switzerland). TRIMP were calculated using the classical procedure, and the proposed accumulative method (TRIMPa), which adds partial TRIMP values computed for each lap during the workout. Session RPE (s-RPE) (Foster et al., 2001) was self-administered within 30 min after each workout. **RESULTS** Data were obtained from 328 individual pool sessions. Mean ( $\pm$ sd) session TRIMPa values (116.6 $\pm$ 53) were greater than TRIMP (107 $\pm$ 47.4) (+9.2%;  $P<0.001$ ). Inter-method differences were larger with increasing HR standard deviation (HRsd) and number of recorded time intervals (Nint). TRIMPa values could be estimated using the equation ( $r^2=0.994$ ;  $p<0.001$ ):  $TRIMPa = -6.348 + 1.086 TRIMP + 0.266 HRsd + 0.013 Nint$ . Both TRIMPa and TRIMP showed a strong correlation with s-RPE ( $r=0.724$  and  $0.702$ , respectively,  $p<0.001$ ). **DISCUSSION** Our results agreed with previous studies in showing a good association between subjective (s-RPE) and objective HR-based quantification methods (Wallace et al., 2009). In contrast to TRIMPa, s-RPE and the classical TRIMP methods do not discriminate the different character of each training interval during a workout. Therefore, TRIMPa appears to be a more accurate and appropriate procedure for quantifying training load, particularly when monitoring interval training sessions. **REFERENCES** Banister EW & Hamilton CL (1985). *Eur J Appl Physiol*, 54, 16-23. ### IS-SH08 Strategies for preventing sexual harassment in sport – in between voluntariness and obligation

#### SEXUAL HARASSMENT PREVENTION IN EUROPEAN SPORT: SCIENCE, ACTIVISM AND POLICY

Brackenridge, C.

*Brunel University London*

This paper will address the rise of scientific enquiry into sexually exploitative behaviour in sport. It will start by examining contested definitions and move on to explore how scientific enquiry has driven activism for social change. The paper will posit that a tipping point is approaching whereby the combined forces of science and activism will result in acceptance of athlete welfare within European sport policy agendas. Possible consequences for sport management and coaching will also be discussed. SYMPOSIUM ID: 5234 - Session-ID: IS-SH08

#### PREVENTING SEXUAL HARASSMENT AND ABUSE IN SPORT - THE NORWEGIAN PERSPECTIVE

Fasting, K.

*Norwegian School of Sport Sciences*

The first Norwegian study surveying the prevalence of sexual harassment and abuse in Norway took place in 1998. About the same time, a big scandal occurred in Norwegian Sport. The coach of Vebjørn Rodahl, a Norwegian runner who had won a gold medal in 800m in the Olympics in 1996, was sacked by the Norwegian Track and Field Association, by his club, and a couple of days later by Vebjørn Rodahl himself. The coach was accused of having sexually harassed and abused two female athletes. The case never got to court, because it was settled out of court. The case received extensive media attention, and raised many questions inside Norwegian sport, because it became clear that Norwegian sport didn't have a system to handle such cases. When the report from the above mentioned survey was released some time later it led to The Norwegian Olympic, Paralympic and Confederation of Sport (NIF) deciding upon the first guidelines to prevent sexual harassment (NIF 2000). More empirical studies have now been done. Also the numbers of criminal court cases involving abuse in sport have been more visible in the Norwegian media. A short overview of the knowledge produced by these empirical studies about sexual harassment and abuse in a Norwegian Context is presented. This knowledge led to the revision of the guidelines of 2000. As a consequence of that "An open and inclusive sport" had been chosen as the aim for future sports policy by the Norwegian Olympic and Paralympic and Confederation of Sports (NIF), it became a goal "to develop tolerance, understanding and to establish recognition of people's equality in order to avoid discrimination, harassment and bullying" (NIF 2007). At the General Assembly the motion "Zero tolerance for discrimination and harassment irrespective of gender, ethnic background, religious faith, sexual orientation and disability" was passed. Soon after the board of NIF decided "that all sports clubs from 1 January 2009 are obliged to procure a police certificate of good conduct for persons who are to carry out tasks for the club that entail a relationship of trust and responsibility in relation to minors or persons with mental disability" (NIF 2008). A police certificate contains information about whether a person is charged with or has earlier been convicted of violations of certain provisions in Penal Code on sexual offenses. Some figures from this police checking are presented and discussed. Ten new guidelines on preventing sexual harassment and abuse were then adopted in 2010. A booklet has been developed which, in addition to definitions and general information, has paragraphs about the prevention of sexual harassment and abuse and suggests mandatory procedures when sexual harassment and abuse occur. The guidelines are presented and their consequences discussed particularly in relation to how a sport club/organization should and could react when an incident occurs.

#### INTERVENTIONS AGAINST SEXUAL EXPLOITATION IN SPORT FROM A GREEK PERSPECTIVE

Chroni, S.

*University of Thessaly*

Abstract for the ECSS-Invited Symposium ID: 5234 – Session-ID: IS\_SH08. Strategies for preventing sexual harassment in sport – in between voluntariness and obligation. Neither prevention nor control laws, policies, procedures against sexual exploitation are in effect specifically covering the world of Greek sport. The media repeatedly has brought to light sexual exploitation sport stories concerning both genders. Greek data revealed sexual harassment experiences in 71.5% of 308 female athletes asked (Chroni & Fasting, 2009); yet no other study has been conducted to inform us on sexual harassment experiences of male athletes or on sexual abuse incidents in sport. Today, the state of Greece has still not taken any initiative toward safeguarding sport participants and thus confronting sexual exploitation incidents remains a privately held issue. The present paper will discuss individual efforts put forth by a local football association to educate parents and coaches on sexual abuse; a local women's football team that was formed by the parents of the athletes in order to leave behind an abusive coach; and the research findings based on Greek data that highlight the need for action by the state. Consequences for coach education will also be discussed.

#### CHILD PROTECTION AND PREVENTION OF SEXUALIZED VIOLENCE IN SPORT – THE GERMAN PERSPECTIVE

Rulofs, B.

*German Sport University Cologne*

Due to the media coverage of severe cases of child abuse in institutions, the topic of preventing sexual harassment and abuse has once again been put on the agenda of sport organisations. In 2011, the German Olympic Sport Federation – as the head of all sport organisations in Germany – finally started a broad campaign against sexualized violence in sport. Yet, the governing bodies of German sport were initially slow to adopt measures to prevent sexualized violence. This paper aims at investigating the steps and changes that were necessary in order to establish a comprehensive campaign for child protection in the German sport system. The model of "activation states", developed by Brackenridge et al. (2005), is used as a heuristic device for analysing the development of policy and action against

sexualized violence in German sport. Furthermore the German status quo in child protection in sport is compared to the progress in other European countries. A project funded by the European Commission in the year 2012, that aimed at compiling a catalogue of European initiatives for child protection in sport, serves as a basis for this comparison (cp. Chroni et al. 2012). Taking into account the policy and action that have been undertaken by the German governing bodies in sport throughout the last two years, it can be stated that they have quit the state of being "opposed" or "inactive" in the field of child protection in favour of being "active" (cp. Brackenridge et al., 2005). For example, all regional sports confederations have officially appointed a commissioner for child protection in sport and have integrated child protection as a topic in their educational system (cp. UBSKM, 2012, p. 12). Yet, with regard to the progress that some European neighbour countries have made (e.g. United Kingdom, Norway), it has to be concluded that further measures have to be taken in Germany. Considering the quite complex and decentralized structure of the German sport system, the main challenge is to carry the action through the various member organisations down to the bottom of the sport system, namely to 91,000 sport clubs. ##### PERCEPTIONS AND AWARENESS OF PARENTS ABOUT PEDIATRIC OVERWEIGHT: THE ACORDA PROJECT

Lagoa, M.J.1,2, Mota, J.1, Pizarro, A.1, Ribeiro, J.C.1, Aires, L.1,2

*1Research Centre in Physical Activity, Health and Leisure (CIAFEL) Faculty of Sports – University of Porto. 2 High Education Institute from Maia (ISMAI), Portugal*

**Introduction** Parents are important influences on children's lifestyle but there is lack of research on strategies to increase parents' effectiveness as part the process. The aim of this study was to evaluate parents' awareness about restrictions, decisions, concerns and certainties of children's eating habits of that took part in a school-based intervention program to prevent obesity. **Methods** Parents of 79 children from 6 schools in Porto district took part in this study. The students included in the project ACORDA i.e. obese children and adolescents involved in PA (PE classes 5 days per week) and diet counseling. The program lasted 8 months. To evaluate parental awareness, attitudes and practices about infant feeding, a Child Feeding Questionnaire (CFQ) was used with 7 factors: i Perceived responsibility (PR); ii Parent perceived weight (PPW); iii Perceived child weight (PCW); iv Parents' concerns about child weight (CN); v Restriction (RST); vi Pressure to eat (PE); vii Monitoring (MN). For physical activity levels accelerometers ActiGraph GTX3 were used for 7 days. %BF and %TF was obtained through DXA (whole body protocol). Additional android region (AR) was defined using the software provided by the manufacturer. The lower boundary was the top of the pelvis line of demarcation. The upper boundary was placed above the pelvis line of demarcation at a position that was equivalent to 20% of the distance between the pelvis and the femoral neck. Lateral boundaries were the lines for the arms when in normal position for a whole-body scan. To analyze how variables changed over time, deltas ( $\Delta$ ) (Time point 1 minus Time point 0) were calculated. Pearson correlations were used. Results The results showed that there were significant correlations between Factor 2 PPW:  $\Delta$ %BF (-0,41;  $p=0,041$ )/  $\Delta$  TF (-0,357;  $p=0,019$ ); Factor 4 CN:  $\Delta$  AR (-0,329;  $p=0,033$ )/ mother's schooling (0,266;  $p=0,019$ )/ mother's profession (-0,301;  $p=0,009$ ); Factor 6 PE:  $\Delta$  AR (0,406;  $p=0,009$ )/  $\Delta$  %BF (0,420;  $p=0,006$ )/ mother's profession (0,251;  $p=0,035$ )/  $\Delta$  %TF (0,388;  $p=0,012$ ); Factor 7 MN:  $\Delta$  Time MV PA (0,395;  $p=0,016$ )/  $\Delta$  weight (0,306;  $p=0,017$ ). **Conclusions** There is concern about children's weight mainly by mothers, depending on their education level and profession. The inverse correlations observed between PPW and  $\Delta$ %BF and  $\Delta$  TF, as well as the positive correlations between parents' PE and loss of % BF, %TF and AR, can highlight the importance of an knowledgeable family for an efficient support of overweight children to a successful change to an healthy lifestyle. **Acknowledgments:** DGS (General Health Board); Project PEst-OE/SAU/UI0617/2011 and PTDC/DTP-DES/1328/2012.

##### THE REAL ENERGY EXPENDITURE OF OBESE ADULTS IN A FITNESS WORKOUT

Vallejo, L.1, Porta, J.1

*INEFC Barcelona*

**Do not insert authors here** THE REAL ENERGY EXPENDITURE OF OBESE ADULTS DURING A FITNESS WORKOUT: A PILOT STUDY. To fight against the XXI's century obesity pandemia, it's of primary interest to propose the type of exercise that maximizes caloric expenditure (CE). Although walking has become very popular, doesn't provide, in a normal 60 min workout session, the necessary overload to achieve the desired goal. Luckily, nowadays, the different types of ergometers we can find in the fitness centers can help the professionals in promoting an effective "burning-fat" workout. But, despite the many studies on exercise metabolism available, we haven't been able to find any intending to quantify the real CE of overweight or obese subjects through a real fitness workout. This justifies the aim of this study being: "quantification of the energy expenditure of obese adults in a 60 min workout" **Methods** Subjects: 6 moderately active subjects volunteered to participate in this study signing an informed consent; 3 women aged  $52.0 \pm 9.4$  with a BMI=  $33.4 \pm 7.1$ , and 3 men aged  $54.0 \pm 8.1$ , with a BMI=  $30.4 \pm 4.6$ . **Materials:** Gas analyzer Fitmate-Pro (Cosmed, Italy), bicycle, hand-bicycle, treadmill, elliptical, rower. **Protocol:** after evaluating their Basal Metabolic Rate (BMR), and the maximum walking speed during 1 min (MWS-1) in a treadmill, the subjects, were asked to exercise in all the ergometers at 75 % of their MHR ( $208-(0.7 \times \text{age})$ ), and/or at the level 6 (somewhat hard) in the Borg 10-RPE Scale®, during 5 min (podal bicycle, elliptical and treadmill) or 3 min in the manual bicycle and rower. **Results** The 3 women's mean BMR for a period of 10 min ( $\text{VO}_2 = 201 \pm 24 \text{ ml} \cdot \text{min}^{-1}$ ) was lower ( $p < 0,001$ ) than the 3 males ( $\text{VO}_2 = 262 \pm \text{ml} \cdot \text{min}^{-1}$ ). The level 6 of the Borg Scale was much related to the 75% of MHR ( $\approx 65\% \text{ VO}_2\text{max.}$ ) in the treadmill, elliptical and rower, but not in the manual & podal bicycles. As expected the women had a much lower energy expenditure in all the ergometers than the males ( $p < 0,0001$ ). Women & men had a maximum caloric expenditure rowing ( $x= 540 \text{ kcal} \cdot \text{h}$  and  $745 \text{ kcal} \cdot \text{h}$  respect.) and walking ( $x= 430 \text{ kcal} \cdot \text{h}$  and  $569 \text{ kcal} \cdot \text{h}$ ) Discus-

sion/conclusion This study demonstrates that's very difficult to "burn-fat" just exercising. Even a motivated and fit overweight or obese adult can't sustain a caloric expenditure of 745 kcal•h. The only way to get thinner and healthy should be to diet and exercise with the "interval-fitness" method. That's, 5-10 min exercise at 85% followed by a 5-10 min at 65-75% of MHR. ### CHANGES IN ADIPOSITY AMONG PORTUGUESE YOUTH WITH OR WITHOUT INDIVIDUALIZED COUNSELING APPROACH AS PART OF A SCHOOL-BASED PROGRAM: THE ACORDA PROJECT

Aires, L.1,2, Martins, C.1,2, Silva, G.1, Rego, C.3, Marques, E.A.1,2, Ribeiro, J.C.1, Santos, M.P.1, Mota, J.1

*1Research Centre in Physical Activity, Health and Leisure (CIAFEL) Faculty of Sports – University of Porto 4200-450 Porto, Portugal 2 High Education Institute from Maia (ISMAI), Portugal 3 Child and A*

Introduction School-based interventions show inconsistent results in reducing weight-related problems. Some limitations can be due to sensitivity of methodology, as the use of BMI or waist Circumference (WC) as a single marker of adiposity response to intervention. Another limitation is that type of interventions do not easily allow for individualized targeted messages. Therefore, the aim of this study was to explore the changes observed in BMI, WC, percentage of Body Fat (%BF) and Trunk Fat (%TF) observed in a school-based intervention program, with or without individualized counseling for diet. Methods 75 children and adolescents (46 girls, 61.3%) from 6 schools in Porto district took part in this study. "ACORDA Project" (e.g. obese children and adolescent involved in PA and diet program) is an 8-month interdisciplinary, school-based intervention program. The Project consists of regular physical exercise (one hour/session; 4 to 5 days/week) plus dietary individualized counselling. Dietary counseling was delivered in through medical appointments. Two groups of 16 subjects each with and without individualized counselling accomplished all evaluations, respectively with, 54.1% and 44.7% of overweight and 45.9% and 55.3% of obesity. To analyze changed over time, deltas  $\Delta$  (Time point 1 minus Time point 0) were calculated. %BF and %TF was obtained through DXA. Tanner scale was used to characterize maturation status and logistic regression, adjusted for gender and maturation to examine associations between  $\Delta$  %BF and  $\Delta$  % TF according to groups. Results Results showed that there was inverse associations of  $\Delta$  % BF ( $\beta=-0.768$ ; 95% CI: 0.054;4.015;  $p<0.046$ ),  $\Delta$ %TF ( $\beta=-0.527$ ; 95% CI:0.359;0.972;  $p=0.038$ ) and take part of individualized counseling group. No significant associations were observed in changes of BMI and WC. Conclusions School-based intervention programs can be an important key of counteracting obesity in children and adolescents. However our results point out for the low sensitivity of BMI and WC, in opposition to % BF and %TF, measured by DXA, proving to be a better marker of body composition. In addition, the link between schools and health centers should be prioritized including individualized counseling for overweight children. Acknowledgments: This study was supported by DGS (General Health Board), Projeto PESt-OE/SAU/UI0617/2011 and PTDC/DTP-DES/1328/2012

### INFLUENCE OF THE BMI ON THE MOTOR DEVELOPMENT OF CHILDREN AND ADOLESCENTS

Albrecht, C.1, Worth, A.1, Oberger, J.1, Schlenker, L.2, Schmidt, S.2, Bös, K.2

*1: University of education Karlsruhe (Germany); 2:Karlsruhe Institute of Technology (Germany)*

Introduction Several studies have shown a negative association between overweight/ obesity and motor performance (MP) in children and adolescents (Bös et al., 2009; D'Hont et al., 2009). However, it is unknown how overweight influences the development of MP over the lifespan. The purpose of this longitudinal study is to investigate, whether inter-individual changes in MP from baseline (base) to wave 1 depend on BMI-group affiliation. Methods To examine the influence of overweight/obesity on the development of MP longitudinally, we tested MP in two waves with a 3-year-interval in a representative, nationwide sample of 4,529 (base)/ 5,290 (wave 1) children and adolescents aged 4 to 23 years in Germany (MoMo longitudinal study). MP was assessed by means of the MoMo test profile including 11 test items (Bös et al., 2009). For the statistical analysis ANOVAs for repeated measurements were conducted. BMI-group affiliation was defined according to the international cut-off points from Cole et al. (2000). Results Results of the ANOVA revealed significant differences in MP development from base to wave 1 between over- and normal weight participants (time\*group:  $F(1, 1249) = 10.70$ ,  $p < .01$ ,  $\eta^2 = .01$ ) for the test item standing long jump. Participants with normal weight show an increase of MP from baseline to wave 1 of 32.1%, overweight participants of 23.7 %. For the test item balancing backwards, the ANOVA revealed no significant differences in MP development from base to wave 1 between over- and normal weight participants (time\*group:  $F(1, 1257) = 2.55$ ,  $p = .11$ ,  $\eta^2 = .00$ ). Discussion The development of MP from base to wave 1 differs significantly among children/adolescents with over- and normal weight in tasks which are conditional-determined (standing long jump) but not in tasks which are coordinative-determined (balancing backwards). Our results indicate that obesity prevention should begin as early as possible due to the fact that overweight children show a significantly lower development of MP. In further studies we examine whether the shown scissors effect between over- and normal weight children/adolescents reinforces in adulthood. The BMI as a tool to assess the body constitution is often criticized. In future analyses, alternatives, such as waist-to-hip ratio or data from bioelectrical impedance analysis will be included. ### EFFECTS OF HOSPITALIZATION ON OXIDATIVE STRESS AND BODY COMPOSITION IN PATIENTS WITH RHEUMATOID ARTHRITIS

Stavropoulos-Kalinoglou, A., Bourokosta, Z., Georgakouli, K., Kitas, G.D., Jamurtas, A.

*University of Thessaly*

Oxidative stress is considered to be central in the development and progression of Rheumatoid Arthritis (RA), a chronic inflammatory condition affecting mainly synovial joints. A mechanistic link between inflammation and oxidative stress has been described and higher levels of oxidative stress are observed during more active periods of the disease. In a similar line, inflammation is considered to be the main reason why RA patients loose muscle mass. However, the short-term effects of effective control of inflammation by medication on oxidative stress and body composition in RA have not been studied. Purpose: To investigate the effects of short (2 weeks) hospitalisation on oxidative stress and body composition in patients with RA Methods: 12 RA patients (8 females) admitted to the hospital due to a flare in disease activity were assessed for oxidative stress (total anti-oxidant capacity: TAC; and uric acid: UA; Thiobarbituric acid reactive substances: TBARS) and body composition (height, weight, body mass index: BMI; body fat percentage: BF; fat free mass: FFM) at the day of

admission, one week later, and at check-out. Moreover, markers of inflammation (C-reactive protein: CRP) and disease activity (Disease Activity Score: DAS) were assessed as per routine clinical practice at the same time-points. Repeated measures ANOVA were used to identify differences in the assessed parameters between the three time-points. Results: Mean length of stay was  $14 \pm 1.2$  days. Inflammation, was significantly reduced from baseline to check-out (ESR:  $p=0.018$ ; CRP  $p=0.004$ ), and disease activity was lowered (DAS:  $p<0.001$ ). However there was no statistically significant change in TAC, UA, or TBARS. On the contrary body weight, BMI, BF, and kilograms of body fat were slightly but significantly reduced during hospitalisation ( $p<0.001$  in all cases) as was FFM ( $p=0.001$ ) Conclusions: Control of inflammation following two weeks of hospitalization does not affect markers of oxidative stress in patients with RA while body weight is significantly reduced. This comes as a result from reductions in both BF and FFM. Given the mechanistic association of inflammation with oxidative stress, possibly medication-induced oxidative stress might explain this outcome. Moreover, very limited physical movement for the two weeks might induce oxidative pathways and muscle wasting.

### DIETARY HABITS, BODY MASS INDEX AND PHYSICAL ACTIVITY OF BRITISH AND SAUDI YOUTH: A CROSS-CULTURAL CLUSTER ANALYSIS

Al-Nakeeb, Y.1,2, Dodd, L.2, Collins, P.2, Al-Nuaim, A.3, Lyons, M.4

1: Qatar University (Qatar), 2: Newman University College (United Kingdom), 3: King Faisal University (Saudi Arabia), 4: University of Limerick (Ireland).

Do not insert authors here Introduction Obesity is a leading risk factor for global mortality, promoted by poor dietary habits and sedentary behaviour in youth and in later life (Swinburn et al., 2011). This study explores the clustering and differences in dietary habits, body mass index (BMI) and physical activity (PA) amongst youth from United Kingdom (UK) and Saudi Arabia (SA). Methods 2,290 males and females aged 15–17 years completed a validated self-report questionnaire to assess dietary habits, BMI and PA. Based on the metabolic equivalent (MET-min) values of each activity reported by the participant, total energy expenditure per week was calculated (Ridley et al., 2008). The questionnaire also included specific questions designed to quantify the frequency of healthy and unhealthy dietary habits of youth. BMI was calculated using the formulae: Weight (kg)/Height (m<sup>2</sup>). In accordance with the International Obesity Task Force (IOTF) criteria, age and gender-specific BMI cut-off points were used for overweight and obesity classification (Cole et al., 2000). Results Youth from SA had a higher prevalence of overweight/obesity and lower levels of PA than youth from the UK. Males were more physically active than females across both countries. Three clusters were identified: (1) a "high risk" cluster with least healthy dietary habits, low PA and high BMI; (2) a "moderate cluster" with moderate healthy dietary habits, PA and BMI; (3) a "low risk" cluster with healthiest dietary habits, most active and the least BMI compared to the other two clusters. There were more SA youth in the high and moderate risk clusters. Discussion While males from both the UK and SA had healthier lifestyle and dietary habits than females, the younger the youth the healthier the lifestyle and dietary habits. Overall, youth from the UK pursued a comparatively healthier lifestyle and followed better dietary habits than SA youth. These findings reveal a worrying picture of young people's lifestyle and recognise some important practical implications for both countries that could be of interest to policy makers, teachers and health professionals. Furthermore, the findings reaffirm the notion that health practices tend to occur in clusters rather than in isolation and indicate that one should consider the patterns within these clusters of behaviours when planning policies and designing intervention strategies regarding obesity, PA and nutritional habits of youth. #### OP-PM57 Training and Testing [TT] 11

##### EFFECT OF INTEGRATIVE TRAINING ON INJURY FREQUENCY IN PROFESSIONAL SOCCER PLAYERS

Reer, R., Stein, D., Wellmann, K., Braumann, K.M.

*University of Hamburg*

Introduction FIFA Medical Assessment and Research Center (1) and the Oslo Sports Trauma Research Center (2,3) and other organizations have attempted to determine and quantify the frequency and causes of soccer injuries. These injuries are also associated with excessive costs for various professional clubs due to inability of players to participate in soccer matches. Therefore, the aim of this study was to assess if the frequency of injuries can be reduced or even eliminated by employing a specific injury prevention and reduction training program. In a previously conducted pilot study with a group of professional soccer players we were able to determine that employment of an injury prevention training program resulted in significant reduction and frequency of soccer related injuries. Methods We collected injury data over 4 soccer seasons of the same professional soccer team. The program consisted of sport specific endurance, sprint and jumping ability as well as strength/power of various muscle groups. We documented the occurrence of injuries of professional soccer players over 4 subsequent soccer seasons. The specific injury prevention program was not employed during the first season. We subsequently compared injuries that occurred during the first to the fourth playing season. Players were divided into three groups. Group 1 (G1) consisted of players who played at least one game during each season. Group 2 (G2) consisted of players that played at least 50% of the time during each season and group 3 (G3) consisted of players who played in all games during all four playing seasons. Results We found that our injury prevention program that was implemented after the first soccer season revealed the following results: G1 (N=25) had  $4.15 \pm 2.2$  injuries during the first season and injury rate was reduced to  $2.35 \pm 1.2$  (N=26) at the end of fourth season ( $p<0.01$ ). In G2 (N=12) the injury reduction was from  $4.92 \pm 1.4$  to  $2.36 \pm 1.4$  (N=11) ( $p<0.01$ ) and in G3 from  $4.33 \pm 1.7$  (N=9) to  $2.67 \pm 1.6$  (N=9) ( $p<0.05$ ). Discussion The results of our study revealed that our injury prevention and reduction program significantly reduced the injury rate of our professional soccer players from first to fourth playing season and that systematic and consistent application of our program had a positive effect on injury prevention and reduction in our professional soccer players. ## EFFECTS OF AN INJURY PREVENTION WARM-UP PROGRAM ON POSTURAL CONTROL MEASURES IN YOUTH TEAM ATHLETES. A RANDOMIZED CONTROLLED TRIAL

Zech, A.1, Hoefft, J.1, Klahn, P.1, Steib, S.2

1University of Hamburg; 2University of Erlangen-Nuremberg

**Introduction** Young team athletes in the age of 10 to 16 years are at increased risk of sustaining lower extremity injuries. Exercise interventions have shown to be effective in preventing injuries in this population (Hübscher et al 2010). These effects have been partly attributed to sensorimotor (postural) control adaptations. The objective of this study was to determine how various measures of postural control respond to an injury prevention warm-up program in youth field hockey athletes. **Methods** Thirty youth (14.9±3 years) field hockey athletes without previous lower extremity injuries were randomized to a control or intervention group. The intervention group performed a 20-minute warm-up program (11+) with strength, plyometric and balance exercises before each practice session. Participants in the control group followed their regular warm-up routine. The interventions were performed twice weekly for ten weeks. All participants completed pre- and post-tests as well as two test after week three and six in order to assess functional balance (star excursion balance test = SEBT, balance error scoring system = BESS), dynamic balance (jump landing time-to-stabilization =TTS) and static balance (center of pressure (COP) sway velocity). Interactions between group and intervention were analyzed by using repeated measures ANOVA. **Results** At baseline, there were no statistically significant differences between groups in age, mass, height, BMI or balance measures. Adherence was at 86% in the intervention group and 77% in controls. Significant group by time interactions were found for the BESS ( $p < 0.001$ ). The intervention group demonstrated larger error score reductions ( $69.3 \pm 10.3\%$ ) after ten weeks compared to controls ( $31.8 \pm 22.1\%$ ). SEBT maximum reach distances ( $p < 0.001$ ), TTS in anterior-posterior direction ( $p < 0.01$ ) and COP sway velocity ( $p < 0.001$ ) also improved significantly, whereas there were no significant differences between groups. **Conclusions** All balance measures improved significantly over time. However, only the changes in the BESS score seemed to be related to the warm-up intervention program. The similar increase in both groups in the other balance measures suggests that (a) test learning effects were still present at post-tests, (b) the regular sports practice had an additional effect or (c) the duration of 10 weeks was not sufficient for significant intervention effects. More studies are needed to identify underlying postural or sensorimotor mechanism of injury prevention. Hübscher M, Zech A, Pfeifer K, Hänsel F, Vogt L, Banzer W. Neuromuscular training for sports injury prevention: a systematic review. *Med Sci Sports Exerc.* 2010;42(3):413-21.

## RELIABILITY OF FUNCTIONAL CAPACITY TESTS IN FIBROMYALGIA PATIENTS.

Carbonell-Baeza, A.1,2, Segura-Jiménez, V.2, Álvarez-Gallardo, I.C.2, Castro-Piñero, P.1, Ruiz, J.R.2, Delgado-Fernández, M.2, Aparicio, V.A.2,3

**Introduction** The assessment of functional capacity in fibromyalgia patients is important for determining the efficacy of treatment interventions. Specially, due to the presence of reduced functional capacity in these patients. Studies analyzing the reliability of fitness test in this population are needed. The aim of this study was to determine the reliability of a functional capacity test battery in female fibromyalgia patients. **Methods** One hundred and three fibromyalgia patients ( $51.2 \pm 9.1$  years) performed the following tests twice (7 days interval test-retest): chair sit and reach, back scratch, handgrip strength, arm curl, chair stand, 8 feet up & go and 6-minute walk. A paired t-test was used to compare mean differences between measurements. Intraclass correlation coefficient (ICC), 95% confidence interval for the ICC, standard error of the measurement (SEM) and Bland-Altman plots were analyzed. **Results** Significant differences between test and retest were found in four tests: back scratch ( $P < 0.05$ ), arm curl, chair stand and 8 feet up & go (all,  $P < 0.001$ ) tests. We found high test-retest reliability in all tests (ICCs from 0.83 to 0.96). The SEMs obtained were: 4.5 and 3.8 cm for chair sit and reach and back scratch, respectively; 2.1 kg for handgrip strength; 1.5 and 1.2 repetitions for arm curl and chair stand, respectively, 0.8 s. for 8 feet up & go and 32.6 m. for 6-minute walk tests. The Bland-Altman plots 95% limits of agreement for the different tests were: chair sit and reach (12.54, -12.78 cm), back scratch (11.51, -9.31 cm), handgrip strength (6.16, -5.72 Kg), arm curl (5.90, -3.16 repetitions), chair stand (4.32, -2.30 repetitions), 8 feet up & go (1.75, -2.57 s.) and 6 minute walk (95.41, -87.2 m). **Discussion** Despite there were significant differences in back scratch, arm curl, chair stand and 8 feet up & go tests, the mean difference between test and retest were only 1 cm, 1 repetition for the next two tests and 0.4 s., respectively. The tests showed a good reliability and can be recommended for evaluating functional capacity in fibromyalgia patients. These results are in agreement with the studies of Manerkoppi et al. (1999) and Pankoff et al. (2000) that concluded that the 6-minute walk test is a reliable measure in people with fibromyalgia. **References** Mannerkorpi K, Svantesson U, Carlsson J, Ekdahl C. ## EFFECTS OF 9 WEEKS OF WHOLE BODY VIBRATION VS. UNSTABLE SURFACE TRAINING ON STRENGTH IN POSTMENOPAUSAL WOMEN

Del Cerro, N., Alcaraz, P.E., Rubio, J.A.

UCAM (Murcia)

**Introduction** One of the biggest expenses in the health sector is caused by hospitalization and intervention of injuries resulting from falls in older people. Thus, the need to create training protocols focused on one of the main factors that cause falls: the loss of strength in the ankle stabilizing muscles which leads to functional instability (3). **Methods** We conducted a quasi-experimental design intra-and inter-subject with a control group of 39 sedentary postmenopausal women ( $58.8 \pm 1.6$  years,  $73.5 \pm 8.9$  kg,  $1.56 \pm 0.06$  m). The participants were divided according to their BMD at three experimental groups and control group (G4). The experimental groups performed an incremental training, WBV (G1), unstable surface (G2) and floor (G3), for 9 weeks 3 sessions/week. All participants maintained a static position of semi-squat and every 6 times (1-0-5, 100bpm) performed ankle plantar flexion. At the beginning and in the end of the process it was assessed maximum isometric and isokinetic ankle plantar-dorsal flexion and eversion-inversion, at angular velocities of  $60^\circ \bullet s$  and  $120^\circ \bullet s$ . **Results** Significant differences, between pre-test and post-test, were observed for isokinetic strength in G1 values were 0.021 in dorsal flexion at  $60^\circ \bullet s$ , and 0.004 to  $120^\circ \bullet s$ ; 0.032 in eversion and 0.001 in inversion at  $60^\circ \bullet s$ ; and 0.018 in eversion y 0.001 in inversion at  $120^\circ \bullet s$ . For G2, values were 0.003 in plantar flexion at  $60^\circ \bullet s$ ; in eversion 0.000 and inversion 0.012 at  $60^\circ \bullet s$ ; and 0.001 in eversion at  $120^\circ \bullet s$ . For isometric strength in G2, values were 0.032 in eversion and 0.007 in inversion. **Discussion** Concerning ankle dorsal flexion, the values of G1 were improved, and as for eversion as inversion in all angular velocities. Due to the position of instability, the gathered strength is added to the MVC (maximum voluntary contraction) of the dorsal flexors through vibration training (1). In group G2, there were improvements in plantar flexion as both investment and investment due to the dynamic instability caused by movement soft surface since

it has a continuous contraction of the musculature (4). In this case, both trainings, unstable surface and wbv, improved significantly the strength values of the stabilizing musculature ankle. Moreover, the unstable surface training improves the muscle strength which deficits are more related to the risk of falls. References 1. ### **WHOLE-BODY CRYOTHERAPY <-110 °C> DO NOT AFFECT VERTICAL JUMP PERFORMANCE AFTER HIGH-INTENSITY EXERCISE**

Vieira, A.1, Ferreira-Júnior, J.B.1, Cleto, V.A.1, Vieira, C.1, Soares, S.1, Magalhães, I.J.1, Simões, H.G.2, Do Carmo, J.1, Bottaro, M.1

1: UNB (Brasília, Brazil), 2: UCB (Brasília, Brazil)

**Introduction** Cryotherapy involves the application of any substance that results in withdrawal of heat energy from the body (Knight, 2000). For decades has been used as part of strategy to enhance recovery post heavy exercises and sports performance. A recent modality of cryotherapy, known as whole-body cryotherapy (WBC), has been using very cold air (-110°C) instead of traditional modalities such as ice pack or cold water (Costello et al., 2012). However, few studies have investigated the effects of WBC after training on functional performance activities such as vertical jump. Therefore, the aim of this study was to verify the effects of WBC on vertical jump parameters performed after high-intensity resistance training. **Methods** Twelve healthy trained males (23.9±5.9 years) participated in the study. On two separated knee-extension resistance training sessions, subjects were assigned in a balanced order to a single bout of 3 min of WBC or rest (control). The resistance protocol consisted of 6 sets of 10 repetitions at 60°.s<sup>-1</sup> for concentric and 180°.s<sup>-1</sup> for eccentric actions in an isokinetic dynamometer (BYODEX System 3). The vertical jump was performed before and after the lower-body resistance training protocol. **Results** There was no difference between both experimental conditions (p>0.05). In addition, pre-post analyzes showed that the vertical jump height decreased (7-11%; p<0.05) after the resistance training protocol for both WBC and control conditions. Also, the power output was reduced during WBC (10%; p=0.005). **Discussion** The main finding of this study was that WBC has not been different of control condition. In addition, it is necessary attention during activities that requires maximal power output after WBC. Richendollar et al., 2006 found similar results using a traditional cryotherapy. According to the authors the reduction in power could be explained by decrease on motor nerve conduction velocity and increase tissue stiffness. Further studies should investigate the effect of WBC for longer recovery period or the use of more than a single bout of WBC between recovery days. **References** Costello JT, Algar LA, Donnelly AE (2012). *Scand J Med Sci Sports*, 22, 190-198. ### **PRESCRIBING AND MONITORING HIGH INTENSITY INTERVAL TRAINING IN CVD**

Christle, J., Pressler, A., Halle, M.

*Technical University of Munich*

The application of interval training in cardiovascular disease has shown great promise. Improvements in physiological, psychological and clinical measures have led to the acceptance of this form of training as superior to moderate training in several populations, including chronic heart disease, coronary artery disease and metabolic syndrome. This has led to novel questions about the best methodologies in prescribing and monitoring this form of training. Until now, the gold standard for prescription of interval (and continuous) endurance training has been the use of maximal exercise testing to establish peak oxygen consumption capacity (VO<sub>2peak</sub>), and to train patients at percentages of VO<sub>2peak</sub>. Monitoring of interval training is performed through a combination of heart rate monitoring and ratings of perceived exertion, both inadequate methods for monitoring patients who typically (1) are not physically active and (2) have irregular heart rate responses to exercise. Therefore this study investigates the utility of using arterial lactate concentrations both in CPX and interval training to superiorly prescribe and monitor interval training in patients with cardiovascular disease. Forty-two stable coronary artery disease patients from a local cardiac rehabilitation clinic volunteered to take part in the study. Stepwise symptom-limited CPX were performed on electronically-braked cycle ergometers, starting at 25W and increasing every three minutes an additional 25W until volitional exhaustion was reached. After approximately one week, patients conducted one bout of 4 x 4 minute cycle ergometer interval training, with load, heart rate, RPE and lactate monitoring. Spearman correlations were conducted for all intensity factors and lactate kinetic curves were visually contrasted with curves for the other factors. No complications during CPX or IT were experienced, and over 85% of target heart rates were reached during IT. Arterial lactate showed the strongest correlations with the other intensity parameters during CPX (VO<sub>2peak</sub> (r<sub>2</sub>= 0.64), HR<sub>peak</sub> (r<sub>2</sub>=0.64), RPE (r<sub>2</sub>=0.72) and W (r<sub>2</sub>=0.54)). However, during IT, arterial lactate kinetics did not match other intensity factor kinetics. Furthermore, arterial lactate kinetic analysis shows that the lower intensities used during recovery intervals does little to reduce overall lactate levels to steady state levels. The primary findings of this investigation suggest that using lactate kinetics may help improve current techniques in interval training prescription and monitoring, in that it adds a parameter that is not dependent on subjective reporting or heart rate variation, and reflects the metabolic environment during training. Further research is necessary to investigate the effect of applying lactate analyses to interval training interventions over longer periods of time and in different patient populations.

#### NOVEL PERIPHERAL TRAINING AS A PRIMER FOR INCREASED GAINS IN FUNCTIONAL CAPACITY IN THE ELDERLY

VanBruggen, M., Pieper, C., Church, T., Johannsen, N., Kraus, W., Welsch, M., Allen, J.

*Duke University, Claude D. Pepper Center OAC, Pennington Biomedical Research Center, Louisiana State University*

**Introduction** From 2005 to 2030 the number of people over 65 will increase by 52% (European Commission, 2005). Aging is associated with a decline in functional capacity (Huang, et al., 2005), increase in disability, and loss of independence. Current exercise guidelines are focused predominantly on whole-body aerobic programs despite evidence to suggest age-associated declines maybe mediated by changes in peripheral muscle beds (vascular function and lean mass) (Fleg, et al., 2005). The FIT for LIFE trial proposes a new paradigm for exercise training in the elderly by initially focusing training on peripheral muscle beds using exercises involving contractions with moderate load and extended duration (RSTS) that causes minimal central cardiovascular stress. **Methods** Elderly subjects who were at risk of losing independence were randomly assigned to: PHASE 1: 4 weeks of training (3 x 1 hour/week) of either: A) aerobic training (AT) which included walking/cycling at 50-85% HRR; or B) RSTS [8 exercises, 3-5 min each at 1 contraction every 4 sec, at ~40-70% of their MVC]. All subjects advanced to PHASE 2: a traditional exercise program, including both AT and resistance training (40 min of AT at 60-85% HRR; 8 sets of 10-15 reps of RT). **Results** Both groups included 54 subjects (age=76±5). After adjustment for baseline, there was a group\*time interaction effect in favor of RSTS for VO<sub>2</sub>peak (19.3 vs. 18.4 mL/kg/min) and 6 minute walk (463 vs. 449m) following PHASE 2 (p<0.05). RSTS also showed greater gains in combined 1RM following both PHASE 1 (+21.3 vs. +3.2 kg, p<0.01) and PHASE 2 (+23.8 vs. +13.6 kg, p<0.01) compared with AT. Data for vascular and muscle physiology outcomes will also be presented. **Discussion** These results suggest RSTS training (compared to AT) may be an effective modality early in a training program to enhance strength, improve aerobic fitness, which may preserve independence in older adults. The underlying mechanisms for these improvements are likely muscle contraction induced hyperemia and local vessel shear stress (Laughlin, et al., 2008). **References** Communication from the European Commission Green Paper (2005). #### THE INFLUENCE OF AGEING AND TRAINING STATUS ON EXERCISE EFFICIENCY AND CYCLING PERFORMANCE

Hopker, J.1, Coleman, D.A.2, Jobson, S.A.3, Von der Haar, T.1, Wiles, J.2, Passfield, L.1

*1: University of Kent (UK), 2: Canterbury Christ Church University (UK), 3: University of Winchester (UK)*

**Introduction** Of the key physiological determinants of performance, VO<sub>2</sub>max has received the most attention with well-documented reductions across the lifespan of approximately 1% per year. By comparison, the influence of ageing on exercise efficiency has received little attention. However, recent publications (Venturelli et al., 2012) and a point-counterpoint (Venturelli & Richardson, 2012; Ortega, 2012) have demonstrated that there is considerable debate on the effects of ageing, exercise efficiency and performance. Consequently, the aim of this study was to assess the effect of training status, age and muscle fiber composition on cycling gross efficiency (GE) and exercise performance. **Methods** Forty males were recruited into one of 4 groups: young and old trained cyclists, young and old untrained individuals. In a series of laboratory visits all participants completed an incremental ramp test to measure their VO<sub>2</sub>max, maximal heart rate (HRmax) and MMP, a submaximal test of GE at a series of relative work rates, and in trained participants only, a 1-hour cycling time trial. Finally, all participants underwent a muscle biopsy of their right vastus lateralis muscle. **Results** A univariate general linear model of VO<sub>2</sub>max and MMP data demonstrated significant main effects of training status (P<0.01), and age (P<0.01), whereas HRmax was only affected by age (P<0.01). At relative work rates of 50% and 60% MMP, 60% MMP 60 rev.min<sup>-1</sup>, and 60% MMP 120 rev.min<sup>-1</sup> there was an effect of training status on GE (P<0.01), the effect of age was only significant at 50% MMP and 60% MMP (P<0.01). The proportion of type I muscle fibers in the vastus lateralis muscle was higher in the trained groups (P<0.01), with no effect of age. Further, performance power output was predicted by performance VO<sub>2</sub> and GE with standardized beta coefficients of 0.94 and 0.34 respectively. Independently, only age significantly added to the prediction for parameters in the model where MMP was included (standardized beta coefficients of 1.21 for MMP and 0.45 for age). **Discussion** These data demonstrate that key physiological factors influencing endurance exercise performance are detrimentally affected by ageing, although exercise training can potentially moderate some of these effects. Further, even though biological ageing provides an influence, oxygen cost is the main factor affecting exercise performance. Therefore, the reductions in exercise performance with age are mostly likely influenced by lower exercise efficiency. **References** Ortega JD. #### THE EFFECTS OF TRAINING INVOLVING SIMULTANEOUS WALKING WITH ISOMETRIC EXERCISE ON RESTING BLOOD PRESSURE IN YOUNG HEALTHY ADULTS

Baross, A.W.1, Hodgson, D.1, Padfield, S.2, Swaine, I.L.2

*1. Sport and Exercise Science, UON (UK) 2. Sport and Exercise Science, CCCU (UK)*

**Introduction** In separate studies, walking and isometric training have been shown to reduce resting blood pressure. Combined aerobic and resistance training, where participants undertake one element of the training programme followed by the second has been seen to produce larger reductions in resting blood pressure (BP) compared to a single exercise protocol such as, walking (Calders et al. 2010). To date, no studies have investigated the effects of simultaneous, combined training on resting BP. Therefore, this study aims to determine the effect of 6-weeks simultaneous, combined isometric (handgrip) and walking training (HGW) on resting systolic (SBP) and diastolic blood pressure (DBP), compared to a walking training programme (WLK). **Methods** A total of 26 healthy sedentary participants (male, n = 16; female, n = 10; age 21.3±2yrs; mass 69.2±12.5kg; height 170.4±9cm) were randomly allocated, into three groups walking training (WLK; n=12), simultaneous walking and handgrip training (HGW; n=12) or controls. Resting SBP, DBP and mean arterial blood pressure

(MAP) were measured at baseline and post-training. Analysis of covariance was used to determine if post-training measures were significantly different to baseline, using the baseline values as the covariate. Results The preliminary data show that, in the three groups, resting SBP was reduced after the 6-weeks, by -12.3, -6.7 and -0.4 mmHg, for HGW, WLK and CON groups respectively. DBP was reduced by -6.4, -3.3 and -0.2 mmHg and MAP by -3.3, -2.2 and -0.2 mmHg. Whilst all changes in the HGW and WLK groups were significant ( $P < 0.05$ ), there were no significant changes in any of the resting blood pressure measured in the control group. Discussion The results indicate that combining walking with simultaneous handgrip isometric exercise, caused greater reductions in resting SBP, DBP and MAP, than walking only. The magnitude of the changes in the HGW group are substantially greater than those observed in previous walking only studies (7.4-1.9 mmHg; Murphy et al. 2007) despite a considerably shorter training intervention. The reductions are also greater than many of the previous studies involving handgrip only training in normotensive participants (McGowan et al. 2007). These sizeable reductions in resting BP emphasise the antihypertensive potential of simultaneous combined exercise training especially since they are evident even in individuals whose BP is considered to be in the normal range. ### DOES HbA1c RESPOND TO STRENGTH TRAINING IN POST-MENOPAUSAL FEMALES?

Viljoen, J., Christie, C.

*Rhodes University*

**Introduction** Physical activity is fundamental to the management of glycaemic control, and it has been reported that for all levels of HbA1c habitually active individuals are protected against risk (Reddigan et al., 2012). However, there is no data on strength training in a cohort of post-menopausal women and whether this is effective in improving glycaemic control in this population. As such, the purpose of this study was to evaluate the effect of 12 weeks of progressive strength training on glycated haemoglobin in healthy post-menopausal females. **Method** Females ( $n=30$ ) aged  $59.76 \pm 3.07$  years were recruited to a 12 week progressive resistance training programme. Participants were post-menopausal, non-smokers, and previously sedentary. No individuals were taking hormone replacement therapy and none were diagnosed diabetics. All were screened by a medical practitioner prior to commencing the study. Training took place on five days of the week and each session lasted 30 minutes. Ten exercises were completed at 70 - 90% of the pre-determined 1-repetition maximum (1RM). Each exercise was repeated for 12 repetitions and for three sets. Progression took place every four weeks following a re-evaluation of the 1RM. Measurements of glycated haemoglobin (HbA1c) were taken at baseline and every four weeks thereafter. Individuals presented for blood withdrawal at 08h30 at a registered commercial laboratory on specified days. A Dimension® clinical chemistry system assay (Flex® reagent cartridge) was used to quantify the HbA1c in the sampled blood by measuring both total haemoglobin content as well as haemoglobin A1c presence. Participants were requested to ensure that dietary intake remained unchanged and this was monitored via three day dietary recall diaries submitted every four weeks. Results HbA1c was measured at  $5.66 \pm 0.54\%$  at baseline and at  $5.81 \pm 0.47\%$  after 12 weeks. The increase of 0.15% was not significant ( $p=0.15$ ) and does not infer an increased clinical risk. Carbohydrate intake during the 12 week programme remained unchanged ( $p=0.658$ ). **Discussion and Conclusion** Previously sedentary females in this sample presented with an HbA1c level equivalent to a multivariate adjusted hazard ratio of 1.86 for diabetes and 1.23 for cardiovascular disease (5.5 - 6.0% category) (Selvin et al., 2010). The addition of exercise to habitual lifestyles did not alter this hazard ratio. CHO ingestion is known to influence HbA1c levels and analysis of diet recalls indicated that carbohydrate (CHO) intake was  $188.92 \pm 60.70$ g at baseline and  $200.14 \pm 83.62$ g at week 12 ( $p=0.658$ ). It is probable that either 12 weeks is insufficient for changes in HbA1c, or HbA1c is not sensitive to exercise without concomitant dietary modifications, as dietary adjustments have previously been found to have an effect on HbA1c levels (Kang & Kim, 2012; Schulze et al., 2004; Xu et al., 2007). Further research into the relationship of physical activity and glycated haemoglobin is required.

### CHANGES IN METABOLIC PROFILES AND MUSCLE FUNCTION OF ELDERLY MEN AFTER ECCENTRIC OR CONCENTRIC TRAINING

Chen, T.C.1, Chen, H.L.1, Tseng, W.C.1, Huang, G.L.1, Tseng, K.W.2, Nosaka, K.3

1: NCYU (Taiwan), 2: TPEC (Taiwan), 3: ECU (Australia)

**Introduction** Performing eccentric exercise of the knee extensors (KE) once a week for 8 weeks has been shown to improve resting blood lipid profile and insulin sensitivity in young women (1). It is possible that eccentric training (ET) is more effective than concentric training (CT) for improving metabolic profiles and muscle function, but no previous studies have compared ET and CT for their effects on elderly individuals. ET is better to be introduced to elderly individuals without muscle damage, thus the training should be progressively increased from low intensity (2). The present study investigated the effects of 12-week progressive ET versus CT of the KE on muscle function and blood profiles related to metabolic syndrome in elderly men. **Methods** Healthy but untrained elderly men ( $65.9 \pm 4.7$  y) were assigned to either a progressive ET or CT group ( $n=13$ /group) based on their pre-training 1RM concentric strength (1RMcon) of the KE. The ET and CT were performed once a week for 12 weeks using 10~100% and 50~100% of 1RMcon, respectively, consisting of 3 or 6 sets of 10 contractions of the KE for each leg, on a leg extension machine. Blood samples were taken one week before the first training session and 4 days after the last training session, and analysed for serum triacylglycerols (TG), total (TC), high-density lipoprotein (HDL) and low-density lipoprotein cholesterol (LDL), glucose (GLU), insulin, homeostasis model assessment (HOMA), whole blood glycosylated hemoglobin (HbA1c) and oral glucose tolerance test (OGTT). Measurements of resting heart rate, systolic and diastolic blood pressure, and 8 functional physical fitness tests (e.g. 30-second chair stand: 30SCST, 6-minute walk) were also performed in the same time points as those for blood samples. Indirect markers of muscle damage were assessed before, immediately after, and 2 and 4 days after the first and last training sessions. Changes in these variables over time were compared between groups by a two-way repeated measures ANOVA. Results No or little indications of muscle damage were evident after neither ET nor CT. Most blood variables changed significantly from pre- to post-training, but greater improvement ( $P < 0.05$ ) of lipid profile (TG, TC, HDL, LDL, GLU, HbA1c, OGTT) and insulin resistance (resting insulin, HOMA) were found for ET than CT. Both ET and CT resulted in improvement ( $P < 0.05$ ) of most of functional physical fitness tests (e.g. ET: 44%, CT: 31% in 30SCST) and muscle function (e.g. ET: 53%, CT: 36% in 1RMcon), but the magnitude of the improvement was greater ( $P < 0.05$ ) for ET than CT. **Discussion** These results show that ET of KE improved metabolic profiles and muscle function better than CT without muscle damage. It is concluded that ET could produce greater improvement of quality of life for elderly individuals when compared with CT. References 1. Paschalis et al. MSSE. 43:64-73, 2011 2. Chen et al. EJAP. ## NO EFFECT OF 16 WEEKS' ENDURANCE TRAINING ON RATE OF LIPID OXIDATION DURING SUBMAXIMAL EXERCISE IN OBESITY AND TYPE 2 DIABETES.

O'Hagan, C., Rodrigues-Krause, J., Medlow, P., Krause, M., De Vito, G., Davison, G., Colleran, G., Newsholme, P., Murphy, C., Boreham, C.

*Sheffield Hallam University*

**Introduction** The ability to oxidise lipids is impaired in obesity and Type 2 Diabetes (T2D). It has been suggested that exercise training at the intensity which elicits the maximal rate of lipid oxidation may improve oxidative capacity and insulin sensitivity (1). The aim of this study was to compare the effects of training at different intensities on lipid oxidation rate, and to determine whether the effect differs in obese participants with and without T2D. **Methods** Seventeen obese males with Type 2 Diabetes (T2D; age  $58.4 \pm 7.0$  years, BMI  $32.8 \pm 4.3$  kg.m<sup>-2</sup>) and 16 BMI-matched controls (CON, age  $49.9 \pm 5.3$  years, BMI  $30.9 \pm 3.1$  kg.m<sup>-2</sup>) participated. Participants completed a submaximal incremental treadmill test for determination of the intensity corresponding to ventilatory threshold (Tvent); maximal rate of lipid oxidation (Fatmax-rate) and the intensity at which this occurred (Fatmax-intensity) were determined by indirect calorimetry during four 6-minute bouts of exercise at 25%, 35%, 45% and 60% of each participant's estimated VO<sub>2</sub>max. Participants were then randomly assigned to train at either Fatmax intensity or Tvent intensity for 16 weeks (walking, 3 times per week, 30 minutes per session). Between-group (T2D vs CON) differences at baseline were compared using a T-test; a three-way mixed ANOVA (time x intensity x disease) was used to compare training responses between groups. Data are expressed as mean  $\pm$  SD, significance was set as  $p < 0.05$ . **Results.** Baseline differences: There were no significant differences in Fatmax-rate at baseline (CON:  $504 \pm 127$  mg.min<sup>-1</sup>, T2D:  $525 \pm 153$  mg.min<sup>-1</sup>) nor Fatmax-intensity (CON:  $49.2 \pm 6.7$  %VO<sub>2</sub>maxEst, CON, T2D:  $45.5 \pm 10.1$  %VO<sub>2</sub>maxEst). **Effects of training:** Adherence to the 48-session training programme was good (mean number of sessions completed:  $45 \pm 7$ , mean difference from prescribed training heart rate  $0.5 \pm 7.0$  bpm). Fatmax-rate did not change in any of the groups after training; Fatmax-intensity decreased in CON-Tvent only (pre training:  $51 \pm 6$  % VO<sub>2</sub>maxEst, post-training  $35 \pm 8$  % VO<sub>2</sub>maxEst). **Discussion** These results support some previous findings that the maximal rate of lipid oxidation and the exercise intensity at which it occurs do not differ between obese T2D and obese controls (2); other authors have reported that maximal rate of lipid oxidation is lower in T2D (3). Furthermore, these results contradict previous findings of increased rate and intensity of maximal lipid oxidation after Fatmax training in type 2 diabetes (2,4) and the obese (2,5) and do not demonstrate the proposed benefits of training at Fatmax-intensity. **References** 1. #### USEFULNESS OF REACTIME SYSTEM IN TRACK AND FIELD

Dolenec, A., Bavdek, R., Strojnik, V.

*University of Ljubljana, Faculty of sport*

**Introduction** In track and field, reaction time has been described as the time elapsed between the sound of the starter's gun, and the first reaction of an athlete. There is a rule in major competitions that the athlete cannot react faster than 100 ms. ReactTime System (Lynx System Developers, Inc., Haverhill) is one of the official IAAF false start detection systems. It is known that in many young and low level athletes this system shows unexpected long reaction time. The aim of the present study was to compare reaction time measured with the ReactTime System with time calculated from force plate data in different level athletes. **Methods** 22 athletes ( $74.6$  kg  $\pm$  12.3;  $179.5$  cm  $\pm$  8; 23 years  $\pm$  7.2) with different knowledge in sprint start participated in the experiment. Each athlete performed 3 sprint starts with official track and field starting block equipped with the ReactTime System, and standing on a force plate (Kistler, Winterthur). The trial with the shortest reaction time of each athlete according to the ReactTime System was used for further analysis. Hierarchical Cluster analyzes and correlation (Pearson's coefficient) statistics were made. **Results** Reaction times were  $0.224$  s  $\pm$  0.109,  $0.115$  s  $\pm$  0.031 measured with the ReactTime System and the force plate respectively. When the athletes were analyzed as a single group there was no correlation in reaction times as measured with different methods. As the athletes were divided into fast (N=11) and slow (N=11) group according to the ReactTime System data ( $0.143$  s  $\pm$  0.018 and  $0.305$  s  $\pm$  0.100, respectively) correlation coefficient between reaction times measured with the ReactTime System became statistically significant in the fast group only ( $r=0.675$ ;  $P=0.023$ ). **Discussion** Reaction times measured with the force platform for all athletes, and reaction times measured with the ReactTime System for the first group were similar to reaction times found by other investigators (Mero and Komi, 1990) while reaction times measured with the ReactTime System for the second group were much longer and were not found in the literature. Also there was no correlation between reaction times measured with the ReactTime System, and the force plate for the second group. Athletes in the second group could be characterized as rookies in sprint start from the starting block. As the ReactTime System showed unreasonably longer reaction times as the force plate in the athletes that are not very familiar with starting blocks we conclude that the ReactTime is not proper system for measuring reaction times in these athletes. It is presumed that the reason is in accelerometer technology and data transformation used by the ReactTime System as exact procedures are not available. **References** Mero A, Komi PV (1990). *Eur J Appl Physiol*, 61, 73-80.

#### SEASONAL PROGRESSION OF MAXIMAL SPRINTING AND AEROBIC SPEEDS IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS

Mendez-Villanueva, A.

*ASPIRE, Academy for Sports Academy*

**Introduction** At least for some playing positions, maximal sprinting speed (MSS) (Mendez-Villanueva et al., 2011) and estimated maximal aerobic speed (MAS) have been shown to impact young soccer player's locomotor performance during games (Buchheit et al., 2011;

Mendez-Villanueva et al., 2013). However, MSS and MAS may respond differently to systematic training at different stages of growth and maturation in children and adolescents (Malina et al., 2004). In this regard, children and adolescents are often suggested to be more responsive to physical training during periods of accelerated improvements, the so-called "windows of opportunity". Thus, the ability to identify those periods of accelerated improvements in MSS and MAS in young soccer players might be important to maximize their physical development. Accordingly, the aim of this study was to quantify, in highly-trained young soccer players of varying age and maturational status, the magnitude of change in both MSS and MAS within a competitive season. Methods Hundred and five players across five age groups (U13-U17) from the same soccer academy were assessed for MSS and MAS at 9 months intervals (i.e., a season) over a 3-y period. Results All the age groups showed moderate-to-large season improvements in MSS (mean changes: +4.4% to +5.4%: Cohen's effect sizes (ESs)=0.55 to 0.93) and MAS (mean changes: +2.2% to +6.3%: ESs=0.49 to 0.81). The largest mean differences in the seasonal responses for MSS occurred between the U14 and U17 groups (ES=0.59 ± (CI:0.58) and qualitative indications of likely greater improvements in the U14 group). For MAS, the largest difference in seasonal response was found between U14 and U16 (ES= 0.98 ± (CI:0.51), with almost certainly greater improvements in the U14 group). Discussion Present results confirm that the magnitude of seasonal changes in physical capacities are age-group dependent. In the present academy, the greater improvements in MSS and MAS over a competitive season appeared to occur in the U14 group. References Buchheit M, Mendez-Villanueva A, Simpson BM, and Bourdon PC. ## REPRODUCIBILITY OF PHYSIOLOGICAL, NEUROMUSCULAR AND PERCEPTUAL RESPONSES TO SMALL-SIDED GAMES IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS

Mayer, N.1,2, Bosquet, L.1,2, Plaine, F.1, Marles, A.1, Jullien, H.1, Lambert, P.1, Buchheit, M.1,3

*1French Football Federation (Clairefontaine, France) 2Faculty of Sport Sciences (Poitiers, France) 3Aspire (Doha, Qatar)*

Introduction While there is extensive research on the acute physiological responses to various forms of SSG in soccer (Hill-Hass, 2012), little is known about their delayed neuromuscular effects (i.e. post 24h), which can have carry-over effects on subsequent performance. Additionally, the reliability of neuromuscular load during and after SSG (e.g., acceleration, post SSG jumping performance) has been poorly described. Understanding the acute and delayed physiological effect of SSG in young soccer players is important for the optimal design and periodization of training drills in this population. The aim of the present study was therefore to examine acute and delayed physiological and perceptual responses to 4 vs. 4 SSG in highly-trained adolescent soccer players. Methods Eleven highly-trained U14 soccer players from an elite academy participated, 2 months apart, in 4 x 3-min 4 vs. 4 SSG (40m x 16.5m, no goal keeper, free touch). Heart rate (HR), rate of perceived exertion (CR10 scale, RPE) and running patterns were recorded with GPS (GPSport, 15 Hz). Average HR, total distance covered (TD), distance >19 km/h, peak game speed (GS), maximal acceleration (Amax), number of acceleration (>2.5 m/s/s, #Acc) and distance covered >2.5 m/s/s were collected. Counter movement jump height was measured pre, immediately post and 24h post SSG. Perception of muscle soreness (1-5 scale) was collected the day of the SSG and the following. Results Coefficient of variations (CV) and intraclass correlation coefficients (ICC) were: HR: CV 2.1%, 90% confidence limits (1.5;3.7) and ICC, 0.85(0.56;0.95); RPE: 15%(1;25) and 0.34(-0.19;0.71); TD: 6.4%(4.7;10.3) and 0.55(0.07;0.82); distance >19 km/h: 105%(69;227) and 0.25(-0.32;0.68); GS: 13%(9.5;21.5) and 0.03(-0.48;0.52); Amax: 10.1%(16.4;16.6) and -0.35(-0.72;0.18); #Acc: 35%(26;61) and 0.22(-0.31;0.65); distance >2.5 m/s/s: 51.1%(35.3;93.4) and 0.15(-0.38;0.60); CMJ pre : 6.4%(4.7;10.3) and 0.53(0.05;0.81); CMJ post: 4.9%(3.6;8.0) and 0.80(0.51;0.93); CMJ post 24h : 2.6%(1.9;4.2) and 0.95(0.86;0.98); soreness pre : 30%(22;53) and -0.27(-0.68;0.26); soreness post 24h: 31%(22;54) and 0.29(-0.24;0.69). Discussion Present results confirm the moderate reliability of HR, RPE and TD during SSG (Hill-Haas, 2011), but show for the first time that acute neuromuscular responses display very large CVs, which may limit the use of such drills to accurately target these factors. The good to moderate reliability of post SSG CMJ and perceived soreness has to be taken into account when interpreting delayed neuromuscular responses. ## RELATIONSHIP BETWEEN EFFICIENCY OF PISTOL SHOOTING AND SELECTED PHYSICAL-PHYSIOLOGICAL PARAMETERS OF POLICE

Kayihan, G.1, Ersoz, G.2, Ozkan, A.3, Koz, M.2

*1: Sakarya University School of Physical Education and Sports (Turkey) 2: Ankara University 3: Bartın University*

Introduction Since the duty of law enforcement is a high-risk profession and often accompanied by high levels of acute stress, personnel have to endure adverse conditions that might arise from this risk, and have to expend very high physical efforts when encountering crime. Police officers may suddenly find themselves in a life-threatening situation (Anderson, Litzenberger, & Plecas, 2002; Sztajnkrzyer, Callaway, & Baez, 2007; Vrij & Dingemans, 1996). Consequently policeman should always be physically, physiological and mentally fit, in compliance with their work and as stated above, for the safety and peace of the community. Therefore, the aim of this study was to investigate the relation between selected physical-physiological parameters and efficiency of pistol shooting. Methods In this study, 237 male volunteers, studying at Police Academy (Ankara) within the age range of 19-20 years old were investigated. The physical fitness levels of the students were evaluated by using valid and reliable physical fitness test batteries. The Spielberger Trait-State Anxiety Inventory for anxiety level and "Polar Team2 Pro" device for heart rate were used as data collection tools. The efficiency of pistol shooting was evaluated by the total points of the bullets which hit the target from 10 metres Results The correlation coefficient between the result of pistol shooting achievement and change in heart rate, anxiety variability, mean heart rate during shooting, coordination, state anxiety, maximal heart rate during shooting, balance, hand-grip strength, biceps circumference, femur diameter, wrist circumference and flexibility ( $p<0.005$ ) were significant. Discussion Some studies indicated that the correlation coefficient between the result of the pistol shooting achievement and selected physical fitness variables were significant (Anderson & Plecas, 2000; Kayihan, 2010; Vučković & Dopsaj, 2007) In general, the results of our study have supported previous studies and produced the profile of a good shooter. This result could be useful for choosing police for Special Forces, Public Security, Anti-Terror and Smuggling branches in which shooting skills are important. In addition, we suggest that this result could be used for choosing marksmen and guiding shooting training. References Anderson, G. S., Litzenberger, R., & Plecas, D. ### ASSOCIATION BETWEEN PHYSICAL FITNESS, MOTOR COMPETENCE, COGNITIVE SKILLS AND INTELLIGENCE LEVEL IN 15 YEAR-OLD ADOLESCENTS

Hafsteinsson, T.1, Sveinsson, T.2

1: RU (Reykjavik, Iceland), 2: UI (Reykjavik, Iceland)

ASSOCIATION BETWEEN PHYSICAL FITNESS, MOTOR COMPETENCE, COGNITIVE SKILLS AND INTELLIGENCE LEVEL IN 15 YEAR-OLD ADOLESCENTS Introduction Participation in sport has been associated with less smoking and alcoholic consumption in adolescents (Thorlindsson et al., 1994). The aim of this study was to examine the association between high level sport participation, physical fitness, motor competence, cognitive skills and intelligence level in adolescents. Methods For the study, 141 adolescents from two elementary schools in Reykjavik, Iceland, were randomly selected to participate. Also, 34 adolescents from the Icelandic youth national team programs (INYTP) in football, team handball and athletics participated. Fitness was tested by four standardized tests: 20 m sprint, 6 min run, standing long jump and sit-and-reach test. Motor competence was measured with Movement Assessment Battery for Children-2 (MABC-2) (Henderson et al., 2007). Cognitive skills were measured with the Ottawa Mental Skills Assessment Tool (OMSAT-3) (Durand-Bush et al., 2001). Intelligence was assessed by the Raven Standard Progressive Matrices (Raven SPM) (Raven et al., 2003). Results The INYTP group scored significantly higher on the fitness tests than the school group (z-score: 2.4 vs -0.8,  $p < 0.05$ ). Also they scored higher on MABC-2 (11.1 vs 9.2,  $p < 0.01$ ), on OMSAT-3 (209 vs 189,  $p < 0.01$ ) and on Raven SPM (48.5 vs 46.0,  $p < 0.01$ ). Discussion The results indicate that high performance youth in sports, not only have higher fitness level than other adolescents of the same age, but also have better motor control, cognitive function and intelligence level. This suggests that sport participation at high level may positively affect both physical and mental skills in adolescents. #### POST-RESISTANCE EXERCISE HYPOTENSION IN NORMOTENSIVE AND HYPERTENSIVE MEN: HEMODYNAMIC AND NEURAL MECHANISMS

Forjaz, C.L.M., Queiroz, A.C.C., Sousa, J.C.S., Cavalli, A.A.P., Silva Jr, N.D., Costa, L.A.R., Tobaldini, E., Montano, N., Ortega, K., Mion Jr, D., Tinucci, T.

*University of São Paulo; University of Milan.*

Introduction A session of resistance exercise promotes post-exercise hypotension in normotensive (NT) and hypertensive (HT) subjects. In NT, mechanisms involved in blood pressure (BP) response have been studied, but in HT, they are unknown. The aim of this study was to compare BP responses and its hemodynamic and neural mechanisms after a session of resistance exercise in NT and HT men. Methods Fourteen NT (44 ± 3 years) and 12 unmedicated HT (50 ± 3 years) underwent 2 experimental sessions, performed in random order: control (40min of rest) and exercise (6 exercises, 3 sets until moderate fatigue, 50% of 1 RM). BP, cardiac output (CO), heart rate (HR) and HR variability were measured before and after 45min and 7h of the interventions. Ambulatory BP was monitored for 24h. Results At 45 min post-exercise, systolic BP decreased similarly in both groups (NT= -8±2 and HT= -13±2 mmHg). Diastolic BP also decreased, but HT presented a greater decrease (NT= -4±1 vs. HT= -9±1 mmHg,  $P < 0.05$ ). In some subjects, exercise promoted a reduction in CO and, in another part of the subjects, exercise promoted a reduction in systemic vascular resistance (SVR). Stroke volume decreased and HR increased similarly in both groups (NT= -14±5 and HT= -11±5 mL; NT= +13±3 and HT= +13±2 bpm). Cardiac sympathovagal balance increased and baroreflex sensitivity decreased similarly between groups after the exercise (NT= +14±6 and HT= +9±3; NT= -5.2±1.2 and HT= -4.3±1.5 bpm/mmHg). After 7h, in both groups, exercise had no effect on any variable. BP, HR and rate pressure product 24h, awake and asleep means were similar between sessions in both groups. Discussion A bout of resistance exercise promotes post-exercise hypotension in NT and HT middle age men. Diastolic BP decrease is greater in HT. The hemodynamic determinant of post-exercise hypotension (decrease in CO or SVR) changes from one subject to another. BP decrease is accompanied by an increase in HR due an increase in cardiac sympathovagal balance and a reduction in baroreflex sensitivity. The hypotensive effect is not maintained under ambulatory conditions. Financial support FAPESP 2009/18219-3 e 2011/06689-5, Capes, CNPq, Pró-Reitoria de Graduação USP.

#### INTER-INDIVIDUAL DIFFERENCES IN CONTROL OF ALVEOLAR CAPILLARY BLOOD VOLUME IN EXERCISE AND HYPOXIA: ANY RELATION WITH INCREASED MIROVASCULAR FILTRATION?

Bartesaghi, M.

*Laboratory of Clinical Physiology and Exercise, Milano-Bicocca*

We explored the hypothesis that inter-individual differences of the air-blood barrier might influence the recruitment of alveolar capillaries in exercise and on hypoxia exposure, conditions causing an increase in microvascular filtration. Twenty two subjects were studied at sea level (SL) and in hypobaric hypoxia (HA, 3269m). We measured: diffusion sub-components capillary blood volume (Vc) and membrane diffusion capacity (Dm), normalized to alveolar volume (Va); respiratory resistance (Rrs) and reactance (Xrs) by forced oscillatory technique. Group1 subjects (N=11) showed lower rest values (mean±SD) of Vc/Va at SL and HA, compared to Group2 (N=11): at SL, 16.1±6.8 ml/L vs 25±7.7, respectively; in HA, 15.9±5.7 vs 19.0±6.0, respectively. During exercise, Vc/Va, an index of alveolar capillary extension, increased

in Group1 at SL ( $26.3 \pm 8.6$ ) and at HA ( $28.75 \pm 10.2$ ) while in Group2 it showed a decrease or not significant change. In hypoxia, the frequency dependence of Rrs (difference between Rrs measured at 5 and 20Hz) increased 4 fold from 0.008 to 0.3 cmH<sub>2</sub>O  $-(s^{-1})^{-1}$  in Group2 and only 1.5 fold, from 0.02 to 0.03 in Group1. Furthermore, in HA, Xrs at 5Hz decreased significantly more in Group2. Both Rrs and Xrs data suggest greater heterogeneity of alveolar ventilation and increase in extravascular water in Group2 in HA. We hypothesize that in exercise and hypoxia, the adaptive response of Group1 favours capillary recruitment and oxygen diffusion, while in Group2 de-recruitment limits microvascular filtration. We suggest that Group1 has a superior control on extravascular lung water, unlike Group2 that appears more prone to develop interstitial lung edema.

### TOTAL HEMOGLOBIN MASS IN RELATION TO BLOOD AND PLASMA VOLUMES: LONGITUDINAL INSIGHTS INTO THE ROLE OF GENDER

Pringle, J., Fudge, B., Spilsbury, K., Turner, T., Wraith, E., Ingham, S.

*English Institute of Sport*

The optimized carbon monoxide rebreathing method is used to determine total hemoglobin mass (tHbmass) and blood volume (BV), with high precision (<1% test-retest variation). tHbmass and BV are predictably linearly related, and changes in tHbmass are classically reflected in commensurate changes in BV. However, there is a paucity of data on tHbmass and BV of elite female athletes or the constancy of these measures over time. We sought to characterize the relationship between tHbmass, BV and PV in males and females, and to identify the nature of their change over longitudinal observations. Over a 20 month period, 21 females and 33 males (age  $26 \pm 6$  y (mean  $\pm$  SD); body mass  $66.7 \pm 9.5$  kg) from British national teams (athletics, triathlon, swimming) were underwent repeat assessments for tHbmass and BV (average visits: 3.7; range: 2 - 18; total of 200 observations). Significance in difference or relationship was declared at  $P < 0.05$ . tHbmass was significantly lower in females than males ( $13.0 \pm 1.8$  vs.  $14.9 \pm 1.9$  g/kg; independent t-test) as was BV ( $104 \pm 14$  vs.  $109 \pm 14$  mL/kg). tHbmass was significantly related to BV ( $r^2 = 0.86$  and  $0.83$  in females and males, respectively). Females showed a significantly greater blood volume per unit of Hbmass than males ( $8.0 \pm 0.4$  vs.  $7.3 \pm 0.4$  mL/gHb), although PV relative to body mass was identical ( $65.2 \pm 9.0$  vs.  $64.9 \pm 9.0$  mL/kg). Notwithstanding the potential for differing time course in their acute temporal changes, longitudinal changes in tHbmass (in g/kg) were significantly related to changes in BV (in mL/kg) in females ( $r^2 = 0.78$ ) but less so in males ( $r^2 = 0.31$ ). There was no relationship between changes in tHbmass (in g or g/kg) and changes in traditionally determined [Hb] or ([Hct]), although changes in the latter were significantly related to changes in PV in males ( $r^2 = -0.56$ ), but not in females ( $r^2 = -0.24$ ). Neither hemoglobin concentration nor hematocrit offer sufficient insight into an athlete's tHbmass or its longitudinal changes. As expected, female athletes of similar performance standard have lower tHbmass and lower BV than males, relative to body mass, but have similar PV. Females have greater BV per unit of Hbmass. The stronger relationship between changes in tHbmass and BV (and PV) in females may suggest a gender-specific role in the regulation of erythropoiesis and/or neocytolysis that is possibly BV mediated.

### HEMODYNAMIC CHANGES DURING DEEP DIVING BY MEANS OF A PORTABLE DEVICE

Tocco, F., Marongiu, E.I, Ghiani, G.I, Sanna, I.I, Palazzolo, G.I, Pinna, M.I, Migliaccio, G.M.2, Olla, S.I, Roberto, S.I, Pusceddu, M.I, Concu, A.I, Crisafulli, A.I

*Cagliari University*

**Introduction.** Stroke volume (SV) and cardiac output (CO) measurements in divers have never been performed during Constant Weight Apnea (CWA), but only in the laboratory settings (Tocco F et al., 2012) or during static and dynamic apnea in a pool (Tocco F et al., 2013). Thus, the knowledge of the real human diving response in this condition is scanty. **Methods.** Three dips were performed by 7 divers: immersion at 10m depth (test A), at 20m depth (B) and at 30m depth (C). Each test consisted of three apnea phases: descent, static on the sea bottom, and ascent. Hemodynamics were assessed through an impedance cardiograph contained within an underwater torch. The impedance method provides non-invasive reliable data of trans-thoracic fluid index (TFI), SV, heart rate (HR) and CO. Besides, at the beginning and at the end of each test we collected blood pressure (MBP), arterial O<sub>2</sub> saturation (SaO<sub>2</sub>) and blood lactate (BLa). **Results.** The group mean duration of three dives was  $76.4 \pm 29.2$ ,  $92.7 \pm 28$  and  $98.6 \pm 18$  s for Test A, B, and C respectively ( $p < 0.01$  both test B and C vs. test A). Both B and C conditions led to a HR increase during descent and ascent phases compared to rest condition and static apnea (+23% and +35% at 20 and 30m depth respectively). A similar behavior was shown by SV (+46% and +27% at 20 and 30m depth respectively). As a consequence, a significant rise in CO was detected (+50% and +25% at 20 and 30m depth respectively). MBP was augmented at the end of both B and C tests compared to rest (+30%), while SVR decreased during descent and ascent phases with respect to both rest and static apnea conditions (-6%). A significant SaO<sub>2</sub> drop was present only during test C (-5% vs. rest), contemporary to a BLa increment (+200%). **Conclusion.** We concluded that typical diving response was not present during CWA, probably due to sympathetic activation induced by exercise with bi-fins during descent and ascent phases, which obscured the effects of the diving response. We hypothesized that the exercise pressor reflex and the central command were responsible for the phenomenon. **References** Tocco F, Crisafulli A, Melis F, Porru C, Pittau G, Milia R, Concu A. ### EFFECT OF PROLONGED DYNAMIC EXERCISE AND SLEEP DEPRIVATION ON CARDIOVASCULAR AND PLASMA ADRENOMEDULLIN RESPONSES TO STATIC EXERCISE IN HEALTHY YOUNG MEN

Krzeminski, K.I, Mikulski, T.I, Dabrowski, J.I, Laskowska, D.I, Bogdan, A.2

*1 Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland. 2 Central Institute for Labour Protection – National Research Institute, Warsaw, Poland.*

**Introduction** As the popularity of ultra-endurance events is increasing questions arise, if such an extreme load is healthy and safe for the circulatory system. Thus, the aim of the present study was to examine cardiovascular responses to static exercise performed by subjects submitted to prolonged exercise combined with complete sleep deprivation. **Methods** Eleven endurance trained young men ( $31 \pm 2$  years) performed 3-min static-handgrip at 30% of maximal voluntary contraction before (trial B) and immediately after (trial A) 30 hours of prolonged exercise (simulated adventure race) combined with complete sleep deprivation. Heart rate and arterial blood pressure were measured continuously (Portapress, Netherlands). Before and at the end of exercise venous blood samples were taken for adrenomedullin (ADM), norepinephrine, epinephrine and lactate determination. **Results** There were no significant differences between the two trials in maximal voluntary contraction, resting heart rate and lactate, whilst mean arterial pressure (MAP) was lower and plasma adrenomedullin, norepinephrine and epinephrine concentrations higher in trial A than in trial B ( $p < 0.05$ ). The handgrip-induced increases

in MAP, HR and blood lactate did not differ between the trials, whereas MAP remained lower in trial A than B throughout the whole static exercise period ( $p < 0.05$ ). During handgrip adrenomedullin concentration increased only in trial B (from  $2.80 \pm 0.73$  pmol/l to  $5.11 \pm 0.66$  pmol/l,  $p < 0.05$ ), in trial A and in catecholamines there were no significant differences. Discussion Prolonged physical activity combined with sleep deprivation increased both sympathetic activity and plasma adrenomedullin concentration, but did not increase arterial blood pressure. Present data suggest, that increase in sympathetic nervous activity during prolonged physical activity may be involved in plasma ADM release and that increase in ADM secretion may be a compensatory mechanism against elevation of blood pressure. The possibility of the direct stimulation of ADM secretion in the heart by hemodynamic changes may be considered, since prolonged dynamic exercise results in phenomenon described as "cardiac fatigue". Lower blood pressure in trial A could be caused by decreased vascular sensitivity to some vasoconstricting factors, by attenuated "central command" and/or increased cardiac sympathetic modulation, as well as by changes in the sensitivity of arterial baroreceptors. It is concluded that the prolonged exercise improves cardiovascular response to static exercise in endurance trained young men.

#### MOTOR FITNESS OF HEARING-IMPAIRED PRIMARY SCHOOL CHILDREN

Augste, C., Lichtner, H.

*University of Augsburg*

**Introduction** The acoustic sensory system is a major source of information in sports movements. For hearing-impaired children, verbal information (e.g. for movement descriptions and corrections), but also sensory feedback during movement execution is significantly reduced in the teaching-learning process. There is some evidence of reduced performance of hearing impaired children in coordinative motor skills like balancing (Engel-Yeger and Weissman, 2009). In the present study the effects of different degrees of hearing impairment in primary school children should be examined not only for coordination but also for further motor fitness aspects like flexibility, strength, and endurance. **Methods** 85 hearing impaired primary school children (age:  $M = 9.1$ ,  $SD = 1.5$ , 32 female) and 97 hearing children (age:  $M = 8.3$ ,  $SD = 0.9$ , 44 female) performed the 8 tasks of the German Motor Test 6-18 (Bös, 2009). The raw data of each task were transformed into a Z-score according to gender and age specific normalized data. According to their audiogram the children were classified into impairment categories: severely deaf, completely deaf, auditory processing and perception disorder. **Results** Hearing impaired children performed significantly worse in balancing backwards ( $T = 5.61$ ;  $df = 177$ ,  $p < .001$ ), in bidirectional jumping ( $T = 5.61$ ;  $df = 177$ ,  $p < .001$ ), in the 20 m sprint ( $T = 2.48$ ;  $df = 166$ ,  $p = .014$ ), and in the 6-min endurance run ( $T = 7.41$ ;  $df = 140$ ,  $p < .001$ ). In the strength endurance tasks push-ups ( $T = 1.19$ ;  $df = 167$ ,  $p = .232$ ) and sit-ups ( $T = 0.98$ ;  $df = 178$ ,  $p = .327$ ) as well as in the stand-and-reach test ( $T = 0.94$ ;  $df = 175$ ,  $p = .386$ ) and the standing long jump ( $T = 0.993$ ;  $df = 175$ ,  $p = .152$ ) they had no significant deficits. Regarding the category of the hearing impairment significant differences only occurred in bidirectional jumping, where completely deaf children fell behind their mates ( $T = 3.01$ ,  $df = 38$ ,  $p = .005$ ). **Discussion** The findings on speed and coordination are quite in line with previous research (Engel-Yeger and Weissman, 2009). The poorer performance in the aerobic endurance, however, is not documented so clearly. As there is little evidence for purely physiological reasons, performance improvements through specific programmes in this area seem very likely. New aspects could be contributed for the areas of flexibility, strength endurance, and springiness, where hearing impaired children are on par with hearing children. **References** Bös, K. (2009). #### EFFECTS OF A 6-MONTH INTEGRAL PROGRAM OF EXERCISE ON PHYSICAL FITNESS AND BODY COMPOSITION IN LIVER TRANSPLANTATION RECIPIENTS.

Moya-Nájera, D.

*University of Valencia*

After transplantation, the patients adopt a hypoactive and unhealthy lifestyle that increases the gain of body fat percentage, loss of bone and muscle mass, leading them to have metabolic problems which very often result in heart problems. There is a lack of knowledge about the effects of exercise programs that integrate different physical fitness activities because it is believed that they cannot perform them. In fact, it is not known an integral program of exercise in this population applied during a long term. **Purpose:** To check the effects of a long term integrative training program on the physical capacity, strength, functional performance and body composition in patients who underwent liver transplant. **Methods:** A prospective randomized study involving 30 voluntary subjects (17 control group -CG-, and 13 intervention group -IG-) was performed. The following assessments were performed before and after the program: 1) Isokinetic strength (hip flexion/extension, elbow flexion/extension, shoulder flexion/extension, shoulder abduction/adduction and knee flexion/extension); 2) Agility (stand up and go); 3) Flexibility (sit and reach); 4) Balance (star excursion test); 5) physical capacity ( $VO_2$  max); and 5) Body composition (body weight and %fat). During the 6 months the IG trained 2 one-hour sessions per week. The training sessions involved balance (Soft Stability Trainers of Thera-Band®), strength (Thera-Band®elastic bands), endurance (walking activities), and flexibility (passive stretching activities). The heart rate was controlled by a heart rate monitor (bpm) and the resistance intensity with the OMNI-RES Scale for elastic bands. **Results:** IG showed significant ( $p \leq 0.05$ ) increases by 19.52% of the initial  $VO_2$ max. value ( $16.37$  mL/kg/min), by 15.24% of the initial peak torque value (N), by 20.13% of the initial peak torque/body weight value (N/kg), by 185.15% of the initial sit and reach value (cm), by 19.03% of the initial dynamic balance value (cm) and by 14.89% of the initial stand up and go value (s). IG showed significantly ( $p \leq 0.05$ ) reduced by -3.08% of the initial body weight value (kg) and by -13.51% of the initial fat mass value. No significance differences were measured on pre-post test in the control group. **Conclusions:** These results suggest that including this kind of integrative programs of physical exercise may be positive for these patients, because an improvement of physical fitness is important to perform daily activity tasks successfully and this could lead to improving their quality of life.

## HEALTH-RELATED PHYSICAL FITNESS IN MARTIAL ARTS AND COMBAT SPORTS PRACTITIONERS

Franchini, E., Schwartz, J., Antonietti, L.S., Del Vecchio, F.B., Takito, M.Y.

*University of São Paulo*

**Introduction** Nowadays, people practice martial arts and combat sports with different purposes and physical fitness is among the main ones. However, little information is available concerning the health benefits of such activities (Bu et al., 2010). Thus, the purpose of this study was to evaluate health-related physical fitness in martial arts and combat sports practitioners in the city of São Paulo, Brazil. **Methods** The study included 935 males (20-35 years), practitioners of karate (n=229), Brazilian jiu-jitsu (n=136), judo (n=180), kung-fu (n=140) and taekwondo (n=250), in São Paulo, Brazil. They were evaluated using the fitness assessment tests proposed by the ACSM (2005): body mass index (BMI), waist-hip ratio (WHR), and body fat percentage; the maximal oxygen uptake (VO<sub>2</sub>max) estimated by the Queens College test; muscle strength, measured by the handgrip strength test; muscle endurance, obtained by using a one-minute sit-up test; and flexibility, measured using the sit-and-reach test. Analysis of variance was used to compare groups, followed by Tukey test (5% as significance level). **Results** Most subjects had a BMI between overweight (karate, Brazilian jiu-jitsu and judo) and normal (kung-fu and taekwondo). WHR and body fat percentage indicated moderate risks for all groups. Regarding VO<sub>2</sub>max, the kung-fu group showed lower scores compared to the Brazilian jiu-jitsu and judo groups, although all groups were above average in comparison with the standard population. Furthermore, most practitioners were classified as below average concerning muscle strength in all styles, while the kung-fu group was rated as poor. Concerning strength endurance all groups were classified as above average, and the Brazilian jiu-jitsu group showed higher scores when compared to taekwondo and judo groups, the latter showing lower scores than the kung-fu group. Flexibility was classified as average in all groups, and the Brazilian jiu-jitsu group had lower scores when compared to the karate, taekwondo, and kung-fu groups, with this last one showing better results when compared to the judo group. **Discussion** The practice of the various styles investigated is associated with above average health-related fitness, except concerning muscle strength and body composition. Thus, martial arts and combat sports instructors should create strategies to improve these variables or practitioners should engage in other physical activities to achieve a better result in these components. Bu B, Haijun H, Yong L, Chaohui Z, Xiaoyuan Y, Singh MF (2010). *J Evid Based Med*, 3(4), 205-19. American College of Sports Medicine (2005). ACSM's health-related physical fitness assessment manual. ## VALIDITY OF AEROBIC FITNESS ESTIMATED BASED ON THE SUBMAXIMAL OXYGEN PULSE IN INDIVIDUALS WITH CEREBRAL PALSY

Satonaka, A.1,2, Terada, K.3, Suzuki, N.1,2

*1: Nagoya U. (Nagoya), 2: IDR (Kasugai), 3: Nagoya College (Toyoake)*

**Introduction** Aerobic fitness is an indicator of physical endurance and is usually evaluated by the peak oxygen uptake (VO<sub>2</sub>peak) that is achieved during exercise under maximal effort up to exhaustion (ACSM, 2000). However, it is hard for the individuals without sufficient experience of exercise to perform such maximal exercise. The aim of this study was to provide alternative method rather than the maximal exercise test to evaluate aerobic fitness of the individuals with cerebral palsy. **Methods** We recruited 14 individuals with cerebral palsy (averaged 42.4±14.2 years) who underwent two types of exercise tests. **Test 1** (maximal test): VO<sub>2</sub>peak was determined by the maximal test. The participants pedaled the cycle ergometer. The work rate was initially 10W. After 1 min at 10 W, the work rate was increased at 5 W/min in a ramp fashion. The participants were encouraged to perform until exhaustion. VO<sub>2</sub>peak was defined as the plateaued oxygen uptake (VO<sub>2</sub>) despite of increase of work rate and as the VO<sub>2</sub> when the respiratory exchange ration was greater than 1.0. The work rate was also recorded when heart rate reached 120 beats/min (WHR120). **Test 2** (Oxygen pulse at WHR120): The participants pedaled the cycle ergometer at WHR120 for 3 min. Oxygen pulse (Wasserman, et al., 1994) was calculated by the oxygen uptake and the heart rate during the last 30 min. **Results** The average VO<sub>2</sub>peak was 923.3±187.4 mL/min. Average WHR120 was 22.1±13.5 W. There was a significant correlation between VO<sub>2</sub>peak and oxygen pulse (r=0.83, P<0.001). It was also found that VO<sub>2</sub>peak correlated with what was produced by WHR120 times age-predicted maximal heart rate (HRmax) (r=0.86, P<0.001). **Discussion** It is apparent that oxygen pulse at WHR120 well represents VO<sub>2</sub>peak in the individuals with cerebral palsy. Not all individuals with cerebral palsy can undergo the maximal test. Even the multistage submaximal cycle ergometer test (Satonaka, et al., 2012) could be difficult for certain individuals with cerebral palsy though we validated the method for individuals with cerebral palsy. The work rate that corresponds to 120 beats/min of heart rate is not difficult at all for individuals who have no sufficient experience of exercise. Therefore, it will be very easy to evaluate the aerobic fitness for those with physical challenges like cerebral palsy. **References** American College of Sports Medicine. (2000). #### EVALUATION OF FLUID STATUS AND EFFECT OF AN INDIVIDUAL INTERVENTION IN FEMALE SOCCER PLAYERS BEFORE MATCH PLAY

Domnik, K., Braun, H., Koehler, K., Mester, J., Schänzer, W.

*German Sport University Cologne*

**Introduction** It is recommended that athletes should start training and/or competition well hydrated (Maughan & Shirreffs, 2008). While studies show a substantial number of athletes being hypohydrated at the start of a match (Gibson et al., 2012; Silva et al., 2011), data on fluid status in female soccer players are described rarely. Moreover, to our knowledge, there is no information about the influence of an intervention on the fluid status in soccer. Therefore, one aim of the present study was to evaluate the fluid status of female soccer players

immediately before competition. Furthermore, the effect of an individual intervention on the fluid status prior to the match was examined. Methods 63 female senior (age:  $21.2 \pm 4.2$ ) and 40 female junior soccer players (age:  $15.6 \pm 0.8$ ) were recruited. Urine specific gravity (USG) was measured on matchday to evaluate the hydration status prior to the game. USG  $> 1.020$  g/ml was defined as cut-off for hypohydration. After the first match (Pre-Test) every athlete received individual coaching (lecture, evaluation sheet, poster) based on Pre-Test results. Four to six weeks after the intervention hydration status was assessed again prior to a match (Post-Test). Results Mean USG in the Pre-Test was  $1.020 \pm 0.008$  g/ml for seniors and juniors. We found the majority of the players (37 seniors (65%) and 23 juniors (59%)) were hypohydrated prior to the game, of which 16 seniors (25%) and 12 juniors (30%): showed USG values  $> 1.025$  g/ml. After the educational intervention mean USG decreased to  $1.014 \pm 0.008$  g/ml (seniors) and  $1.018 \pm 0.009$  g/ml (juniors). Players who were stated hypohydrated in the Pre-Test improved their fluid status significantly in the Post-Test (seniors:  $p=0.001$ ; juniors:  $p<0.05$ ). Discussion This study shows that based on USG measurement a large number of female athletes can be considered not adequately hydrated prior to a game. Individual coaching turned out to be a successful intervention to positively affect the players' fluid status. However, we propose a higher support of the juniors during the intervention in order to achieve a greater effect. References Gibson, J.C., Stuart-Hill, L.A., Pethick, W. & Gaul, C.A. ## EFFECTS OF FLUID REPLENISHMENT IN HYPOHYDRATED INDIVIDUALS DURING EXERCISE IN THE TROPICS

Lee, J., Fun, D., Teo, Y., Nio, A.

*Defence Medical and Environmental Research Institute, DSO National Laboratories, Singapore*

**INTRODUCTION** An individual's pre-exercise hydration status is an important factor determining the impact of fluid intake during exercise (Armstrong et al. 1997). We profiled the associated thermoregulatory, circulatory and fluid balance parameters during a military exercise in a warm and humid environment, and examined the effect of fluid replenishment on physiological strain in mostly hypohydrated individuals. **METHODS** Seventeen heat-acclimatised male soldiers (Mean $\pm$ SD; age  $21 \pm 1$  years) performed an 11.5-km tactical walk in a warm and humid environment (WBGT= $32.3 \pm 1.4^\circ\text{C}$ ). Thermoregulatory, circulatory and fluid balance parameters were measured. The cumulative heat strain index was calculated (Frank et al. 2001). Participants were divided into two groups: (A) euhydrated ( $n=3$ ) and hypohydrated with greater percent sweat loss replenished ( $n=7$ ; MW) and (B) hypohydrated with less sweat loss replenished ( $n=7$ ; LW). **RESULTS** Twelve soldiers completed the infantry exercise in 297 min, two were stopped with core temperatures  $>39.5^\circ\text{C}$ , and three withdrew with symptoms of exhaustion. Fourteen soldiers were hypohydrated pre-exercise (urine osmolality  $824 \pm 186$  mOsmol $\cdot$ kg $^{-1}$ ). Change in body mass was  $-1.5 \pm 1.1\%$  and ad libitum water intake replenished  $78 \pm 23\%$  of sweat loss. Mean heart rate was  $151 \pm 9$  bpm, maximum heart rate was  $176 \pm 8$  bpm, mean core temperature was  $38.5 \pm 0.3^\circ\text{C}$ , and maximum core temperature was  $39.2 \pm 0.4^\circ\text{C}$ . Greater percent sweat loss was replenished in MW ( $89 \pm 24\%$ ) than LW ( $63 \pm 8\%$ ;  $P<0.01$ ). Maximum heart rate (MW  $172 \pm 5$ , LW  $181 \pm 8$  bpm;  $P<0.05$ ) and maximum core temperature (MW  $39.0 \pm 0.3$ , LW  $39.4 \pm 0.4^\circ\text{C}$ ;  $P<0.05$ ) were raised in hypohydrated soldiers with less sweat loss replenished. When the cumulative heat strain index was extrapolated using individual quadratic equations in participants who did not complete the exercise ( $n=5$ ), a greater physiological strain at exercise completion was predicted in those who had less sweat loss replenished (MW  $2346 \pm 1102$ , LW  $4631 \pm 2205$ ;  $P<0.05$ ). **CONCLUSION** The additional replacement of 26% sweat loss by fluid intake during exercise significantly reduces thermoregulatory and circulatory strain in pre-exercise hypohydrated soldiers. When commencing military activity hypohydrated, adequate rehydration during exercise mitigates the physiological stress experienced and improves the likelihood of task completion. **REFERENCES** Armstrong LE, Maresh CM, Gabaree CV, Hoffman JR, Kavouras SA, Kenefick RW, Castellani JW, Ahlquist LE (1997). *J Appl Physiol*, 82, 2028–2035. ## THE EFFECT OF EXERCISE-INDUCED HYPOHYDRATION UPON TREADMILL RUNNING PERFORMANCE

Baker, D., Coleman, D.A., Wiles, J.D.

*Canterbury Christ Church University*

**Introduction** Whilst it is often cited that hypohydration (HYP) levels ( $>2\%$  body mass (BM) losses) result in impaired endurance performance, it has been suggested that endurance runners that drink ad libitum (AL) during exercise and avoid becoming thirsty can negate this impairment (Sawka & Noakes 2007; Noakes 2012). Speculation also exists in the literature that HYP during exercise can potentially benefit the runner by reducing BM leading to improved running economy (RE) during exercise. However little research exists investigating the links between BM lost during exercise-induced HYP, alterations to RE, and performance (Saunders et al. 2004). Therefore the aim of this study was to investigate the impact of variations in exercise-induced HYP on 5km time-trial (TT) performance in trained runners. **Methods** Forty-eight trained male runners were familiarised to procedures and reported to the laboratory on five occasions. An initial visit established  $\text{VO}_{2\text{peak}}$  which preceded four 90 minute treadmill running trials performed at a running speed equivalent to  $65\% \text{VO}_{2\text{peak}}$ . During the 90 minute trials hydration status was manipulated through fluid ingestion with participants completing trials at  $0\% \text{HYP}$ ,  $\sim 1\% \text{HYP}$ , No Fluid, and AL in a random order. Expired gases were analysed at 30, 60 and 90 minutes of the trials. On completion of each 90 minute trial participants undertook a self-paced, blinded maximal 5km performance TT on the treadmill. **Results** The AL trials resulted in a  $1.7 \pm 0.4\%$  reduction in BM and a 5km TT of  $1404 \pm 177$ s. AL trials did not result in the fastest performance time; where individual fastest trials were analysed, a significantly faster mean time of  $1361 \pm 171$ s ( $p<0.05$ ) was recorded at a significantly higher BM (only  $1.2 \pm 0.7\%$  BM loss) when compared to AL ( $p<0.05$ ). RE was significantly lower during the 90 minute run prior to fastest 5km TT performance compared to the AL trial ( $p<0.05$ ). **Discussion** This study demonstrates that an AL drinking strategy did not result in fastest 5km treadmill TT performance following a 90 minute preload run. Faster times were recorded by participants with increased fluid ingestion during the preload where significantly better RE was also apparent despite a higher mean BM when compared to AL trials. A drinking strategy with water ingestion  $0.5\% \text{BM}$  above AL in a 90 minute period when exercising at this intensity would appear to be more appropriate in attempting to maximise performance using this protocol. **References** Noakes, T.D. ## EFFECT OF VITAMIN D SUPPLEMENTATION ON PERFORMANCE IN ELITE RUGBY UNION PLAYERS OF SOUTHERN NEW ZEALAND

Fairbairn, K.A.1, Perry, T.L.1, Ceelen, I.J.M.2, Cameron, C.M.1, Skeaff, C.M.S.1

*University of Otago*

1: UNIVERSITY OF OTAGO (NEW ZEALAND), 2: UNIVERSITY OF APPLIED SCIENCES OF ARNHEM AND NIJMEGEN (THE NETHERLANDS) INTRODUCTION: There is evidence that vitamin D status may affect athletic performance (Cannell et al, 2009). Low vitamin D status has been shown in many athletic groups globally (Galan et al 2012; Hamilton et al, 2010; Lovell 2008). However, randomised controlled trials investigating the effect of vitamin D supplementation on performance in athletes are lacking. Thus, the aim of this study was to investigate the impact of vitamin D supplementation on strength and speed performance during 12 weeks of pre-season training in elite rugby union players living in southern New Zealand (34-48°S). METHODS: We conducted a randomised, double blind, placebo controlled intervention trial in 57 elite rugby union players. Players received either 3,570 IU/day vitamin D (n=28) or placebo (n=29) for 11-12 weeks during pre-season training. Fasting serum samples and standardised performance tests were conducted at baseline (autumn/fall), Weeks 5-6 and Weeks 11-12 (winter). Performance testing consisted of 10m and 30m sprints, the Yoyo Intermittent Recovery Test, and 1RM for Bench Press, Bench Pull, Box Squat and Weighted Chin-up (reverse grip). RESULTS: At baseline, mean (SD) serum 25-hydroxyvitaminD (25(OH)D) concentrations were 93 (19) nmol/L and 95 (17) nmol/L in the vitamin D and placebo groups respectively. As there was no time by treatment interaction effect between weeks 5-6 and Weeks 11-12 for performance outcomes, these time-points were combined for analysis. There was a significant treatment effect for serum 25(OH)D, with serum 25(OH)D concentrations 32 nmol/L higher (95% CI, 26 to 38 nmol/L;  $p < 0.001$ ) in the group supplemented with Vitamin D compared to the placebo group. Of the performance measures tested in this study, only weighted chin-up demonstrated a significant treatment effect, where the Vitamin D group lifted 5.5kg more (95% CI, 2.0 to 8.9kg;  $p < 0.01$ ) compared to the placebo group. DISCUSSION AND CONCLUSION: This is the first randomised controlled trial to investigate the effect of vitamin D supplementation on strength and speed performance in elite athletes. These results suggest that vitamin D supplementation in a vitamin D replete population has minimal effect on speed and strength in elite rugby union players, however we cannot exclude the possibility of a performance effect. ## SIMILAR FUNCTIONAL RECOVERY AND SORENESS RESPONSE TO THE INGESTION OF A COMMERCIAL OR HOMEMADE BEVERAGE AFTER AN EXHAUSTIVE ECCENTRIC PROTOCOL

Sousa, M.1, Brito, J.1, Carvalho, P.2, Pinto, L.1, Guimarães, J.T.3, Teixeira, V.H.2,4, Soares, J.1

1: CIFI2D (Porto, Portugal), 2: FCNAUP (Porto, Portugal), 3: FMUP (Porto, Portugal), 4: CIAFEL (Porto, Portugal)

Introduction The aim was to compare the effect of 2 isoproteic and isoglucidic recovery beverages (commercially available vs. homemade) on functional response and muscle soreness after an eccentric protocol until exhaustion. Methods Thirteen male athletes (21.6±3.2 yrs; 72.4±6.6 kg) completed 2 trials separated by ≈2 weeks. In each trial, using alternate lower limbs, participants performed an exhaustion protocol on an isokinetic device comprising concentric/eccentric knee extension/flexion bouts at 60°/s. The protocol consisted on 3 sets, with a 200-sec rest time between sets. The 1st and 2nd sets comprised 100 repetitions (rps); in the 3rd set, n rps were performed until the torque of 3 consecutive rps fell below 25% of the eccentric peak torque of the quadriceps (PTq). During the 2 h after the protocol, participants ingested 0.8 g/kg/h carbohydrates and 0.3 g/kg/h protein, in 2 bolus/h of a commercially available supplement or a milk-shake with skimmed milk, strawberries and banana. PTq and jumping height (countermovement jump) were determined before (M1), immediately (M2), 24 h (M4), and 48 h (M5) after the protocol. General muscle soreness (DOMS) and soreness from palpation, using a 100-mm visual analogue scale (VAS), were evaluated at the same moments and 2 h after the protocol (M3). The VAS was also used to assess the flavour enjoyment of the beverage. Results There was a main effect of time for PTq ( $p < 0.001$ ;  $\eta^2 = 0.72$ ), with significant differences between M2 and the remaining moments and between M4 and M1 and M5 (M1, M2, M4, M5: 389.2±70.6, 276.3±64.2, 347.0±49.5, 368.1±50.8 N•m;  $p < 0.05$ ). Also, a main effect of time for jumping height ( $p < 0.001$ ;  $\eta^2 = 0.64$ ) was detected between M2 and the other moments (46.8±4.7, 40.8±5.4, 45.1±5.2, 45.1±4.7 cm;  $p < 0.05$ ). There was a main effect of time for general DOMS ( $p < 0.001$ ;  $\eta^2 = 0.60$ ), with M1 different from the remaining moments, and M3 from M4 (7.5±13.1, 43.2±21.4, 34.0±15.8, 49.5±20.6, 46.1±23.3 mm;  $p < 0.05$ ); also, a main effect of time for soreness from palpation ( $p < 0.001$ ;  $\eta^2 = 0.47$ ) was detected, with M1 different from M3, M4 and M5 (5.3±9.3, 21.7±22.2, 20.2±19.6, 34.7±26.3, 37.5±28.7 mm;  $p < 0.05$ ). Neither a main effect, nor an interaction effect was found in beverages for any of these parameters. The participants found similar the flavour of both beverages (homemade: 67.9±15.7, commercial: 67.3±24.5 mm;  $p = 0.935$ ). Discussion Given that the effect of functional parameters and muscle soreness did not differ among the tested beverages, it can be concluded that similar recovery processes can be obtained regardless of the nature (commercial or natural food) of the beverage.

#### ALTERATIONS IN MUSCLE STRENGTH, MUSCLE THICKNESS AND LEAN MASS UPON WORK ECONOMY IN ELDERLY MEN FOLLOWING STRENGTH TRAINING

Salvesen, S.1, Bjørnsen, T.1, Lohne-Seiler, H.1, Hetlelid, K.J.1, Stea, T.H.1, Paulsen, G.2, Berntsen, S.1

*University of Agder*

1Department of Public Health, Sport and Nutrition, Faculty of Health and Sport Sciences, University of Agder, Kristiansand, Norway, 2 Department of Physical Performance, Norwegian School of Sport Sciences, Oslo, Norway Introduction In addition to increases in strength and muscle mass, it seems that resistance exercise can improve the capacity of the oxygen transport and/or utilization and increase the aerobic capacity in elderly subjects. Since most daily activities are based on submaximal efforts, the aim of the present study was to

examine the effect of traditional strength training upon work economy among elderly men. Methods Fifty elderly men (60 – 81 years) participated in this 12 week undulating periodized strength training program. The strength training consisted of three full body workouts per week; two of these were 8-10 repetitions maximum (RM) with 1 min rest, and the third differed between 3-5 RM with 2 min rest, and 13-15 RM with 45 sec rest. The load and volume increased progressively throughout the intervention. Measurements before and after the intervention: Lean mass (Dual-energy X-ray absorptiometry), muscle strength (1RM; leg press and knee extension) and muscle thickness (ultrasound; vastus lateralis and rectus femoris). Work economy, determined as body mass adjusted oxygen consumption, was measured while walking on a treadmill at 5 km/h at three different inclinations: 0 %, 4 % and 8 %; 5 min at each work load. Blood lactate (La-), heart rate (HR), oxygen consumption (VO<sub>2</sub>), respiratory gas exchange ratio (RER) and minute ventilation (VE) was measured during each test period. Seventeen participants were excluded in the analyses due to high lactate levels (>2.5 mmol/l). Results In addition to significant increases in muscle strength and muscle mass ( $p < 0.001$ ), the participants significantly improved their work economy, at the three different work loads by, respectively, 4.0% (0.3-7.4) (median and 95% confidence intervals ( $p = 0.01$ )), 2.8% (-1.4-7.1 ( $p = 0.016$ )) and 2.5% (-0.2-5.0 ( $p < 0.06$ )). However, there were no significant differences between the work loads. No significant positive associations were found between changes in muscle strength and work economy, nor muscle mass and work economy. However, changes in muscle thickness for rectus femoris were significantly and negatively associated ( $r = -0.425$ ;  $p = 0.014$ ) with work economy at the steepest inclination (8%). There was no association between muscle thickness of vastus lateralis and work economy. Discussion In the present study, walking work economy improved after 12 weeks of strength training in elderly men. However, these data suggests that other factors than changes in muscle strength, mass and thickness are the mechanisms behind the improved work economy.

### PHYSICAL ACTIVITY IN OLD AGE – A CROSS-SECTIONAL ANALYSIS OF GERMAN PRIMARY HEALTH CARE PATIENTS

Gaedtke, A., Hinrichs, T., Klaatzen-Mielke, R., Trampisch, U., Platen, P., Moschny, A.

*University of Bochum*

Background To date, little is known about the physical activity behaviour of older adults in Germany. Existing studies focus exclusively on sports and exercise. They thereby overlook activity domains that are particularly important for people in old age. The aim of the study was thus to analyse the engagement in different types of physical activity that are relevant for older men and women in Germany. Methods Within the 7-year follow-up telephone interviews of the getABI cohort (community-dwelling primary health care patients in Germany), participants were surveyed on their everyday physical activity patterns using the PRISCUS-PAQ. Detailed information on the development, structure, and quality criteria of the 10-item PRISCUS-PAQ has already been published [1]. Participants had to state the number of days for each activity and the mean duration for activities performed in the week prior to the interview. Time and energy expenditure per week were then calculated for the single items and for the following activity categories: housework [H], sporting activities [S], walking [W], gardening [G], total [T]. Descriptive analyses were performed for all respondents and stratified by sex. Median values are presented. Results A total of 1503 primary health care patients (50.4% women) with a median age of 77 (range 72-93) years were included into the analyses. Looking at the activity categories, results for time (hh:mm) per week were as follows: H=9:00, S=1:30, W=4:05, G=0:30, T=21:30; and H=4:15/14:00, S=1:45/1:10, W=4:30/4:00, G=1:00/0:15, T=18:15/25:00 for men and women, respectively. The energy expenditure (MET-hours) per week was H=23.8, S=6.1, W=14.3, G=2.0, T=72.1; and H=11.8/38.7, S=8.0/5.8, W=15.8/14.0, G=4.0/1.0, T=65.0/78.1 for men and women, respectively. Discussion This study contributes to the understanding of physical activity behaviour in the older population in Germany. In addition to sports, walking and housework markedly contributed to total physical activity. Studies of older adults' physical activity thus should not be limited to the assessment of sports and exercise alone. Moreover some distinctive gender-related differences were shown, which may have implications for activity programs addressing older men and women. The study was conducted within the research cooperation PRISCUS and funded by the German Federal Ministry of Education and Research (01ET0720). 1. Trampisch, U., et al., Measurement of physical activity in older adults: Correlation between the PRISCUS-PAQ and accelerometry. *Zeitschrift für Gerontologie und Geriatrie*, 2012. 45(3): p. 212-217.

### EFFECTS OF A SPECIFIC PHYSICAL ACTIVITY PROGRAM ON FITNESS IN POST-MENOPAUSAL WOMEN

Mateu, M.1, Peirau, X.2, Iruñia, A.3, Planas, T.2, Torrents, C.2

1: *INEFC-Barcelona, UB (Spain)*, 2: *INEFC-Lleida, UdL (Spain)*, 3: *GRCE, INEFC-Barcelona, UB (Spain)*

Introduction Postural dysfunctions and loss of balance control and stability are among the many well-documented consequences of musculoskeletal changes that occur over the lifespan. Some of these age-related changes can be minimized through proprioceptive, postural stability and core-strengthening physical activity programs (De Souza Santos et al., 2011). On the other hand, the menopausal process represents a biological and psychological turning point in the lives of the women that can be conducted by the benefits of an adequate proposal of physical activity program (Slaven & Lee, 1994) The objective of this study was to evaluate the effect of specific postural stability program on body composition, physical aptitude and body balance in post-menopausal women. Method A total of 14 post-menopausal women (age: 55,3±5,4 years) participated in this study. They performed, two times weekly for 16 weeks, an exercise session lasted approximately 65–70 min, subdivided into: 1) proprioceptive and postural stability exercises based on classical ballet barre exercises (e.g plié, relevé...); 2) physical fitness exercises based on centre floor ballet exercises; 3) stretching. The assessment protocols used were the following: a) body composition (weight -Wt-, fat mass -FM-, lean body mass -LBM-, total body water -TBW-); b) physical aptitude (adapted sit & reach test -SR-, grip strength dynamometer test -GS-, abdominal crunch test -AC-); c) body balance (balance eyes closed test -BE-). Data pre-post were analyzed by non-parametric Wilcoxon test for paired samples. The adopted significance level was  $p < 0.05$ . Results No significant differences were found in body composition ( $p > 0.05$ ): Wt: 71,7±9,8 kg vs 71,7±9,9 kg; FM: 35,2±6,9% vs 34,9±6,2%; LBM: 46,0±3,9 kg vs 46,2±3,9 kg; TBW: 45,0±3,8 L vs 45,1±3,4 L. Significant differences were found in physical aptitude (SR: 43,8±3,5° vs 39,9±4,8°  $p = 0,003$ ; GS: 21,5±3,9 kg vs 26,5±4,1 kg  $p = 0,003$ ; AC: 25,6±7,7 rep/min vs 33,8±6,8 rep/min  $p = 0,001$ ) and body balance (BE: 5,1±3,2 falls/min vs 3,3±2,7 falls/min  $p = 0,03$ ). Discussion The physical activities employed during the specific postural stability program based on simple classical ballet exercises resulted in significant improvements in the physical aptitude and the body balance of post-menopausal women. Our results are in general agreement with previous studies using similar methods such as Pilates (Babayigit Irez et al. 2011). ## **NUTRITIONAL HABITS, PHYSICAL ACTIVITY, SEDENTARY TIME AND WEIGHT STATUS OF SAUDI YOUTH FROM RURAL AND URBAN COMMUNITIES.**

Alnuaim, A., Al-Nakeeb, Y.

*Newman University College, King Faisal University, Qatar University*

**Introduction** Over the past three decades, the Kingdom of Saudi Arabia has witnessed significant lifestyle changes as a result of the economic boom. During this time period, studies have indicated that the prevalence of obesity in Saudi Arabia has overtaken many Western countries, including the USA (Alhyas, et al 2011, Al-Nakeeb et al, 2012). Therefore, the aims of this study were to: (1) explore the nutritional and lifestyle habits of Al-Ahsa youth; (2) evaluate the association between the dietary habits and behavioural factors; (3) investigate differences due to gender and geographical location. **Methods** 1270 volunteered youth (15–19 years) from different geographical locations (i.e. urban, rural farm and rural desert) completed a self-report questionnaire that contained 47 items relating to patterns of physical activity (PA), sedentary activity, and eating habits. The questionnaire allows the calculation of total energy expenditure in metabolic equivalent (MET-min) values per week. **Results** Significant differences in the PA levels of youth were evident with regard to gender and geographical areas. A higher proportion of males compared to females exceeded the cut-off scores for most of the dietary habits, including daily consumption of breakfast, fruit, vegetables, fast food, milk and dairy products. On the other hand, a higher proportion of females than males exceeded the cut-off scores of more than 3 days consumption per week of chips/crisps, cake /doughnuts, and sweets/chocolate. In males, TV viewing (OR=1.112; 95% CI 1.011-1.223), missed breakfast (OR=.926; 95% CI .863-.994) chips consumption (OR=.894; 95% CI .822-.974) and energy drink consumption (OR=1.106; 95% CI 1.021-1.198) were all positively associated with obesity. In females, there was a positive association between obesity and missed breakfast (OR=.922; 95% CI .859-.989) and energy drink consumption (OR=1.209; 95% CI 1.117-1.308). **Discussion** In general, males were more physically active and had a healthier diet compared to females. In addition, normal weight males reported the highest levels of PA compared to overweight and obese. With regards to geographical location, youth living in the rural desert were less physically active than those living in urban or rural farm environments. **In conclusion**, lifestyle and environment factors appear to play a major role in the prevalence of obesity. It is recommended that future research should identify effective policy actions and evaluate intervention strategies designed to prevent obesity and promote physical activity and healthy lifestyle habits. **References** Alhyas, L., McKay, A., Balasanthiran, A. and Majeed, A. (2011). *J. Roy. Soc. Med.* vol. 2, article 55. Al-Nakeeb, Y., Lyons, M., Collins, P., Al-Nuaim, A., Al-Hazzaa, H., Duncan, M.J. and Nevill, A. (2012). *Int. J. Environ. Res. ## **THE IMPACT OF PHYSICAL INACTIVITY ON FUNCTIONAL LIMITATIONS IN OLDER BRAZILIAN ADULTS**

Sebastiao, E., Schwingel, A., Chodzko-Zajko, W.

*University of Illinois*

**Introduction** Physical Inactivity (PI) is a major health concern worldwide due to its negative health outcomes. The present study explored the association between PI and limitations (FL) in advanced activities of daily living (AADL) in community dwelling older Brazilian adults. **Methods** The 2008 Brazilian National Household Survey was analyzed for 38,406 individuals aged 60 years and over (44% men). PI was assessed for transportation and leisure domains, using the following questions. Do you usually walk or ride your bicycle from home to work? Did you engage in exercise or sports within the last three months? Participants were considered active if reporting "yes" for at least one of the questions; otherwise they were considered inactive. FL was assessed based on an individual's self-reported ability to do the following activities; run or perform hard physical work, lift heavy objects, climb stairs; and walk more than one kilometer. Data were analyzed using the chi-square test to compare proportions and logistic regression to test the association between FL and PI. The significance level was set in 5%. **Results** Nearly 90% of both older men and women were classified as physically inactive. Regarding FL, 35.7% of men and 49.5% of women reported being unable to perform at least one AADL (chi-square;  $p < 0.001$ ). After adjusting for sociodemographic variables, PI presented a strong association with FL. Those classified as inactive were found to be 2.05 more likely to report FL than their active counterparts. **Discussion** PI rates were high for both sexes with women reporting more FL than men. After controlling for various sociodemographic variables, PI was found to be positively associated with FL. The PI rates reported here are higher than those reported in the literature (VIGITEL, 2010). These differences could be partially explained by the criteria adopted to classify individuals as active and inactive. However, the findings observed for FL and the association between FL and PI are consistent with findings published in the literature (Guerra et al., 2008). PA is strongly recommended for all ages and especially for older adults due to its positive effects on health outcomes (Chodzko-Zajko et al., 2009). **References** VIGITEL. ## **REACTIVE VS. ANTICIPATORY BALANCE TRAINING IN OLDER ADULTS.**

Welman, K.E., Robertson, N., Fourie, C.

*Stellenbosch University*

**Introduction** Good balance is one of the most important components in controlling body movement and independence (Stemplewski et al., 2012). However, with increased age, the ability to maintain postural control deteriorates, and is therefore one of the important predictors of falls within the elderly population. More specifically, ageing leads to changes in the ability to counteract unexpected and expected perturbations (Chen et al., 2012). Limited studies have investigated the effect of anticipatory (expected perturbations) vs. reactive (unexpected perturbations) balance training (BT) techniques distinctly. The objective of this study was thus to explore the changes in postural control among elderly after following either an anticipatory (ABT) or a reactive (RBT) balance training program. **Methods** The study involved 12 healthy elderly individuals (77.2±5.3 years) from 2 retirement homes. Two BT programs, i.e. RBT and ABT, were administered over 5 weeks followed by a 2 week retention period. Perceptual ratings of confidence (ABC questionnaire and falls efficacy scale), limits of stability (LoS), anticipatory- (APC) and reactive postural control (RPC) (BESTest; Horak et al., 2009), overall stability (PS), sway index (SI), eyes open (EO); eyes closed (EC) and postural sway (anterior-posterior (AP), medial-lateral (ML); Balance Biodex) as well as lower leg endurance (LB; sit-to-stand) were assessed pre-, post-intervention and at retention. **Results** Improvements in LoS, APC, RPC, PS and LB ( $p < 0.05$ ) were observed in both BT programs from pre- to post-intervention, but with no significant differences between the two groups ( $p > 0.05$ ). RPC benefits were not maintained after cessation of the RBT program ( $p = 0.03$ ). ABT improved confidence and ML sway compared to RPC

( $p=0.05$ ). During the retention period AP postural sway improved by 35% in RBT ( $p=0.05$ ) compared to 14% in ABT ( $p>0.05$ ). Discussion Both reactive and anticipatory balance training techniques improved balance similarly during the 5 week training and could therefore be used as alternative training methods in elderly to prevent falls. However caution should be taken when prescribing RBT programs which may attenuate confidence and increase perception of fall risk. Interestingly practice-related improvements in RPC are not maintained 2 weeks after training was terminated. The absence of such effects upon retention assessment suggests that benefits are transient and subject to issues related to compliance of RBT training. References Chen, E. W., Fu, A. S., Chan, K. ### OP-PM16 Neuromuscular Physiology [NP] 3

#### QUANTIFICATION OF MOTOR UNITS BETWEEN FUNCTIONAL TASKS AND ANISOMETRIC CONTRACTIONS

Cornett, K.M.D., Neubauer, N., Harwood, B., Jakobi, J.M.

*University of British Columbia*

**Introduction** Task specific force control is accomplished through adjustments in the number of active motor units (recruitment) and through modulation of motor unit (MU) discharge rate. Task specificity is well documented between isometric and anisometric contractions where MU recruitment thresholds are lower and discharge rates higher in anisometric contractions (Harwood et al, 2010; Linnamo et al, 2002). Whether adjustments in MU activity are exhibited for goal directed movements is unknown. The purpose of this study is to measure steadiness and MU activity in young females in anisometric contractions and functional tasks. It is hypothesized that discharge rates will be higher during functional tasks than anisometric contractions and that functional tasks will be steadier. **Methods** Three tasks, representing different degrees of complexity, were completed. The functional task involved lifting a water bottle from a table, drinking through a straw and returning the bottle to the table. The movement of the second task was identical but drinking was not executed. Finally an anisometric contraction with an equivalent load (0.8kg) was executed. Tasks were completed at a constant velocity through the same range of motion (30°). A computer monitor 125cm in front of subjects provided visual feedback of acceleration. Surface EMG of the short (SH) and long head (LH) of the biceps brachii, triceps brachii and brachioradialis was recorded. Intramuscular fine wire electrodes were placed in the SH and LH to track MUs in the 3 conditions and quantify recruitment thresholds and discharge rates. Steadiness was measured as the standard deviation of acceleration. **Results** Thirteen female subjects ( $23\pm 3$  y) participated in this study. Surface EMG and steadiness was similar across the three conditions. In 5 females, analysis of 21 MUs indicates that discharge rate was highest during the functional task (~15.94Hz) compared with the water bottle lift (~14.01 Hz) and anisometric contractions (~13.85Hz). Five additional MUs were recruited during the functional task. Across all tasks, discharge rate was higher during the lifting (shortening) phase than the lowering (lengthening) phase of the contraction. **Discussion** Steadiness and surface EMG did not differ among the three tasks. Yet, the functional task exhibited different mechanistic control. The higher discharge rate and recruitment of additional MUs in the functional task indicates there was an increase in motor neuron excitability related to the complexity of the task. This suggests that when movement patterns are matched, the intent of the task also influences motor neuron output. **References** Harwood B, Davidson AW, Rice CL (2010) *Exp Brain Res*, 208, 103-113. #### IS V-WAVE A RELEVANT TOOL TO INVESTIGATE THE LEVEL OF CORTICAL NEURAL DRIVE ?

Grospretre, S., Martin, A.

*INSERM U1093*

**Introduction** V-wave is an electrophysiological variant of the H-reflex obtained by stimulation of a peripheral nerve at a supramaximal intensity (maximal M wave) during a voluntary contraction. This response is a result of a collision in motor axons between antidromic impulses generated by the electrical stimulation and the descending neural drive generated by the voluntary motor command (Upton et al. 1971). V-wave is often used as a tool to reflect the amount of cortical command (Aagaard et al. 2002; Pensini and Martin 2004). However, the nature of this antidromic collision has never been investigated, questioning if the amplitude of V-wave could really be considered as an index of the level of the descending neural drive. **Method** This study was carried out on 9 young healthy subjects. Subjects were asked to reach 10 percents of their maximal voluntary contraction (MVC) in plantar flexion, and posterior tibial nerve (PTN) was electrically stimulated in order to elicit V-waves and maximal M-waves of triceps surae muscles (Soleus and gastrocnemii). Maximal Motor Evoked Potentials (MEPmax) of the same muscles were obtained by transcranial magnetic stimulation (TMS) of M1 area. Then, V-waves were conditioned by a preceding TMS stimulation at an inter-stimuli interval of 10 ms. MEPmax and 50 percents of MEPmax intensities were used to condition V-waves. **Results** V-waves amplitudes were higher with a conditioning TMS compared to unconditioned value. The greatest increase (about 3 times its initial value) of V-waves was observed with a conditioning TMS at a maximal intensity (MEPmax). V-wave facilitation was radically reduced when the conditioning TMS intensity was reduced to 50 percents of its maximal motor evoked potential. **Discussion** The amount of this facilitation was linked to the amplitude of the cortical magnetic stimulation. **In conclusion**, V-wave could be a reliable clue to estimate the amplitude of the final cortical command reaching the muscle. **References** Aagaard P, Simonsen EB, Andersen JL, Magnusson P, and Dyhre-Poulsen P (2002), *J Appl Physiol* 92: 2309-2318. ## IS THE SPINAL REFLEX EXCITABILITY OF POSTURAL MUSCLES MAINLY AFFECTED BY MUSCLE ACTIVITY OR BODY POSITION?

Cattagni, T., Martin, A., Scaglioni, G.

*Université de Bourgogne*

**Introduction:** There is substantial evidence in the literature that the segmental reflex response of the postural muscles decreases as the complexity of the postural task increases (Capaday and Stein 1986; Kocaja et al., 1993). This modulation essentially depends on: (i) muscles background activity and (ii) body orientation. The aim of the present study was thus to determine the specific contribution of each of these factors to the triceps surae H-reflex modulation, observed when an individual passes from sitting to standing. **Methods:** The maximal H-reflex (Hmax) and M-wave (Mmax) were evoked in soleus (SOL), medial gastrocnemius (MG) and lateral gastrocnemius (LG) of both legs in 10 healthy males (age:  $24.4 \pm 2.3$  yrs), in three experimental conditions: i) seated passive (SP); ii) upright standing (US); iii) seated active (SA) with the same level of SOL background EMG as that recorded in the upright stance. The Hmax/Mmax ratios were calculated in order to assess the proportion of motor units activated by the Ia afferents. **Results:** Hmax/Mmax was significantly ( $P < 0.05$ ) lower in SA ( $0.57 \pm 0.15$ ) compared to SP ( $0.67 \pm 0.13$ ) in SOL while in the gastrocnemii the ratio was not modulated by muscle background activity. For the three muscles, the ratio was significantly ( $P < 0.05$ ) lower in US (SOL:  $0.44 \pm 0.16$ ; MG:  $0.17 \pm 0.08$ ; LG:  $0.17 \pm 0.08$ ) compared to SA (SOL:  $0.57 \pm 0.15$ ; MG:  $0.26 \pm 0.1$ ; LG:  $0.28 \pm 0.12$ ). **Discussion:** It thus appears that the SOL H-reflex is similarly affected by the increase of background activity of postural muscles and by change in body orientation. Indeed, these two parameters account respectively for 43% and 57% of the down-modulation of  $\alpha$ -motoneurons excitability while the H-reflex of the synergists (MG and LG) was only affected by change of posture. The lack of modulation of gastrocnemii H-reflex amplitude by the muscle contraction could be due to the fact that gastrocnemii are less affected by the peripheral inhibitory mechanisms. **Reference:** Capaday C and Stein RB. ## AGE-RELATED CHANGES IN CORTICAL EXCITABILITY DURING UPRIGHT STANDING

Baudry, S., Penzer, F., Duchateau, J.

*Université Libre de Bruxelles*

**Age-related changes in cortical excitability during upright standing** **Introduction** It has been hypothesized that ageing could induce a greater cortical involvement in the control of leg muscle activity during upright standing (Baudry and Duchateau, 2012). Moreover, greater body sways during upright standing in elderly adults have been associated with a decrease in maximal force of the plantarflexor muscles (Billot et al. 2010). This raises the additional question of whether the force required to keep upright standing can influence the cortical contribution to the control of the plantarflexor muscles during postural activities in elderly adults. This study investigated the motor cortical excitability in young and elderly adults during upright standing. **Methods** Ten young and ten elderly adults were asked to stand upright on a rigid surface with eyes open and closed, and on a foam mat with eyes open; all conditions being performed on a force platform to compute the displacements of the centre of pressure (CoP). The maximal amplitude of the Hoffmann (H) reflex (Hmax) and M wave (Mmax), and the motor evoked potential (MEP) by transcranial magnetic stimulation (TMS) were recorded in soleus muscle. Cortical excitability was investigated by assessing the facilitation of the H-reflex induced by subthreshold TMS. The torque developed by plantar flexor muscles during a maximal voluntary contraction (MVC) was also assessed. **Results** Data indicate that the Hmax/Mmax ratio was smaller for elderly ( $20.3 \pm 5.8\%$ ) than young adults ( $44.3 \pm 17.6\%$  Mmax;  $P < 0.001$ ) whereas the amplitude of the MEP/Mmax ratio was similar for both groups (elderly:  $19.1 \pm 7.5\%$ ; young:  $19.0 \pm 16.4\%$ ;  $P = 0.99$ ). The H-reflex facilitation was greater for elderly ( $211.5 \pm 82.2\%$ ) than young adults ( $137.8 \pm 27.6\%$ ;  $P = 0.013$ ). Moreover, the MVC torque was negatively associated ( $P < 0.05$ ) with plantarflexor EMG ( $r^2 = 0.55$ ), maximal excursion of CoP ( $r^2 = 0.64$ ) and H-reflex facilitation ( $r^2 = 0.45$ ) for elderly adults when standing on a foam mat. **Discussion** The results indicate that motor cortical excitability during upright standing increases with ageing whereas the H-reflex amplitude was depressed, suggesting a greater cortical involvement in postural leg muscle activity in elderly adults. Moreover, when standing on unstable support, the negative association of maximal torque with cortical excitability suggests that cortical involvement can be modulated depending on the relative force level required by the upright standing posture. **References** Baudry S, Duchateau J. *J Physiol* 590:5541-5554, 2012. ## NEUROPHYSIOLOGICAL ALTERATIONS DURING 800M RUNNING AND FATIGUE

Poulsen, M.K., Brøchner, N.P., Pedersen, M., Jørgensen, R.M., Voigt, M., Mrachacz-Kersting, N.

*Aalborg University*

**Introduction** In a maximal 800m run velocity decreases progressively (Thomas et al., 2004) possibly as a result of fatigue. Metabolic limitations contribute though alterations in neurophysiologic factors are unknown. Studies have been conducted during sustained (Walton et al., 2002) and intermittent contractions (Nordlund et al., 2004) to fatigue. Here we investigate the changes in the amplitude of the human soleus H-reflex during maximum effort to investigate possible changes in neural drive. Data may provide insights into the underlying mechanisms (Taylor et al., 2008) associated with the decreased running velocity in the final 100m and help to optimize running performance. **Method** In this ongoing study, 3 highly trained 800m runners were asked to run at their race pace on a 400m tartan track. Subsequently they partook in two trials on a treadmill. In trial one, electrical stimulation was applied to the tibial nerve at mid-foot ground contact for each stride, to evoke an H-reflex in the soleus of 25% of the maximum M-wave. Trial two consisted of another maximal run to quantify stride time and muscle activation. The Borg rating was measured every 100m of each trial. **Results** The preliminary results showed a decrease in the H-reflex amplitude for all subjects ( $19.5$ ,  $6.1$  and  $2.8\%$ ) from the first to the last 100m. This was inversely related to ratings of perceived exertion. Modulation of the reflex during the 800m showed a steep decline during the first 200m ( $22.1$ ,  $9.1$  and  $4.6\%$ ) followed by a plateau and a decrease in the final 100m. No modulation of EMG activation or stride-length were observed. **Discussion** The magnitude of the H-reflex decrease was different between subjects likely due to variations in voluntary activation. The relative decrease of the H-reflex amplitude was similar for all subjects, indicating that reflex modulation is evident as fatigue is occurring. Presynaptic inhibition or supraspinal alteration might be the mechanisms responsible for the decrease and require further investigation. Given the possible impact of supraspinal factors, V-wave measures and MVC twitch data are being conducted. **References** [1] Thomas C, Hanon C, Perrey S, Le Chechali J & Vandewalle H (2004) Oxygen uptake response to an 800-m running race *Int J Sports Med* 25: 1-6. ### CHANGES IN BALANCE STRATEGY AND NEUROMUSCULAR CONTROL IN RESPONSE TO FATIGUE – A STUDY IN UN-ANTICIPATED PERTURBATION DURING UNILATERAL STANCE

Ritzmann, R., Freyler, K., Gollhofer, A.

*University Freiburg*

**Introduction:** Fatigue impairs motor performance, considerably affects neuromuscular control, diminishes spinal reflexes and comprises the interaction of antagonistic muscles in complex motor tasks (Gandevia 2001). Although there is literature dealing with the interference of fatigue and postural control, the interpretation is confounded by the variety of paradigms used to study it. Further, little is known regarding modulations in dynamic balance control occurring within the neuromuscular system induced by fatigue. Therefore, the objective of this study was to evaluate the effect of fatigue on postural stability and to gather knowledge about its influence on balance strategy and neuromuscular control. **Methods:** In 22 subjects a fatigue protocol (FAT) consisting of continuous exposure to medio-lateral and anterior-posterior perturbations (PERT) until exhaustion was compared to a volume-matched standard protocol (CON, consecutive 30s PERT/30s rest). Centre of pressure displacement (COP), ankle, knee and hip kinematics, electromyographic activity of the soleus (SOL), tibialis anterior (TA), rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF) and gluteus maximus muscles (G) and spinal excitability of SOL at the peak of the short-latency responses (SLR) were recorded after posterior PERT. Cocontraction index (CCI) was calculated for TA/SOL, VL/BF and RF/G (Lewek et al. 2004). **Results:** (1) The number of failures in response to a balance PERT increased (+8%,  $P < 0.05$ ) and (2) COP amplitude (FAT vs. CON -9%,  $P < 0.05$ ) and velocity (-13%,  $P < 0.05$ ) decreased with fatigue. These changes were accompanied by (3) a decreased angular excursion at the knee (-1°,  $P < 0.05$ ) and hip joints (-2°,  $P < 0.05$ ), and (4) an increasing CCI of SOL/TA (+14%,  $P < 0.05$ ), VL/BF (+15%,  $P < 0.05$ ) and RF/G (+32%,  $P < 0.05$ ). (5) Spinal excitability in SOL declined in response to fatigue (-18%,  $P < 0.05$ ). **Discussion:** As a main outcome we found a distinctly deteriorated balance ability that occurred with a modified neuromuscular control due to fatigue. Hence, the increase in cocontraction reflected by simultaneously activated agonists and antagonists is accompanied with smaller knee and hip joint excursions indicating an elevated level of joint stiffness. These functional and neuromuscular modulations may be associated with an exaggerated postural rigidity and could have caused the delayed and reduced postural reactions that are reflected in the changes in COP displacement when compensating for sudden PERT. The reduction in spinal excitability in SOL may either be caused by fatigue itself (Gandevia 2001) or by an increase in reciprocal inhibition due to an augmented TA activity. **References:** Gandevia SC (2001). *Physiol Rev*, 81, 1725-89 Lewek MD et al. #### KINETICS STUDY OF EXERCISE-INDUCED HYPOXEMIA AT MODERATE ALTITUDE VERSUS SEA LEVEL IN TRIATHLETES

Hapkova, I., Estribeau, P., Gaston, A.F., Durand, F.

*Performance Health and Altitude Laboratory.*

**Introduction** The purpose of this study was to determine the impact of 1850 m altitude on the kinetics of Exercise-Induced Hypoxemia (EIH) and performance endurance-trained athletes. Among athletes are adepts of endurance at moderate altitude for which acclimatization is materially impossible, also lack of time and / or resources. However, acute exposure to altitude has physiological consequences that could increase EIH present at the sea level (SL) and reach the performance of athletes. Indeed, a recent study by Chapman et al. (2011) indicates that the altitude performance is closely linked to the level of arterial saturation O<sub>2</sub> (SpO<sub>2</sub>) measured in normoxia, that is to say, the amplitude of EIH. **Methods** 9 triathletes (41 ± 2 years) participated. All developed EIH at SL. Athletes performed two maximal exercise tests in the field (Leger-Boucher track) with measurements of gas exchanges, heart rate (HR) and SpO<sub>2</sub>: one at SL (Perpignan) and the other at 1850 m (ALT, Font-Romeu), randomized in blocks 4 and 5. EIH was defined as a decrease in SpO<sub>2</sub> by 4% from the baseline. **Results** No difference at SL vs ALT of SpO<sub>2</sub> was measured in rest. SpO<sub>2</sub> measured at maximal exercise was different between SL and ALT (respectively 92 ± 0.9 vs 84 ± 1%,  $p < 0.001$ ). Amplitude of EIH was significantly lower at SL vs ALT (respectively 6 ± 0.8% vs 12 ± 1%,  $p < 0.001$ ). SpO<sub>2</sub> was different and decreased significantly from 60% VO<sub>2</sub>max between SL and ALT. VO<sub>2</sub>max was significantly lower at ALT than at SL (66.3 ± 2 vs 57.2 ± 2 ml.min<sup>-1</sup>.kg<sup>-1</sup>,  $p < 0.001$ ), as well as maximal aerobic speed (MAS; 16.4 ± 0.5 vs 15.4 ± 0.6 km.h<sup>-1</sup>,  $p < 0.01$ ) and HRmax. No significant difference was observed in maximal ventilation. **Discussion** The most interesting aspect concerns the kinetics and amplitude of SpO<sub>2</sub>. Lack of a difference in levels up to 50% VO<sub>2</sub>max between both conditions suggest that hyperventilation induced by acute exposure to hypoxia could compensate the alveolar hypoventilation in first phase of EIH. The second phase of EIH indicates gas exchange abnormality, the difference of SpO<sub>2</sub> decrease from 60% VO<sub>2</sub>max until VO<sub>2</sub>max suggest impairment of gas exchange abnormality. It is well known that exercise at ALT can induce a sub-edema (West et al., 1991). Whereas the possibility to a shift of the Barcroft's curve as well related to acute hypoxia high levels of lactatemia could be discussed. This study shows that athletes exhibit EIH are more impacted at 1850 m altitude and less performance. **References** Chapman RF, Stager JM, Tanner DA, Stray-Gundersen J, Levine BD. (2011). Impairment of 3,000m Run Time at Altitude Is Influenced By Arterial Oxyhemoglobin Saturation. *Med Sci Sports Exerc*, 43(9):1649-56. West JB, Tsukimoto K, Mathieu Costello O, Prediletto R. (1991). ### INFLUENCE OF AEROBIC CAPACITY IN RECOVERY AND INFLUENCE OF RECOVERY CAPACITY IN RSA TEST

Rodríguez-Fernández, A.1, Sánchez-Sánchez, J.2, Rodríguez-Marroyo, J.A.1, Morante-Rabago, J.C.1, Ogueta-Alday, A., Villa, J.G.1

1 *Institute of Biomedicine, University of León.* 2 *Pontifical University of Salamanca.*

**INTRODUCTION** Team sports are characterized by efforts acyclic and discontinuous with recovery after different intensities. RSAtest provide a simple way to evaluate the basic physical characteristics to excel in multiple-sprint sports [1]. The aim was checking if soccer players who have a better aerobic performance are the best in RSAtest and have better recovery at different intensities in field test, TIVRE-Futbol@Test interval, progressive and maximal. **METHODS** 45 young soccer players made: an incremental running test in laboratory (start at 8 km/h with increased 1 km/h every 1 min so that exhaustion) with electrocardiograph, on a motorized treadmill (Cosmos® Pulsar 4.0), expired gases were analyzed (Medisoft®). TIVRE-Futbol@Test (start at 9 km/h with 30 s of recovery every 256 m increases of 0.6 km/h each interval controlled by audio beeps; wore a PolarTeam® to register HR) to estimate the speed of anaerobic interval threshold (UAI) (Probst methodology) and determine Total Recovery (%REC-Tot), and pre (%REC-PreUAI), and post interval anaerobic threshold recovery (%REC-PostUAI). RSAtest of 8x30 m sprints with 25 s of active recovery, analyzing: total time (TT), mean time (MT), best time (MT), decrement (%DEC), and differences between best and worst (CHANGE). **RESULTS** The group with high %REC-Tot in field test (=15%) obtained significantly ( $p=0.001$ ) better fatigue index in %DEC ( $3.00\pm 1.45\%$ ) and CHANGE ( $6.05\pm 3.59\%$ ) than the group with mean recovery (=10% & <15%)  $5.03\pm 2.26\%$  and  $9.79\pm 4.53\%$ , and the group with low recovery (<10%)  $5.15\pm 2.06\%$  and  $9.27\pm 2.98\%$ . The soccer's with high  $VO_{2max}$  (>60 ml/kg-1/min-1) have significantly better HR recovery to 30 s after laboratory test (%RECHRmax) that the subjects with low  $VO_{2max}$  (<60 ml/kg-1/min-1) ( $10.17\pm 0.67\%$  vs.  $8.11\pm 0.65\%$ ) ( $p=0.042$ ); better %REC-Tot ( $14.24\pm 1.60\%$  vs.  $11.37\pm 0.51\%$ ) ( $p=0.037$ ); and better %REC-PreUAI ( $16.99\pm 2.16\%$  vs.  $13.31\pm 0.52\%$ ) ( $p=0.019$ ) **DISCUSSION** Studies reported higher levels of recovery in subjects with better  $VO_{2max}$  [2]. The subject with high %REC-Tot obtaining significant better results than other subjects with low recovery, in the fatigue index. TIVRE-Futbol@Test evaluated the recovery in different levels of intensity, have that subject with high aerobic capacity not only have significant best recovery at the end of lab test, but also they have significant best recovery into the different intensities that composite an interval and progressive field test. This highlights the importance of aerobic capacity in the recovery and the influence of the recovery in RSAtest. **REFERENCES** 1. Glaister, M. ### COMPARISON OF HIGH INTENSITY AEROBIC AND REPEATED SPRINT TRAINING ON PERFORMANCE AND PHYSIOLOGICAL VARIABLES OF JUNIOR SPRINT KAYAK ATHLETES

Oliveira Borges, T.1,2,3, Dascombe, B.J.4, Bullock, N.2,3, Coufts, A.J.1

1. *UTS, AUSTRALIA*, 2. *AIS, AUSTRALIA*, 3. *AUSTRALIAN CANOEING* 4. *UNIVERSITY OF NEWCASTLE, AUSTRALIA*

**Introduction** The purpose of the present study was to compare the effects of high intensity aerobic training (HIA) vs. repeated sprints (RS) the on physiological and performance adaptations in Junior Sprint Kayak athletes ( $n=20$ ,  $17\pm 1.2$  y). Methods Athletes were matched by  $VO_{2max}$  and TT performance and randomly allocated to complete 5 weeks of either RS or HIA training on water (6 session/wk) and resistance training (3 session/wk). Training was monitored using heart rate, session-RPE and GPS. On-water Sprint Kayak performance (200 m and 1000 m), aerobic fitness ( $VO_{2max}$  and lactate threshold (LT)), muscle and whole body oxygen ( $O_2$ ) kinetics were assessed pre, and post training. Results There was very likely difference in average training heart rate between groups ( $136\pm 8$  vs.  $146\pm 8$  bpm for the RS vs. HIA, respectively, [7.2%, 90%CL [2.3 to 12.3], ES=1.0]. The difference in the internal training load was unclear ( $1004\pm 460$  vs.  $1030\pm 372$  AU for the RS vs. HIA, [12.6% 90%CL [-26.0 to 73.1]); whilst the external training load (distance) was most likely different [ $6131\pm 275$  vs.  $7659\pm 543$  m, 24.8%, 90%CL [19 to 30.8], ES=1.7]. Performance changes over 200 and 1000-m were unclear for both groups [1.7 and -0.4%, 90% CL [-0.3 to 3.9 for 200-m and -3.5 to 2.8 for the 1000 m]]. The change in  $VO_{2max}$  was possibly trivial [0.9% [-3.2 to 5.3]] for both groups. Power at LT showed a very likely difference between groups [-18.3% [-30.6 to -3.9] and a possible change [-2.7% [-14 to 10]] after the training period. The HIA group demonstrated a likely speeding of the  $O_2$  kinetics at moderate [-7.5% [-20.2 to 7.1]] and severe [-17.6% [-37.1 to 8.1] ES=-0.5] domains. Muscle  $O_2$  kinetics were likely different between groups for moderate [-21.2% [-41.3 to 5.9]], heavy [-4.6% [-9.8 to 0.5]] and severe [-32.5% [-54.8 to 0.8]] domains. Speeding of the muscle  $O_2$  kinetics possibly occurred in the RS group for the heavy [1.5% [-2.9 to 6.0] ES=0.2] and severe [13.9% [-27.5 to 79.1] ES=0.2] domains. Discussion Despite different external training loads, Junior Sprint Kayak athletes reported similar internal training doses and demonstrated trivial changes in on-water time trial performance and  $VO_{2max}$ . In contrast, there were large changes in power at LT in both training groups, with faster whole body  $O_2$  kinetics with HIA training, and increased muscle  $O_2$  kinetics with RS training. The present findings show that 5-weeks of HIA or RS training induce different positive physiological adaptations in Junior Sprint Kayak athletes. These different adaptations are important considerations for coaches when periodising training programs.

### EFFECTS OF LOCAL BODY COOLING ON ENDURANCE PERFORMANCE DURING CYCLING UNDER WARM AND HUMID ENVIRONMENTAL CONDITIONS

Clijisen, R.1,2,4, Allemann, A.1, Baeyens, J.P.1,2, Cabri, J.1,3, Clarys, P.2

1. *University College Physiotherapy „Thim van der Laan”, Switzerland* 2. *Vrije Universiteit Brussel, Brussels, Belgium* 3. *Norwegian School of Sport Sciences, Oslo, Norway* 4. *SUPSI Landquart, Switzerland*

**Introduction** Humidity and temperature have an influence on physical and psychological performance. Especially in exhaustive endurance sports, high environmental temperatures can increase body temperature and decrease endurance capacity. To avoid a strong decrease of performance the body must adjust rapidly by increasing heat loss through evaporation, radiation and conduction. The goal of this study was to examine the effect of cooling devices, like vests and wristbands, on the endurance cycling performance in warm and humid environmental conditions. **Methods** Thirteen young healthy subjects, male ( $n=2$ ) female ( $n=11$ ) volunteered in this study. A random, cross-over design was used. Subjects were tested under two different conditions, with cooling and without cooling and performed a 60-minute work out on a bicycle ergometer at 60% of their maximal capacity, directly followed by a workout at 80% of their maximal performance until complete exhaustion. Cycle time to exhaustion was determined and used as the independent variable for endurance performance. Every three minutes the following variables were measured: heart rate, skin temperature, body temperature and perceived exhaustion (BORG scale). Environmental temperature (35°C) and relative humidity (44%) were kept constant during the tests. Results Evaluation of the data revealed a significant difference ( $p=0.02$ ) in the mean cycle time to exhaustion when subjects were using cooling devices ( $72.9\pm 8.8$  vs.  $69.1\pm 5.6$ ). There was no significant effect on the heart rate nor on core temperature, both ( $p>0.05$ ). The skin temperature in the chest region was significantly lower during the first 15 minutes of cooling. No differences were found in the individual

perception of the exercise intensity with or without cooling ( $p > 0.05$ ). Discussion Although we did not observe any significant changes in body temperature, heart rate and rated perceived exertion, our preliminary results indicate that wearing a cooling device in the form of a cooling vest can increase the cycling performance in warm and humid environmental conditions. ### **ALTITUDE TRAINING FOR ELITE ENDURANCE ATHLETES PRIOR MAJOR COMPETITIONS: A SIMPLE MEANS FOR INCREASING THE RELATIVE TRAINING INTENSITY?**

Pugliese, L., Serpiello, F.R., Millet, G., La Torre, A.

*University of Milan*

**Background.** Altitude training has long been used by elite endurance athletes to attempt improving sea-level performance. Traditionally, Live High-Train High (LHTH) interventions were adopted, where athletes trained and lived at altitude to try maximising the benefits offered by hypoxic exposure. However, inconsistent scientific research proposed that the possible haematological benefits of hypoxia would be offset by the inability to maintain high training intensity, mainly due to altitude-induced reduction in maximal oxygen uptake. However, "true" elite athletes have been rarely used as experimental population, and training intensity has almost never been monitored during LHTH research. This led to confusion regarding the applicability of LHTH with world-class endurance athletes. **Purpose.** This case study is an attempt to provide a practical experience on successful LHTH interventions and subsequent performances in two Olympic gold medalist (Athens 2004) endurance athletes. **Methods.** The training diaries of two Italian elite endurance athletes (athlete 1, race walker; athlete 2, marathon runner) were collected during 9 weeks of training, divided in three 3-week periods before, during, and after a LHTH camp, respectively. Total training volumes and volumes at different intensities expressed as percentage of race pace (RP) were recorded. Sea-level performance results were recorded before and after LHTH. Typical race-to-race variability, expressed as percentage of coefficient of variation, was calculated to assess the magnitude of training effects on performance after-LHTH. **Results.** Both athletes successfully completed the LHTH camp (2090 m) without injury or illness. Total training volume was increased during compared to before LHTH by 11.2 and 8.7%, while dropping by 35 and 17% after LHTH for athlete 1 and 2, respectively. During LHTH, respect to before, absolute training intensity was maintained and training volume at high-intensity ( $> 91\%$  of RP) was similar (28.7% vs 30.8%) for athlete 1 and increased (17.9% vs 9.9%) for athlete 2. After the intervention both athletes improved performance. In both cases, enhancements in performance after LHTH overcame the individual race-to-race variability. **Discussion.** This case study provides a view of a unique LHTH experience of elite endurance athletes. In our opinion, LHTH interventions can be used as a simple, yet effective, method to maintain absolute and improving relative training intensity in elite endurance athletes with beneficial effects on sea-level performance. ### **CHARACTERIZATION OF POLAR TRAINING LOAD IN PROFESSIONAL SOCCER TRAINING**

Bruch, A., Roecker, K., Kinnunen, H., Kuchno, H., Stapelfeldt, B.

*Albert-Ludwigs-Universität Freiburg*

**Introduction** Finding the optimal balance between training and recovery for an individual athlete is one key factor for successful team training. The novel Polar Training Load (TL) feature (Polar Electro Oy, Finland) aims at determining this balance. TL has been studied in cycling training with good results (1). Input information for cumulative TL (CTL) include gender, weight,  $VO_2\max$ , HRmax, HRrest, lactate threshold (LT), anaerobic threshold (IAT) and previous training. A training software (Polar Team2) collects the data of every player and gives feedback about the individual CTL-score of each player at any given point of time. This study evaluated the TL-concept in the training of a professional soccer team (2nd German soccer league). The purpose of this study was to describe professional soccer training in terms of CTL (without being TL controlled) and correlate CTL in soccer with individual performance outcome based on standardized incremental maximal exercise test (IET). **Methods** 30 male professional soccer players participated in this study (mean $\pm$ SD age 25.3 $\pm$ 4.2yr, height 182.6 $\pm$ 6.0cm, weight 78.4 $\pm$ 6.5kg). All players wore Polar HR-transmitters during all training sessions within a 12-week training period (8 weeks before, 4 weeks during the season). Training time and HR-profile of each player during every training session were recorded and CTL-scores calculated. At the beginning and end of the study an IET was performed by 14 players (age 28.5 $\pm$ 5.3yr, height 178.5 $\pm$ 5cm, weight 75.5 $\pm$ 4.9kg) on a treadmill with lactate-analysis including LT and IAT (2). Paired t-tests were used to analyze differences from pre to post IET. **Results** The 30 players completed 52 $\pm$ 19 training sessions with an average HR of 136 $\pm$ 6bpm and 64 $\pm$ 7 minutes (per training session) over 100 bpm. CTL-scores before a training session were on average 72 $\pm$ 24, after a training session 103 $\pm$ 32 resulting in an average TL-impact of one training session of 31 $\pm$ 9. IET showed unchanged running speed from pre to post-test at LT ( $p=0.35$ ) and an increase of 0.42km/h at IAT ( $p=0.01$ ). We found no significant correlations between CTL-values during the training period and performance development in terms of LT or IAT. **Discussion** In this study, the training routine of a professional soccer team during 12 weeks has been documented consistently in terms of HR-profiles and the novel CTL feature. The absence of a significant correlation between TL-values and results from IET could be explained by several reasons including the limited singular relevance of IET-markers (LT, IAT) in specific soccer performance as well as the small absolute increase in performance according to IET-markers. #### COGNITIVE FUNCTIONING IN YOUTH ELITE SOCCER PLAYERS

Verburgh, L., Scherder, E.J.A., Goedhart, E.A., Oosterlaan, J.

*VU University Amsterdam*

Background: Cognitive functions might be important for successful performance in sports, particularly in team sports requiring quick anticipation and adaptation to the continuously changing and unpredictable situations in the field. In the present study, we examined executive functioning in youth elite soccer players. Executive functions are higher order cognitive functions that manage other more basic cognitive functions and consist of functions such as various aspects of attention, visuospatial and verbal working memory, as well as motor inhibition. Method: Eighty-four youth elite soccer players and forty-two matched amateur soccer players in the age range 8 to 16 years ( $M = 11.8$ ), performed a Stop Signal task (motor inhibition), the Attentional Network Task (alerting, orienting, and executive attention), and two types of working memory tasks (verbal and visuospatial). Group differences were tested using univariate and multivariate analyses of variance. Results: The elite group showed superior performance on the Stop Signal task (stop signal reaction time) ( $F(1, 124)=7.84$ ,  $p < .0001$ ), indicating enhanced inhibitory control. Furthermore, the elite group showed a significant larger alerting effect ( $F(1,123)=4.78$ ,  $p < .05$ ) and a smaller orienting effect ( $F(1,123)=5.43$ ,  $p < .05$ ) on the Attentional Network Task, together indicating extreme efficiency in alerting attention. No significant group differences were found for the executive network of the Attentional Network Task ( $F(1,122)=1.30$ ,  $p=.26$ ) and verbal and visuospatial working memory ( $F(1, 108)=.64$ ,  $p=.42$  and  $F(1,124)=.24$ ,  $p =.62$  respectively). Conclusion: Results show that youth elite soccer players outperform youth amateur soccer players on suppressing an ongoing motor response and show superior alerting attention already at a young age. These executive functions indicates the presence of specific excellent cognitive functions in talented soccer players. Future research should investigate whether these cognitive functions are predictive for future success in soccer.

#### "GET IT OUT THE WAY. THE WAIT'S KILLING ME." HASTENING AND HIDING DURING SOCCER PENALTY KICKS.

Furley, P., Dicks, M., Memmert, D.

*German Sport University Cologne*

Introduction A recent study by Jordet and Hartmann (2008) suggested that performance pressure leads penalty takers to display "hastening and hiding" behavior—not looking at the goal when preparing the penalty kick and rushing through the penalty preparation—which in turn is associated with negative penalty taking performance. In the present study (Furley, Dicks, Stendtke, & Memmert, 2012), we extend these findings by (i) investigating how opposing goal-keepers perceived these nonverbal behaviors, how they affect outcome expectations, and (ii) how they affect the behavior of opposing goalkeepers. Method We examined the perception of nonverbal hastening and hiding behavior using the point-light technique during the soccer penalty kick among goalkeepers ( $n=20$ ). We measured how these nonverbal preparation behaviors affected the impression of the penalty taker, the expected performance against him, and the anticipated penalty. Furthermore, we analyzed how these respective penalty preparation strategies influenced the behavior of high-level goalkeepers ( $n = 12$ ) under in situ conditions. Results The results from Experiment 1 demonstrated that penalty takers showing hastening and hiding behaviors are perceived more negatively by soccer goalkeepers: (i) they are considered to possess less positive attributes, (ii) to have less accuracy in their penalties, and (iii) likely to perform less well in penalty situations. In Experiment 2, we provide first evidence that goalkeepers initiate their movement later following the observation of hastening and hiding behaviors during the penalty preparation as these are perceived as signs of an anxious, unconfident penalty taker. Discussion Our findings demonstrate the importance of investigating nonverbal behavior in sports as these have a major impact on impression formation, expected performance, and actual behavior of opposing players in the soccer penalty situation. #### DISTINGUISHING BETWEEN PENALTY KICK STRATEGIES

Noël, B.1, Furley, P.1, van der Kamp, J.2, Dicks, M.2, Memmert, D.1

*1:German Sport University, 2:VU Amsterdam*

Distinguishing between penalty kick strategies Introduction A small number of rules cause many aspects of penalty kicks in association football (e.g. ball position) to be constant. That seems to play a major role in the increasing prominence of penalty kicks as a research environment in sport science and related fields. However, penalty kick attempts can differ on aspects outside the official rules under which penalty kick strategy plays an important role (van der Kamp, 2006). Penalty kickers can either employ a keeper independent or keeper dependent strategy. Though there are indications that measures of interest (e.g. gaze behavior) differ dependent on the penalty kick strategy employed (Noël & van der Kamp, 2012) there is currently no method that allows distinguishing between/predicting of penalty kick strategies. Methods We advised soccer players to carry out penalty kicks under the terms of certain penalty kick strategies. Video footage of these penalty kicks was used for Experiment 1. That is, participants rated twelve different aspects of penalty kicks that were part of the created video footage. Based on data of Experiment 1 we calculated a logistic regression model to predict penalty kick strategy in Experiment 2. To this end participants rated the same twelve aspects of penalty kicks carried out at FIFA World Cups and UEFA European Football Championships. Results Results of Experiment 1 showed that penalty kick strategies differed in several aspects like gaze behavior, ball speed, run-up and kick accuracy as a consequence of different penalty kick strategies employed. This could be used to predict penalty kick strategies in Experiment 2. Discussion The results of this study can be useful for scouting in professional soccer as well as for scientific purposes. In research using a penalty kicking paradigm there should be controlled for effects of different penalty kick strategies. Scouting of opposing penalty kickers in professional soccer should also include preferred penalty kick strategy because different strategies call for different behavior of the goalkeeper. Incidence and success rates of both penalty kick strategies in professional soccer are

also discussed. References Noël, B., & van der Kamp, J. (2012). Gaze behaviour during the soccer penalty kick: an investigation of the effects of strategy and anxiety. *Int. J. ### **POSITIVE SELF-TALK IMPROVES 10 KM CYCLING TIME TRIAL PERFORMANCE FOLLOWING THE EVOLUTION OF A PACING TEMPLATE IN CONTRAST TO A NEUTRAL SELF-TALK INTERVENTION**

Barwood, M., Corbett, J., McVeigh, D., Wagstaff, C.

*Portsmouth University*

**Introduction** Pacing strategy is the spontaneous variation in speed during self-paced exercise and represents the interplay between previous exercise experience, available physiological resource and motivation (Corbett et al., 2009). The psychological demands of pacing strategy may manifest themselves as negative cognitions that impair performance (Barwood et al., 2008). The present study examined whether positive self-talk statements, to counteract negative cognitions, could influence pacing strategy and performance after the evolution of an initial pacing strategy. **Methods** Fourteen untrained male participants volunteered for this ethically approved study; mean [SD] age 19 [1]yr, mass 76.2 [8.9]kg, height: 1.82 [0.12]m; n=14. Participants undertook a total of four 10 km cycling time trials (TT) on a static bike. Following the third TT participants were matched in to two equal groups based on completion time and allocated to one of two self-talk intervention groups who received an intervention comprising 1) positive self talk (P-ST) or 2) neutral self-talk (N-ST). They then completed the final TT. Completion time, split time (1 km), RPE, and VO<sub>2</sub> were measured and anaerobic and aerobic energy distribution were estimated (PANAER & PAER). Data were compared within participant and between group using factorial ANOVA to an alpha level of 0.05. **Results** Prior to the final trial (i.e. after matching in to separate groups) TT completion times were 18.4 [1.9] and 18.4 [2.0] minutes in the P-ST and N-ST groups respectively. In the final TT completion time was faster in the P-ST group compared to the N-ST group who got slower relative to their pre-intervention TT; 17.7 [1.5] and 18.7 [1.9] minutes, p<0.05. In the P-ST group, this was achieved by a higher power output sustained from the 6th to 10th km of the TT and a greater contribution of PANAER to the energy distribution of the TT. The remaining variables were unchanged. **Discussion** Our data suggest that P-ST has a positive influence on cycling performance and pacing characterized by a faster completion time, a sustained power output, through greater usage of anaerobic energy resources in the latter part of the TT. In contrast, N-ST culminated in a slower performance time and gradual decline in power output as the 10 km TT ensued. Clearly P-ST can be ergogenic in untrained participants and the valence of self-talk is an important determinant of the efficacy of this psychological intervention. These data support previous work examining the efficacy of psychological skills (Barwood et al., 2009) with the important addition of a suitable control condition. **References** Barwood M, Thelwell R, Tipton M. (2008). *Med Sci Sport Exerc*; 40: 387-96. Corbett J, Barwood M, Parkhouse K. (2009). *Br J Sports Med*; 43:770-4.

### **I SPY WITH MY QUIET EYE. TRAINING CATCHING IN CHILDREN: A PILOT STUDY.**

Wood, G.1, Miles, C.1, Vine, S.J.1, Vickers, J.N.2, Wilson, M.R.1

*1. University of Exeter 2. University of Calgary*

**Introduction:** Recent research has identified differences in the quiet eye (QE) of children with high and low motor coordination (Wilson et al, 2012). Children with high motor coordination displayed earlier and longer QE durations in a catching and throwing task. The aim of the current study is to examine the efficacy of a QE training (QET) intervention designed to improve the throwing and catching performance of a sample of typically developing (TD) children. **Methods:** Thirty-eight year 5 primary school children were randomly allocated into either a QET group or a technical training (TT) group. Children wore a gaze registration system and performed 10 baseline and retention catching trials before and after a training intervention. The training consisted of three video demonstrations of an instruction followed by a series of practices. The QET group received gaze strategy instructions whereas the TT group received traditional throwing and catching instructions. **Results:** The performance results revealed that children who underwent the QET intervention experienced a greater training effect than their TT intervention counterparts; catching 22% (as opposed to 5%) more balls after training. This training effect was underpinned by fundamental changes in gaze control. Specifically, the QET group significantly increased both their targeting and tracking QE durations. **Conclusion:** QET appears to proffer a learning advantage over traditional training instructions when learning fundamental interception skills that are key building blocks for sport and playground games. Such interventions may therefore help children with low motor coordination break the negative cycle linking low motor skill competence with low levels of physical activity and cardio-respiratory fitness. A further study is underway to determine if these training effects are observed in children with developmental coordination disorder. **References:** Wilson, M. R., Miles, C. A., Vine, S. J., & Vickers, J. N. (2012). Quiet Eye Distinguishes Children of High and Low Motor Coordination Abilities. *Medicine and science in sports and exercise*.

### **CALIBRATION PROCESSES IN A SERIAL TALENT TEST**

Fasold, F.1, Memmert, D.1, Unkelbach, C.2

*1: German Sport University Cologne, 2: University of Cologne*

**Introduction** Serial evaluations like talent tests in which no objectives measured (e.g. times, heights) are available to assess the presented performances represents an intriguing problem for the talent scouts. Initially, they have to assess the talents without knowledge about following performances. Based on previous research (e.g. Memmert & Unkelbach, 2012; Unkelbach, Ostheimer, Fasold & Memmert, 2012) we assume that scouts have to observe a certain number of performances to calibrate their judgment scale on given context. This calibration process leads to systematic biases (avoidance of extreme judgments) in the beginning of the series and therefore to inconsistent judgments. To develop measures to ensure consistent and fair judgments, independent from the position in a series, it is important to determine the number of assessed performances that evaluators have to observe until their judgment scale is calibrated. Therefore we investigated how many performance observations are necessary to calibrate the internal judgment scales on performance context in a specific talent-test. **Methods** Twenty performances (videos) of a talent-test (team-handball) were used and the order was systematically varied three times. Thus, we presented same performances on three different positions (early, medium, late) in this series and tested the effect of the position on the assessment. Thirty participants were randomly assigned to these series. **Results** We found significant differences between the early and the later positions. Best and worst performances are rated more average in the early positions. On average, after nine judged performances the assessment of the same performances remains stable and consistent. **Discussion** Based on the results, we expected as well for other evaluations that up to a specific position good and bad performances become rated

more average. Alternative approaches for the explanation of biases in subjective judgments (e.g. social comparison, Mussweiler, 2003) could not explain these results. In conclusion, we assume that calibration is a necessary requirement for consistent judgments over the entire judgment series. Further research should be focused on the practicability and effectiveness of interventions to prevent talents and athletes from the negative calibration effects. #### GRADUATED COMPRESSION SLEEVES DO NOT ATTENUATE MUSCLE DAMAGE DURING EXERCISE IN TRAINED MEN

Bottaro, M.1, Pereira, M.C.C.1, Martorelli, S.1, Rocha-Júnior, V.A.1, Neumann, M.C.1, Nóbrega, O.T.1, Souza, V.C.1, Castanheira, R.P.M.1, Brown, L.E.2

1: *University of Brasília (Brasília, DF, Brazil)*, 2: *California State University, Fullerton (Fullerton, CA, USA)*

**Introduction** The rapid recovery of performance when engaging in multiple exercise bouts within a short period of time is of importance to maximize competitive success. Thus, professional basketball players and others have worn graduated compression sleeves during games to enhance both performance and post-exercise recovery. The effects of using lower-body compression garments on post-exercise clearance of muscle damage markers have been extensively studied (Duffield et al., 2010). However, to date, studies on the effects of using compression sleeves on muscle damage recovery following high-intensity exercise are lacking. Thus, the aim of this study was to investigate the effects of wearing graduated compression sleeves on recovery of muscle damage indirect markers. **Methods** Twenty-two trained male subjects were randomly assigned to two groups: 1) compression sleeves (CS, n= 11) or placebo sleeves (PS, n= 11). The participants performed 4 sets of 10 unilateral maximal elbow flexion' eccentric actions on an isokinetic dynamometer at 120°s<sup>-1</sup>. Peak torque (PT) and muscle soreness were measured at baseline, immediately post exercise (T1), and at 24, 48, 72 and 96 hours after exercise. Creatine Kinase (CK) was measured at baseline, 48 h and 96 h post-exercise. **Results** There were no significant differences between groups for peak torque (p>0.05) or muscle soreness (p>0.05) throughout 96 hours of recovery. However, strength was significantly lower (p<0.05) than baseline from T1 to 96h for both groups. Perceived muscle soreness peaked at 48 h post exercise-induced muscle damage for both groups. There was also no significant difference between groups for CK (p>0.05) which peaked at 96 h post-exercise in both groups. **Discussion** Our findings suggest that the use of compression sleeves during exercise has no effect on muscle damage marker recovery after 96 h in young trained subjects. It has been proposed that the compression garments may assist muscle contraction via the reduction of muscle oscillation and vibration during vertical jumps (Doan et al., 2003; Bringard et al., 2006). This drop in oscillation may reduce muscle damage. Thus, one of the reasons for the lack of differences may be related to the exercise mode used in the present study. Isokinetic elbow flexion contractions are very stable and controlled and may have produced low muscle oscillations and vibrations during the exercise protocol. **References** Duffield R, Cannon J, King M. (2010). *J Sci Med Sports*, 13, 136-40. Doan BK, Kwon YH, Newton RU, et al. (2003). *J Sports Sci* 21, 601-10. Bringard A, Perrey S, Belluye N. (2006). *Int J Sports Med* 27, 373-8.

#### ACUTE NEUROMUSCULAR AND METABOLIC RESPONSE AFTER A BOUT OF TWO DIFFERENT STRENGTH TRAINING PROTOCOLS: HIGH RESISTANCE CIRCUIT VS. TRADITIONAL STRENGTH TRAINING.

Márquez, G.1, Romero-Arenas, S.1, Marin-Pagan, C.1, Fernández del Olmo, M.2, Alcaraz, P.E.1

1) *Catholic University of Murcia*; 2) *Universidade de A Coruña*

**Introduction.** Recent research has shown that healthy adults produce the same amount of muscular force and power output both in a high resistance circuit (HRC) as in a traditional strength (TS) training session, under the same loading condition [1,2,3]. It has also been revealed higher cardiorespiratory responses during HRC than during TS training [3]. However, it still remains unknown the neuromuscular and metabolic effects after a bout of both training protocols. The main objective of this study was to investigate how HRC and TS training bout affects the neuromuscular function and metabolic response. **Method.** For this purpose, we recruited 11 volunteered healthy trained subjects (21±2 yr; 178±5 cm, 79±4 kg). After a familiarization session, subjects performed two different strength training sessions (HRC and TS) in a counterbalanced order. Each session consist in 8 sets of 6 repetitions maximum (6RM) of three different exercises (bench press, upright row and back squat). The amount of work load (set and session volume, and velocity) and local muscular rest period (3 minutes) were equated, however, the time between exercises was different (HRC: 35 sec.; TS: 180 sec.). Neuromuscular function of knee extensor muscles was explored using twitch interpolation technique. Metabolic response was assessed by means of blood acid lactate concentration. Subjects were tested before and after (1, 4, 7 and 10 minutes) both training protocols. A two way RM-ANOVA (training type and trial time) were performed for the next parameters: isometric MVC torque (N•m), voluntary activation (%), resting twitch amplitude (N•m) and blood lactate (mMol). **Results.** Results showed a significant reduction in the MVC after HRC, without changes after TS training bout. RM-ANOVA have also revealed lower resting twitch amplitudes after both protocols, however, it displayed a significant greater decrease in the HRC session. Blood lactate was significantly higher after HRC compared to TS training. Analysis has also shown a significant reduction in the amount of voluntary activation after both training bouts. **Discussion.** Present results have shown clear neuromuscular and metabolic differences after both training protocols. In this line, we can speculate that fatigue produced by HRC is a peripheral dependent effect since the reduction in MVC seems to be paralleled with the decrease in resting twitch amplitude. It could be related to the higher blood lactate concentrations found after this kind of training bout. However, although a reduction in voluntary activation reflects central fatigue, it is no type of training dependent. Our results could improve the understanding related to the chronic effects provoked by both HRC and TS training methods. **References.** [1] Alcaraz et al. ### LOCALIZATION OF MUSCLE DAMAGE AFTER NEUROMUSCULAR ELECTROSTIMULATION DETECTED BY MULTIMODAL MAGNETIC RESONANCE IMAGING

Fouré, A.1, Duhamel, G.1, Wegrzyk, J.1, Vilmen, C.1, Jubeau, M.2, Nosaka, K.3, Mattei, J.P.1, Bendahan, D.1, Gondin, J.1

1: Aix Marseille University (Marseille, France), 2: University of Nantes (Nantes, France), 3: Edith Cowan University (Joondalup, Australia)

**Introduction** Neuromuscular electrostimulation (NMES) is useful for improving muscle function. However, it has been reported that NMES induces muscle damage mainly due to the specificity (i.e. non-selective, spatially fixed and synchronous) of motor unit recruitment, especially when it is used for the first time (1). Moreover, it is documented that NMES results in a preferential activation of muscle fibers close to the stimulating electrodes (2), so that one could expect heterogeneous damage between directly and indirectly stimulated muscles. The present study aimed to test the hypothesis that NMES-induced muscle damage would be different between directly and indirectly stimulated muscles of the knee extensors using multimodal magnetic resonance imaging (MRI) including T2 mapping and diffusion tensor imaging (DTI). **Methods** Eleven male subjects ( $22 \pm 1$  y) took part in a single bout of NMES (frequency = 75 Hz, 5 s on / 15 s off, 45 contractions) with the stimulation electrodes being placed over the belly of vastus lateralis (VL) and vastus medialis (VM) muscles. MRI was taken before and 4 days after the NMES session using a 1.5T scanner. Changes in T2 values and DTI metrics including diffusivities ( $\lambda_1$ ,  $\lambda_2$  and  $\lambda_3$ ) that quantify water molecules diffusivity within muscle, were compared between the directly stimulated VL and VM muscles and the indirectly stimulated rectus femoris (RF) and vastus intermedius (VI) muscles. **Results** Mean increases in T2 were larger for the VL (+17.7%) and VM (+8.0%) when compared with the VI (+3.5%) muscle ( $P < 0.05$ ). Diffusivities significantly increased for the VL [2.1 - 5.8%], VM [1.7 - 3.0%] and VI [1.1 - 2.0%] without difference among them. Both T2 values and DTI metrics remained unchanged for the RF. **Discussion** T2 and DTI metrics changes measured after the NMES session indicated that the extent of muscle damage was greater for the directly stimulated muscles (VL and VM) than indirectly stimulated muscles (VI). It should be noted that RF muscle was unaffected. Results obtained in the present study might be related to the activation of deep intramuscular nerve branches and shear stress between superficial (VL and VM) and deep (VI) muscles. The extent of MRI changes varied between T2 and DTI metrics suggesting that they reflect different physiological processes. Thus, combined T2 and DTI analyses would be of interest for monitoring in vivo skeletal muscle injury. **References** 1) Nosaka K et al. ### LONG-TERM EFFECTS OF ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION ON NEUROMUSCULAR ASYMMETRIES IN ELITE ALPINE SKI RACERS

Jordan, M.1, Maurer, C.1, Aagaard, P.2, Herzog, W.1

1: University of Calgary (Calgary, Canada) 2: University of Southern Denmark (Odense, Denmark)

**Introduction** The long-term effects of ACL reconstruction (ACL-R) in elite ski racers are unknown yet neuromuscular asymmetries implicated in re-injury may persist [1, 2]. ACL re-injury occurs frequently in elite ski racers [4] and a deeper understanding of the neuromuscular changes with ACL-R may improve return to snow outcome. The purpose of this study was to measure between-limb asymmetry in muscle mass, quadriceps/hamstrings strength, vertical ground reaction force (GRF) production in countermovement jumping (CMJ), and quadriceps/hamstrings muscle activity in the CMJ in elite ski racers with a history of ACL-R. ACL-R skiers (AS) were hypothesized to show greater asymmetry in these parameters compared to healthy skiers (HS). **Methods** Leg muscle mass was measured with Dual Energy X-Ray Absorptiometry in active elite skiers (8 HS; 8AS 33±11 months post-op). Using dual force plate analysis simultaneous measurement of GRF from each limb was used to evaluate asymmetry over 10 CMJs by calculating phase-specific impulse for the right and left leg [5]. Subsequently, 8 athletes (4 HS; 4 AS) performed isometric knee extensor and flexor maximal voluntary contractions (MVCs), and synchronized surface electromyography (EMG) recordings from the quadriceps and hamstrings muscles were obtained during 10 CMJs. EMG windows (100ms) were obtained over phases of the CMJ. An asymmetry index (AI) was calculated for all variables and compared between groups [3]. A within-group comparison of muscle activity levels between the left and right leg was also made. **Results** AS demonstrated greater AI in muscle mass (HS= -1.9%±2.7; AS= 4.7%±3.4) and impulse in the ascent phase of the CMJ (HS= -0.6%±2.0; AS= 8.8%±5.3) ( $p < 0.01$ ). Furthermore AS had a larger AI in explosive hamstring strength (MVC Impulse over 200ms: HS= -7.7%±5.7; AS= 12.4%±12.6; Impulse over 150ms: HS= -6.7%±7.1; AS= 11.4%±11.9) ( $p = 0.05$ ) along with a trend of increased semitendinosus muscle activity (Healthy Leg =  $0.06 \pm 0.02$ ; ACL-R Leg =  $0.24 \pm 0.13$ ) in the flight phase of the CMJ ( $p = 0.08$ ). **Discussion** Consistent with the literature [1], bilateral asymmetries (i.e. deficits) were found in AS. Asymmetry in explosive hamstring MVC strength and a trend towards asymmetry in semitendinosus muscle activity during the CMJ suggests an attenuated capacity for ACL protection in the operated limb of ACL-R skiers [6, 7]. **References** [1] Castanharo et al, *J Orthop Sci* 16, 2011; [2] Ford et al, *Med Sci Sports Exerc* 35, 2003; [3] Impellizzeri et al, *Med Sci Sports Exerc* 39, 2007; [4] Pujol et al, *Amer J Sport Med* 35, 2007; [5] Thorlund et al, *Scand J Med Sci Sports* 18, 2008; [6] Zebis et al, *J Strength Cond Res* 25, 2011; [7] Zebis et al, *Am J Sports Med* 37, 2009

### EFFECT OF COLD WATER IMMERSION FOR THE RECOVERY OF MUSCLE DAMAGE AND MUSCLE STRENGTH AND POWER AFTER RUGBY GAME

Takeda, M., Sato, T., Hasegawa, T., Shintaku, H., Kato, H., Radak, Z.

*Laboratory of Exercise Physiology*

**Introduction** Efficacy of cold water immersion (CWI) for endurance performance after endurance exercise has been reported (Vaile, et al., 2008; Peiffer et al., 2010). However, positive effect of CWI for the recovery to the reduction of muscle strength and muscle power or to the muscle damage after the severe muscle activity has not been clearly demonstrated (Bryane & Eston, 2002; Selwood et al., 2007). This study examined the effect of CWI used after the rugby game simulation training including severe body contact on biochemical parameters representing exercise-induced muscle damage and muscular functional test on rugby players. **Methods** Twenty collegiate male rugby players (age:  $20.3 \pm 0.6$  years old, body height:  $173.8 \pm 5.1$  cm, body weight:  $85.4 \pm 2.0$  kg) volunteered in this study. They were randomly assigned CWI group ( $n = 10$ ) or control group ( $n = 10$ ) matched body height and weight. They tried as 1st trial 80 minutes rugby game simulation training including tackles and body contacts. CWI group was immersed cold water ( $15^\circ\text{C}$  for 10 minutes) after the training. Serum creatine kinase (CPK), aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatinine (Cre), blood lactate, 50 m dash running performance, vertical jump, reaction time, side step for 20 seconds, maximal anaerobic cycling power for 10 seconds, and subjective feeling of fatigue were measured before, immediately after, and 24 hours after the training. One week later, 2nd trial was conducted as interchangeably classified groups, cross over design. Two way repeated measure ANOVA was used for statistical evaluation. **Results** Body temperature was significantly reduced immediately after CWI ( $20.5 \pm 1.0^\circ\text{C}$  vs  $28.2 \pm 1.4^\circ\text{C}$  for control condition). Subjective feeling of fatigue was significantly low immediately after CWI. However, no statistically significant interactions were found in

any of blood variables and muscle functional tests in both between groups and time courses. Main effects of time courses were found in all blood variables and muscle functional tests except for 10 seconds maximal pedaling power. Conclusion Our results suggested that rugby game induces muscle damage and reduces muscle function. However, CWI has no restorative effect of 80 minutes rugby game in terms of muscle damage and muscle function. References Byrne C, Eston R. (2002), *J Sports Sci*, 20(5), 417-425. #### OP-PM38 Rehabilitation [RE] 1

##### **SUPERIOR DAILY PHYSICAL ACTIVITY AND EXERCISE ADHERENCE IN CARDIAC REHABILITATION USING INTELLIGENT TECHNOLOGY**

Hautala, A.J., Kiviniemi, A.M., Mäkikallio, T.H., Koistinen, P., Rynnänen, O.P., Huikuri, H.V., Tulppo, M.P.

*Verve Research*

**Introduction** Daily physical activity (PA) and exercise training (ET) are core tasks in cardiac rehabilitation (CR). However, the majority of cardiac patients are not engaging in targeted PA, even when they are enrolled or completed in CR (1). We hypothesized that CR concept using intelligent technology will increase PA and ET adherence in acute coronary syndrome (ACS) patients. **Methods** Angiographically documented coronary artery disease patients (n=33, age 61±13 yr, BMI 28±5 kg/m<sup>2</sup>, left ventricular ejection fraction 63±9%, 82% on β blockade) completed a six month exercise based CR program. PA and ET prescription was guided according to current guideline (2). A wrist-worn accelerometer PA device (Polar Electro, Kempele, Finland) was used to collect PA during the intervention. The patients were able to self-monitor their daily realized vigorous PA (> 3.5 METs) by the device aiming to 30 min/day. Once a week the patients performed a guided exercise session followed by a physiotherapist in fitness room equipped with intelligent strength devices (HUR Oy, Kakkola, Finland). After each session patients received an individual feedback from health related indexes, e.g. aerobic fitness and muscular strength, which were gathered during exercise. Instructions were also given for home based training and patients wrote all the training sessions in a diary. The realized ET was summed up from the diaries by calculating training load (Rating of Perceived Exertion (RPE) x duration of exercise session) (3) at monthly basis. PA data was analyzed accordingly to calculate daily vigorous PA. **Results** The average of monthly realized ET exceeded the prescribed ET (training load 14262±1033 vs. 9653±99, main effect p=0.019). 79% of patients (26/33) crossed the target amount of ET during intervention. Accordingly, the average of objectively measured vigorous PA was 46±1 min/day meaning that 25 out of 33 patients (76%) surpassed the daily 30 min of vigorous PA. **Discussion** The exercise based CR concept using intelligent technology seems effective to increase PA to the recommended level. Self-monitoring techniques such as keeping ET diary, wearing PA device and feedback of health-related indexes at weekly basis contribute markedly to daily PA and ET realized in ACS rehabilitation. **References** 1. ##### **A SIX-WEEK HIGH-INTENSITY VIRTUAL-REALITY INTERVAL TRAINING PROGRAM IN INDIVIDUALS WITH SPINAL CORD INJURY**

Davis, G.M.1, Hasnan, N.1,2, Engkasan, J.P.2, Husain, R.2

1. *University of Sydney (Sydney, Australia)*, 2. *University of Malaya (Kuala Lumpur, Malaysia)*

**Introduction** The aim of this study was to investigate the effect of high-intensity "hybrid" (arm and FES-leg cycling) interval training in a virtual reality environment on aerobic fitness, lipid profiles and glucose tolerance in persons with spinal cord injury (SCI) **Methods** Eight individuals with chronic SCI undertook 6 weeks of high-intensity (80-90% HRpeak) aerobic interval training using an arm+FES-leg tricycle. Training sessions were either 32 minutes, three times per week or 48 minutes, two times per week. The recumbent tricycle (BerkelBike®) was positioned on Tacx i-Magic VR Trainer®, indoors in front of a flat panel monitor displaying simulated outdoor overground cycling. Computer-controlled electrical stimulation was applied bilaterally to the quadriceps, hamstrings and glutei to evoke leg cycling. Voluntary arm cranking was at a cadence selected by the subjects to achieve their desired exercise intensity. The participants were assessed for their peak cardiorespiratory responses and power output before and following completion of the six-week training programme. Lipid profiles, cholesterol and oral glucose tolerance were also measured before and after the training programme. **Results** As a result of the high-intensity hybrid training program, subjects increased their peak aerobic fitness from 1.14±0.18 L/min to 1.37±0.23 L/min (p<0.05). Their body mass-adjusted VO<sub>2</sub> peak also increased from 19.3±3.4 mL/kg/min to 23.2±3.4 mL/kg/min (p<0.05). Arm+ leg peak power output during "hybrid" exercise was raised from 52.5±10.4 W to 70±12.0 W (P<0.05). Lipid profile TChol, HDL, LDL and oral glucose tolerance results were unchanged after training, although modest improvements were observed in some subjects. **Discussion** This was the first study to investigate indoor virtual-reality "hybrid" exercise training in individuals with SCI. These results reveal similar improvements of peak aerobic fitness observed in prior studies. Our 20% increase of aerobic fitness and 33% augmentation of peak power output was more than double that observed by Heesterbeek et al, 2005, for a 4-week BerkelBike® training program. The larger increases of the current study were likely due to a longer training period and our use of high-intensity aerobic interval training. There are no previous studies that have investigated changes of lipid profile and oral glucose tolerance following "hybrid" exercise training in SCI. The lack of changes in these biochemical measures suggests that six weeks of twice- or thrice-weekly training, even at a high intensity, may be too short to modify these biochemical markers of cardiovascular risk in the SCI population. **References** Heesterbeek PJC et al (2005) *Technology and Disability*, 17, 103-110

## EFFECTS OF CONCURRENT VERSUS NON-CONCURRENT REHABILITATIVE CONDITIONING IN AN ACL-RECONSTRUCTED POPULATION

Minshull, C.1, Bailey, A.2, Shepherd, J.1, Yates, C.3, Gleeson, N.3

1. Nottingham Trent University, 2. RJAH Orthopaedic Hospital, Oswestry, UK; 3. Queen Margaret University, Edinburgh, UK

**Introduction** Rupture of the anterior cruciate ligament (ACL) is a potentially career-threatening injury for sports performers, invariably requiring reconstructive surgery to restore knee function (1). The consequences of ACL injury involve considerable temporal and fiscal costs (3) to rehabilitate the patient and restore function to the knee. Concurrently training for strength and cardio-vascular endurance in close proximity may attenuate strength gains in healthy populations via the interference effect (2). This type of training is widely used in contemporary rehabilitative practice and as such, may have implications for patient rehabilitation. This study assessed the effectiveness of segregation of strength and endurance rehabilitative exercise compared to concurrent exercise methods. **Methods** 61 patients (54 males, 7 females) with arthroscopically verified unilateral ACL rupture were randomly assigned into either: i) non-concurrent rehabilitation (NCON, n = 36) involving phasing of strength and endurance exercise, or: ii) concurrent rehabilitation (CON, n = 25). Patients were assessed at pre-, 6 weeks, 12 weeks, 24 weeks and 48 weeks following surgery. Assessments of ACL laxity and peak force (PF) of the knee extensors and the knee flexors were obtained from the injured and non-injured limb on each occasion. Data were analysed by separate 3-way mixed-model repeated-measures ANOVAS. **Results** ACL laxity improved over time similarly in both groups (mean  $\pm$  SD: 11.2 (5.0) mm vs. 2.8 (0.6) mm at pre- and 48 weeks, respectively) ( $p < 0.001$ ). A decrease in KFPF and KEPPF of the non-injured limb was observed at 6 weeks in both groups. A continual increase in KFPF was observed at all time-points thereafter, which was greater in the NCON group compared to CON ( $p < 0.001$ ). At 48 weeks the KFs were 13.6% weaker compared to pre-surgery levels in the CON, compared to 21.0% stronger in the NCON group. KEPPF of the injured limb showed statistically similar improvements in both groups and was restored to within pre-surgery levels at 48 weeks (407.8 (137.4) N vs. 395.1 (106.7) N). Whilst no changes were observed to KEPPF in the non-injured limb, the data suggest a superior and improved performance of KFPF in the NCON group. **Discussion** Segregation of strength and endurance rehabilitative exercise may enhance performance of the knee flexors following surgery. Given the protective role of this muscle group to the ACL, such an approach may facilitate an optimised recovery and prevention of re-injury. **References:** 1. Beynon et al. ## BIOCHEMICAL IMPACT OF SOCCER - MARKERS OF HORMONAL, MUSCLE DAMAGE AND REDOX MARKERS THROUGHOUT THE SEASON

Silva, J.R.1, Rebelo, A.1, Marques, F.2, Pereira, L.2, Seabra, A.1, Ascensão, A.3, Magalhães, J.3

University of Porto

**Introduction** This study aimed to analyze changes in performance, muscle function, as well as stress-related biochemical markers in professional soccer players throughout the soccer season. **Methods** 14 male professional soccer players were monitored throughout the season for hormonal, muscle damage, inflammatory and redox state markers [E1 – before the beginning of the preparation period; E2 - middle of the competitive season (January); E3 - end of the competitive season, and E4 – after the end of the recovery period and before the beginning of the preparation period of the next season]. Sprint, jump and change of direction (COD) performance, and maximal isokinetic knee extension (KE) and flexion (KF) parameters were also measured (E1-E3). **Results** COD increased in E2 and E3 ( $P < 0.01$ ). Cortisol decreased in E3 and plasma testosterone/cortisol ratio (T/C) increased in E2 and E3 ( $P < 0.01-0.05$ ). Myoglobin (Mb) increased in E2 and creatine kinase (CK) and C-reactive protein (CRP) in E2 and E3 ( $P < 0.01-0.05$ ). Superoxide dismutase (SOD), protein sulfhydryls (-SH) and malondialdehyde (MDA) increased in E2 and E3 ( $P < 0.01-0.05$ ). From E2-E3, T/C increased and C, Mb and glutathione reductase (GR;  $P < 0.01-0.05$ ) decreased. T/C, CK, SOD, -SH and MDA decreased and C and GR ( $P < 0.05$ ) increased during off-season (from E3 to E4). Testosterone, glutathione peroxidase, uric acid and total antioxidant status levels were stable throughout the observation period. Hormonal parameters were associated with KE and KF from E2-E3 ( $r = 0.85-0.86$ ) and in E3 ( $r = 0.56-0.68$ ). In E2, significant correlations were observed between match accumulated time (MATE2), performance, hormonal and redox parameters ( $r = 0.456-0.615$ ). **Discussion** The overall analysis of our data point out significant alterations in biochemical parameters of professional players throughout the soccer season period (Heisterberg et al., 2012; Meyer et al., 2011), but not during off-season. However, despite these changes suggest an increased intra-season physiological stress (Kraemer et al., 2004), the neuromuscular performance was not significantly affected during in-season. Additionally, results also suggest that MAT was associated with physical, hormonal and oxidative stress-related parameters. **References** Heisterberg MF, Fahrenkrug J, Krstrup P, Storskov A, Kjaer M, Andersen JL. #### THE LACTATE MINIMUM TEST IN ROWING – A NEW CONVINCING TESTING CONCEPT

Perret, C.I, Vrana, A.2

*1: Institute of Sports Medicine and 2: Institute of Human Movement Sciences and Sport*

**Introduction** The lactate minimum test (LMT) was found to be a valid and reliable testing concept for different sport disciplines (Dotan et al., 2011; Johnson et al., 2009; Knöpfli-Lenzin and Boutellier, 2011; MacIntosh et al., 2002). Thus, it is surprising, that this testing method is still not used in rowing. Therefore, the aim of this study was to implement and validate the LMT concept in rowing. **Methods** 20 experienced male rowers (age: 22.8±6.7years, height: 185.9±5.2cm, body mass: 78.3±8.1kg, peak oxygen uptake (VO<sub>2</sub>peak): 65.6±6.5ml•min<sup>-1</sup>•kg<sup>-1</sup>) participated in this study. They completed two LMT, one 2000m all-out trial and several endurance tests for MLSS determination on a rowing ergometer. Peak performance as well as VO<sub>2</sub>peak during the first part of the LMT (LMTpeak) were compared with performance and VO<sub>2</sub>peak of the 2000m trial. Performance, heart rate, VO<sub>2</sub>peak and lactate concentration at lactate minimum (LM) were correlated with the corresponding data at MLSS. Further, coefficients of variation (CVs) were calculated for data at LM and LMTpeak. Results CVs for performance, heart rate and VO<sub>2</sub>peak at both, LM and LMTpeak, showed a high reproducibility (all CVs <3.5%). As expected according to Morton et al., only lactate concentrations revealed not to be well reproducible (CV>12%). Performance as well as VO<sub>2</sub>peak data highly correlated between LMTpeak and 2000m race performance (performance: r=0.96; p<0.001, VO<sub>2</sub>peak: r=0.93; p<0.001). Performance between LM and MLSS showed a significant correlation (r=0.81; p<0.001) as well. **Conclusions** The present LMT-protocol is highly reproducible and allows the assessment of VO<sub>2</sub>peak, MLSS as well as the prediction of 2000m race performance based on one single test. Therefore, our LMT-protocol represents a reliable and valid diagnostic tool for steering and monitoring the training process in rowing. **References** Dotan R, Zigel I, Rotstein A, Greenberg T, Benyamini Y, Falk B. #### EXTERNAL AND INTERNAL TRAINING LOAD IN AUSTRALIAN FOOTBALLERS.

Gallo, T., Cormack, S., Gabbett, T., Lorenzen, C.

*Australian Catholic University*

**Introduction** Quantifying load is difficult in high-intensity intermittent contact team sport, where acceleration, direction change and collisions contribute to the load experienced by the athlete (Young, Hepner, & Robbins, 2012). Inter- and intra- individual variability in response to external workload further complicates matters. Research on the individual characteristics that impact on the relationship between external load (EL) and internal load (IL) are limited (Impellizzeri, Rampinini, & Marcora, 2005). The purpose of this study was to explore the relationship between EL and IL in elite Australian Football (AF). The primary aim was to determine if running performance and player experience impacts this relationship. **Methods** From 41 elite AF players (22.6 ± 3.0y, 45.4 ± 60.6 senior games), 302 samples were analysed. Global-Positioning Systems provided EL variables including; total distance (TD), relative distance (RD), high-speed running (HSR) (>18.1 km.hr<sup>-1</sup>) and player load (PL). Session-RPE provided IL (Foster et al., 2001). A 2-km time-trial determined running performance and senior playing years determined experience. Players were classified into low running (LR) and high running (HR) groups and young and mature groups using median splits. Relationships were determined using multiple regression and differences between groups were analysed using effect sizes (± 90% CI). **Results** Regression modelling generated the following equation: IL = 385.59 + 0.12 (TD) – 5.59 (RD) – 0.10 (PL) (r<sup>2</sup> = 89%, TEE = 0.33 x/± 1.07). The LR group had higher RPE's compared to the HR group; unadjusted (-0.25 ± 0.19) and adjusted for EL measures of time (-0.33 ± 0.19), TD (-0.43 ± 0.19), RD (-0.40 ± 0.19) and PL (-0.34 ± 0.19). The LR group also had higher IL when adjusted for time (-0.33 ± 0.19) and TD (-0.43 ± 0.19) and TD (-0.43 ± 0.19). There was no difference in RPE between experience groups. The mature group had higher IL when adjusted for TD (0.27 ± 0.19). **Discussion** There was a small effect on RPE between running groups unadjusted and adjusted for each EL variable (except HSR). Small differences were seen in IL when controlled for time and TD. As time and TD are external measures of volume, perhaps components of running performance are related to the internal response to external training volume. A small difference existed in IL based on experience when adjusted for TD. In summary, IL was linked to running performance and player experience when standardised to EL volume. **References** Foster, C., Florhaug, J. A., Franklin, J., et al. (2001). #### SYSTEMATIC BIAS BETWEEN RUNNING SPEED AND METABOLIC POWER DATA IN ELITE SOCCER PLAYERS: INFLUENCE OF DRILL TYPE

Gaudino, P., Iaia, F.M., Alberti, G., Hawkins, R., Atkinson, G., Gregson, W.

*Liverpool John Moores University*

**Introduction** The physical demands of soccer are typically indicated by distance covered or time spent at specific velocities. Nevertheless, these measurements do not reflect the energy demands associated with accelerations and decelerations and, therefore, potentially underestimate the demands of match-play (Osgnach et al. 2010) and training (Gaudino et al., 2013). Small-sided games (SSG) are typically

incorporated into soccer training, but the degree to which the physical demands of SSG are underestimated by traditional monitoring approaches has not been evaluated. The aims of the present study were: i) to compare measurements of high-intensity demands of SSG between estimated metabolic power (di Prampero et al., 2005) and the traditional speed-referenced approach; ii) to evaluate whether any bias between the two approaches is dependent upon playing position or drill characteristics. Methods Three types of SSG (5v5, 7v7, 10v10) were completed by 26 elite soccer players competing in the English Premier League. A total of 420 individual drill observations were collected over the in-season period using portable GPS devices. High-intensity activity was compared in absolute units of distance covered at high metabolic power ( $>20W \cdot kg^{-1}$ ; TP) (di Prampero et al., 2005) and high speed ( $>14.4km \cdot h^{-1}$ ; TS) and, if appropriate, as a percentage of total distance. Players were categorised by playing position: central defender, wide defender, central midfielder, wide midfielder and attacker. Results High intensity activity distance was proportional to total distance, rendering a percentage statistic appropriate. High-intensity demands were on average  $99 \pm 144\%$  greater when expressed as high metabolic power versus high speed ( $p < 0.001$ ). The magnitude of this difference increased from  $55 \pm 33\%$  for 10v10 games to  $196 \pm 253\%$  for 5v5 games ( $p < 0.001$ ). The greatest difference between TP and TS was found to be  $349 \pm 532\%$  in the central defenders particularly during the 5v5 SSG ( $p < 0.001$ ). Discussion The high-intensity demands of SSG in elite soccer players are systematically underestimated by running speed alone particularly during 5v5 games and especially for central defenders. Therefore, estimations of metabolic power provide a more valid estimation of the true demands of SSG. References di Prampero PE, Fusi S, Sepulcri L, Morin JB, Belli A, Antonutto G. ### THE MOXUS MODULAR METABOLIC SYSTEM EVALUATED WITH TWO SENSORS FOR VENTILATION AGAINST THE DOUGLAS BAG METHOD

Rosdahl, H., Lindberg, T., Edin, F., Nilsson, J.

*Swedish School of Sport and Health Sciences*

Introduction Determination of oxygen uptake with the criterion Douglas bag method (DBM) has over the years successively been replaced by automated metabolic systems while the need of further validations of these systems has strongly been emphasized (Macfarlane 2001). The Moxus metabolic system (MMS) is a stationary automated metabolic system equipped with a mixing chamber and ventilation (VE) determined on the inspiratory side with either a turbine flowmeter or a pneumotachometer sensor. It has recently been evaluated against DBM (Medbø et al. 2012) but with the turbine flowmeter only. In the present study (Rosdahl et al 2012) both ventilation sensors were included and MMS was investigated for validity and reliability in a wide measurement range. Methods A serial coupling setup was used to collect the gas exchange variables simultaneously with MMS and DBM. Thirteen well-trained athletes participated in four tests and exercised on a cycle ergometer at five submaximal power levels (50–263W) and at VO<sub>2</sub> max. Results Reliability with both sensors was comparable to DBM. The average coefficient of variation (CV) of all exercise intensities with the pneumotachometer was  $3.0 \pm 1.3$  for VO<sub>2</sub> and  $4.2 \pm 0.8$  for VE. CV with turbine flowmeter were  $2.7 \pm 0.3$  for VO<sub>2</sub> and  $4.8 \pm 1.4$  for VE. Validity was generally acceptable but small differences in VO<sub>2</sub> related to the determination of VE were noticed. The relative differences vs. DBM at the powers including VO<sub>2</sub>max were similar for both sensors with ranges being +5 to -3 % for VO<sub>2</sub> and +4 to -2 % for VE while RER did not differ. Discussion The current study indicate that the reliability of the MMS with both sensors for VE compare well with the results of the criterion DBM and previous investigations. CV at VO<sub>2</sub>max (about 2.5%) was similar to the values ( $\leq 3\%$ ) as reported by Medbø et al. (2012) for the MMS with a turbine flowmeter. These findings suggest a reliability being applicable for most common conditions. Concerning validity, overall the present results show that MMS, with both sensors to determine VE compare reasonably well with DBM. However, since VE determined both with the pneumotachometer and turbine flowmeter setups differed slightly at a few power levels, and resulted in concomitant changes in VO<sub>2</sub> and VCO<sub>2</sub>, we suggest that further validity improvements may be gained by small additional refinements in the measurement of ventilation. ### THE CORRELATION BETWEEN THE KINETIC VARIABLES OF A SPRINT START AND THE FINISHING TIME FOR A DISTANCE OF FIVE METRES FOR GROUPS OF SKILLED AND NON-SKILLED SPRINTERS

Bavdek, R., Dolenc, A., Strojnik, V.

*University of Ljubljana*

Introduction: Sprint start is one of the factors of a successful sprint. Most sprint start research has been done including only trained sprinters (Bezodis, 2009; Mendoza and Schöllhorn, 1993; Mero et al., 1983). It is, therefore, impossible to say whether the results are valid for sprinters who are not as good or are beginners (non-skilled athletes). The aim of this research was to find correlations between kinetic variables of sprint start and the time during the distance of 5 meters in groups of athletes of different skilled categories. Methods The research included 22 sprinters ( $23 \pm 7.2$  years,  $179.5 \pm 8$  cm,  $74.5 \pm 12.3$  kg). Using hierarchical cluster analysis the sprinters were divided into two groups according to their time during the 5m distance (T5). 12 sprinters thus fell into the first group as skilled sprinters (T5 from 1.16 to 1.55 s), while 9 sprinters formed the second one as non-skilled sprinters (T5 from 1.60 to 1.79 s). Kinetic variables were measured with two force plates (Kistler, Winterthur) that carried starting blocks. T5 was measured with photocells. Every sprinter had two tries out of which the one with shorter T5 was used. The following variables were used: T5, velocity at the time of take-off from the starting block (VHSB), reaction time (RT), time of push (TPUSH), time of push with a rear leg (TRL), average horizontal acceleration (ACCH), and average horizontal power (POWH). Hierarchical Cluster analysis and correlation (Pearson's coefficient) statistics were made. Results In both groups of athletes VHSB, RT, TPUSH, ACCH, and POWH held a significant statistic correlation to T5 ( $P=0.00$ ;  $P=0.04$ ;  $P=0.00$ ;  $P=0.00$ ;  $P=0.00$  respectively). In the group of skilled athletes there was a statistically important correlation only among T5 and TPUSH ( $P=0.01$ ), ACCH ( $P=0.00$ ), POWH ( $P=0.00$ ) respectively, while in the group of non-skilled athletes there were no statistically significant correlations. Discussion The research clearly shows that in a heterogeneous group (combined group of skilled and non-skilled sprinters) there is a statistically significant correlation between measured variables and T5 like other authors suggest (Bezodis, 2009; Mendoza and Schöllhorn, 1993). The only exception is the TRL variable. In a group of skilled sprinters variables POWH, ACCH as Bezodis (2009) suggested and TPUSH were correlated to T5. We found no correlation between all variables and T5 in a group of non-skilled sprinters. We believe that the main reason is poor sprint start technique so the caution is needed in interpretation of the results for this group. References Bezodis NE. (2009). Unpublished PhD Thesis. **DEVELOPMENT AND VALIDITY OF A NEW SCALE OF PERCEPTION OF VELOCITY IN LOWER BODY RESISTANCE TRAINING**

Bautista, I.J.1, Chiroso, I.J.1, Chiroso, L.J.1, Reverter, J.2, Hernan, O.3, Gomez, P.1

*1 Universidad de Granada (Granada, Spain) 2 Universidad de Zaragoza (Zaragoza, Spain) 3 Federación Andaluza de Deportes de Invierno (Granada).*

Strength training has undergone a substantial advancement, especially qualitatively, in recent years thanks to advances in new technologies applied to training control (Randell et al., 2011). The use of tools such as linear positioning transducers mean that training variables such as velocity, strength or power can be quantified for each repetition. Therefore, the purpose of this study was to validate a new scale of perceived velocity of the squat exercise in young skiers. Method Eleven subjects (8 boys and 3 girls) participated voluntarily in this research. Age, weight and height of subjects were  $14.52 \pm 2.74$  years,  $58.79 \pm 10.27$  kg and  $170.05 \pm 7.11$  cm, respectively. All subjects were participating in an intensive training program at the High Performance Centre of Sierra Nevada (CARD). Six different intensities were selected based on the 1RM of the subjects (20%, 30%, 40%, 50%, 60% and 70%). Subsequent to the execution of each series, subjects were asked their average perceived bar velocity. Results The linear correlation analysis between the actual velocity (Velreal) and perceived velocity (Velscale) in the entire spectrum of loads analyzed resulted in  $r = 0.978$  ( $p = 0.01$ ) and  $r = 0.979$  ( $p = 0.01$ ) for days 1 and 2, respectively. The linear correlation analysis between Velreal and Velscale in each load range correlated to  $r =$  from 0.58 to 0.96 in the range of loads tested. Discussion It is important to note the difficulty of comparing the results of our research to other studies validating the OMNI-RES scale since the criterion variables used to test the validity of those studies were Hla and Wtot (Robertson et al., 2003) or the Borg CR10 scale itself (Lagally et al., 2006). The criterion variable used to test the validity of this research was the actual velocity of each of the repetitions and sets as measured on a linear displacement device. Since the new scale is designed to measure the average velocity of execution of the bar, it is proposed that this be the 'gold standard' possible for assessing validity. Conclusions The results obtained in this research provide concurrent validity of the new scale of perception of velocity for resistance exercise and demonstrate that it can be used as a means to quantify the intensity of the bench press exercise in a population of trained adults. Introduction Medium-fast bowling in cricket evokes marked physiological demands that are often compounded by high environmental temperatures and brief periods of incomplete recovery between spells. Greater physiological, neuromuscular and perceptual recovery achieved using post-exercise cooling techniques would be of likely benefit for cricketers, though their effect on performance is unknown. This investigation examined physiological and performance effects of mixed-method cooling during recovery for medium-fast bowlers in the heat. Methods Eight, elite medium-fast bowlers completed two randomized trials, involving two sessions performed on consecutive days (Session 1: 10-overs and Session 2: 4-overs) in  $31(3)^{\circ}\text{C}$  and  $55(17)\%$  relative humidity. Recovery interventions were administered for 20 min after Session 1 (mixed-method cooling vs. control). Mixed-method cooling consisted of an iced towel worn over the head, neck and shoulders, ice-vest covering the torso, and ice-packs applied to the thighs. Heart rate, core and skin temperatures were recorded throughout both sessions. Bowling performance (ball speed, accuracy, run-up speed), physical demands (global positioning system, counter-movement jump), biochemical responses for damage and inflammation (creatinase, C-reactive protein) and perceptual variables (perceived exertion, muscle soreness) were measured for both conditions. Results Mean ball speed was higher after cooling in Session 2 ( $118.9(8.1)$  vs.  $115.5(8.6)$  km.h<sup>-1</sup>;  $P=0.001$ ;  $d=0.67$ ). Large effects indicated higher accuracy in Session 2 after cooling ( $46.0(11.2)$  vs.  $39.4(8.6)$  AU;  $P=0.13$ ;  $d=0.93$ ) without affecting total run-up speed ( $19.0(3.1)$  vs.  $19.0(2.5)$  km.h<sup>-1</sup>;  $P=0.97$ ;  $d=0.01$ ). Cooling improved 20 m sprint in Session 2 ( $22.0(1.9)$  vs.  $20.4(1.9)$  km.h<sup>-1</sup>;  $P=0.02$ ;  $d=1.15$ ); however, counter-movement jump performance was unchanged at all time points ( $P=0.25-0.88$ ;  $d=0.03-0.30$ ). Cooling reduced core and skin temperatures throughout the intervention ( $P=0.001-0.05$ ;  $d=1.31-5.78$ ); further, attenuating creatinase ( $P=0.04$ ;  $d=0.56$ ) and muscle soreness at 24 h ( $P=0.03$ ;  $d=2.05$ ). Discussion These data highlight mixed-method cooling as an effective recovery strategy for medium-fast bowling in hot conditions on consecutive days. Lowered thermal, biochemical and perceptual responses were found, corroborating previous findings. In addition, the cooling recovery intervention provided better maintenance of bowling performance between sessions.

**NEUROMUSCULAR FATIGUE DURING RESISTANCE EXERCISE AFFECTS CARDIAC AUTONOMIC MODULATION**

Carballeira, E.1, Iglesias-Soler, E.1, Mayo, X.1, Sánchez-Otero, T.1, Boullosa, D.A.2

*1. A Coruña University (UDC). Spain, 2. Catholic University of Brasilia. Brazil*

Introduction Acute changes in heart rate variability (HRV) have been shown to be a useful tool for quantifying training load on autonomic nervous system (Kaikkonen et al. 2010). Resistance exercise produces a disruption on homeostasis that can modify HRV and heart rate complexity (Heffernan et al. 2008). However, the magnitude of neuromuscular fatigue can be modulated by set configuration (Iglesias-Soler et al. 2012). Therefore, we studied the relationship between cardiac autonomic modulation and neuromuscular performance after

two same volume but different set configuration RE sessions. Methods Nine male subjects completed a session of three sets to failure (FS) of parallel squat with 4 repetitions maximum (4RM), and a rest of 180 seconds between sets (total resting time of 360 s). At least 72 hours after, subjects performed a cluster session (CS) with the same volume (load x repetitions) but total resting time distributed between each repetition. HRV and complexity (SampEn) analysis was performed before, during, and after sessions. Isometric and dynamic explosive performance (IEP) was tested before, immediately after, and seven minutes after every session. Results SampEn decreased during both sessions, whereas SampEn\_CS was higher than SampEn\_FS ( $p=0.047$ ;  $d=0.9$ ). Furthermore, we found a reduction from vagal modulation on the heart after CS and FS, being only high frequency band (HF=0.15-0.4) post-session higher in CS than FS ( $p=0.032$ ;  $d=0.80$ ). However, type of session and time presented no clear interaction. Regarding autonomic and mechanical association, we found that a higher increment in cardiac sympathetic modulation (i.e. higher increment in LF/HF) in FS was linked to a lower loss of mean propulsive power. In addition, Isometric performance changes in CS were positively related with SampEn changes. Discussion Our results agree with previous studies on RE (Heffernan et al. 2008). We speculate that fatigue produced by exercises was not enough to induce greater differences in cardiac autonomic control and studies with more stressful workouts are needed to clarify the effect of different set-configurations. In the other hand, correlations between HRV and IEP were evident in both sessions, therefore, further studies should be made in order to analyse the usefulness of HRV as a tool to monitoring neuromuscular fatigue in RE. ## LACTATE KINETICS AT THE LACTATE THRESHOLD IN TRAINED AND UNTRAINED MEN

Messonnier, L.A.1,2, Emhoff, C.A.W.1, Fattor, J.A.1, Horning, M.A.1, Carlson, T.J.1, Brooks, G.A.1

1: UCB (Berkeley, USA), 2: UDS (Le Bourget-du-Lac, France)

Introduction The lactate threshold (LT) remains unclear in its physiological significance, some interpreting the inflection point to indicate the onset of anaerobiosis (Wasserman and McIlroy, 1964), while others interpret the LT to reflect an imbalance between lactate appearance and removal (Stanley et al., 1985). Because none of the earlier investigations studied lactate kinetics (i.e., rates of appearance and disposal (Ra and Rd,  $\text{mg}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ ) and metabolic clearance rate (MCR,  $\text{ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ ) at the LT, our first aim was to determine lactate kinetics in trained subjects exercising at and just below the LT to test the hypothesis that the LT represents a limitation in lactate clearance. As well, because endurance training has been observed to decrease lactate concentrations by increasing lactate clearance capacity (Bergman et al., 1999), our second aim was to test the hypothesis that endurance training augments rates of lactate disposal and clearance at given relative exercise intensities and blood lactate concentrations ([lactate]b). Methods We studied six each untrained (UT) and trained (T) subjects during 60-min exercise bouts at power outputs (PO) eliciting the LT. Trained subjects performed two additional exercise bouts at a PO 10% lower (LT-10%), one of which involved a lactate clamp (LC) to match [lactate]b to that achieved during the LT trial. Results At LT, lactate Ra was higher in T ( $24.1 \pm 2.7$ ) than in UT ( $14.6 \pm 2.4$ ,  $P < 0.05$ ), but Ra was not different between UT and T when relative exercise intensities were matched (UT-LT vs. T-LT-10%, both 67%  $\text{VO}_{2\text{max}}$ ). Rd imitated Ra. At LT, MCR in T ( $62.5 \pm 5.0$ ) was 34% higher than in UT ( $46.5 \pm 7.0$ ,  $P < 0.05$ ), and a reduction in PO resulted in a significant increase in MCR by 46% (LT-10%,  $91.5 \pm 14.9$ ,  $P < 0.05$ ). At matched relative exercise intensities (67%  $\text{VO}_{2\text{max}}$ ), MCR in T was 97% higher than in UT ( $P < 0.05$ ). During the LC trial, MCR in T was 64% higher than in UT ( $P < 0.05$ ), where % $\text{VO}_{2\text{max}}$  and [lactate]b were similar. Discussion We conclude that: i) lactate MCR reaches an apex below the LT, ii) LT corresponds to a limitation in MCR, iii) endurance training augments capacity for lactate production, and iv) endurance training improves lactate disposal and clearance while exercising at LT (i.e., at a higher relative exercise intensity in trained subjects) as well as at given relative exercise intensities and blood lactate concentrations. ## THE RELATIONSHIP BETWEEN MUSCLE HYPERTROPHY AND ACUTE HORMONAL RESPONSES OR MUSCLE ANDROGEN RECEPTOR CONTENT

Mitchell, C.J., Churchward-Venne, T.A., Bellamy, L., Parise, G., Baker, S.K., Phillips, S.M.

McMaster University

Introduction It is well known that supraphysiological doses of testosterone are potent stimulators of muscle hypertrophy. However, West et al. (2012) have shown that physiological variations in the magnitude of the post exercise testosterone response are not related to muscle hypertrophy following resistance training. The aim of the current study was to assess if changes in concentration of various hormones pre- and post-training, or the muscle androgen receptor (AR) provide a better predictor of muscle hypertrophy following resistance training. Methods Twenty three healthy young adult males ( $177.4 \pm 7.5$  cm,  $84.1 \pm 16.9$  kg,  $23.6 \pm 3.3$  y) completed 16 weeks of full body resistance training 4 x week. Two workouts focused on their upper body and two on their lower body. Muscle biopsies were obtained from the vastus lateralis at rest before and after the 16 week training period. Immunohistochemistry was used to measure changes in fiber type area. Western blotting was used to determine muscle androgen receptor protein content. Serum free testosterone was also measured immediately, 15, 30 and 60 minutes following the first and last workouts of the study. The area under the curve (AUC) was calculated as a single measure of the post exercise free testosterone response. Results Mean type II fiber area increased from  $6284 \pm 1869$  to  $7542 \pm 1736$   $\mu\text{M}^2$  ( $P < 0.001$ ) and type I fiber area increased from  $5355 \pm 1553$  to  $6098 \pm 1486$   $\mu\text{M}^2$  ( $P = 0.001$ ). There was no significant change in muscle AR protein content following training (fold change =  $1.17 \pm 0.61$ ;  $P = 0.186$ ); however, changes were highly variable. There were significant correlations between the fold change in androgen receptor content and the percentage change in type I ( $r = 0.47$ ,  $P = 0.023$ ) and type II ( $r = 0.60$ ,  $P = 0.002$ ) fiber area. There was a decrease in the AUC of the acute free testosterone response  $7557 \pm 1414$  to  $7190 \pm 1417$  (arbitrary units) ( $P < 0.001$ ) pre- to post-training; however, as reported previously there was no relationship between the magnitude of this response and muscle fiber hypertrophy ( $r = 0.06$ ,  $P = 0.772$ ) or for any other hormone including IGF-1 and GH. Discussion In agreement with our earlier findings no hormonal response correlated with hypertrophy. Instead, the findings from this study support the idea the muscle hypertrophy is regulated by local rather than systemic hormonal processes. If testosterone has any regulatory effect on muscle hypertrophy within its physiological range these effects are likely mediated by local changes androgen receptors and not changes in the post-exercise hormonal response. References West DW, Phillips SM. *Eur J Appl Physiol*. 112(7):2693-702.

## PULMONARY OXYGEN CONSUMPTION AND OXYGENATION OF UPPER-BODY MUSCLES DURING ISOLATED UPPER BODY POLING AT DIFFERENT EXERCISE INTENSITIES

Skovereng, K., Van Beekvelt, M., Ettema, G., Sandbakk, Ø.

*Norwegian University of Science and Technology*

**INTRODUCTION** Physiological responses to dynamic physical exercise have been studied extensively throughout history. However, there is limited knowledge on the responses of isolated upper-body exercise. In addition to pulmonary VO<sub>2</sub>, lactate and heart rate, near-infrared spectroscopy (NIRS) can be used to assess changes in local tissue oxygenation and calculate (muscle) tissue O<sub>2</sub> saturation (StO<sub>2</sub>), which represents the balance between O<sub>2</sub> supply and O<sub>2</sub> consumption(1), can provide knowledge regarding the demands of upper-body exercise and the adaptations of such training. To the best of our knowledge, the oxygenation of upper-body muscles in highly trained upper-body athletes has not yet been investigated. Therefore, the purpose of the present study was to investigate pulmonary VO<sub>2</sub> and oxygenation of upper-body muscles during isolated upper body poling at different exercise intensities. **METHODS** Fourteen male elite cross-country skiers (age 25±6.2, body mass 75.4±7.1 and whole body VO<sub>2</sub>max 73.4±4.2) performed three 4-min submaximal constant workloads when poling in a modified Concept2 ergometer, seated with the legs in a locked position. Pulmonary gas exchange was measured breath-by-breath and NIRS was used to measure total hemoglobin (tHb) and TSI on the biceps brachii (BB), triceps brachii (TB), latissimus dorsi (LD) and the vastus lateralis (VL) muscles. Blood lactate was measured after each work period. **RESULTS** The work rates for the three submaximal stages were 69±11, 93±14 and 122±20 W, respectively, with corresponding VO<sub>2</sub> of 22.7±3.6, 28.7±4.1 and 36.5±4.9 mL/kg/min and blood lactate concentrations of 1.28±0.79, 1.93±1.07 and 4.27±1.69 mmol/L respectively. For both the TB and LD muscles TSI decreased ( $p < 0.05$ ) and tHb increased ( $p < 0.05$ ) significantly with increasing intensity. Also in the BB muscle there was a significant decrease ( $p < 0.05$ ) but no significant change in tHb was seen. For the VL muscle, a decrease in TSI was seen from the first to the last workload, while an increase in tHb was seen only from the first to the second work load. **DISCUSSION** The current study shows that isolated upper body exercise elicits a significant physiological response in athletes well trained in the upper body. The oxygenation and TSI of the BB, TB and LD muscles decrease correspondingly with the increase in pulmonary oxygen consumption and heart rate with increasing work rate during upper-body exercise. Total hemoglobin increases in the TB and LD muscles indicating increased blood volume in these muscles. Our results for the VL muscle indicate that the legs have an energy requirement even though they are locked and unable to produce external work. **References:** 1.Buchheit & Uffland. 2011. Eur J Appl Physiol.

## EFFECT OF ALACTIC AND LACTIC TRAINING ON BRAIN DC POTENTIAL IN RECREATIONAL RUNNERS

Fomin, R.I., Masakov, L.I., Vesterinen, V.2, Nummela, A.2

*1: Omegawave (Espoo, Finland), 2: KIHU – Research Institute for Olympic Sports (Jyväskylä, Finland)*

**Introduction** The brain direct current potential (DC) is regarded in physiology and medicine as an integrated system marker for the assessment of the body's functional state, stress resistance, and adaptation capacity [1]. Researchers emphasize that the DC is highly sensitive to short-term and long-term adaptational changes in the body in response to external factors [2]. This research aims to study the specificity of DC changes with different training types in recreational runners. **Methods** Subjects: 27 healthy male recreational runners (35±6.7 yrs, 178±5.9 cm high, and weighing 76±7 kg) performed firstly 'alactic running training' (ALT) on a treadmill (H/P Cosmos Ergometer, Sportgerate, Germany): 30 min; 30 sessions 10 s each; 50 s of rest between sessions; an average speed of 93% of the maximal speed at VO<sub>2</sub>max; lactate not exceeding the anaerobic threshold (AT). Secondly, athletes performed 'lactic training' (LT) at field: 4 sessions 300 m each; the maximum speed; 5 min of rest between sessions; lactate above AT. The DC was recorded using method [1], with the Omegawave V.4 system (Omegawave, Finland). The DC was measured at rest before training, 15 min after training, and on the next 2 days. The lactate concentration was measured using a Biosen S-line Lab (EKF, Germany). **Results** After research, all subjects were divided into 2 subgroups, depending on the initial level of DC: 1) reduced DC (below 9 mV); 2) normal DC (9 to 35 mV). Before ALT, the average 'reduced' group DC was -2.3 mV (n=19). After training, the DC increased by 6 mV ( $p < 0.05$ ), becoming 3.7 mV. The DC did not change during the next 2 days. In the 'normal' group (n=8), a bidirectional trend of DC changes was observed after training; reducing in 5 athletes and increasing in 3 athletes. Before LT, the average 'reduced' group DC (n=20) was -1.5 mV. After training, the DC increased by 6.1 mV ( $p < 0.005$ ), becoming 4.6 mV. In the 'normal' group (n=6), the DC, which was 16.8 mV before training, decreased by 12.4 mV after training, becoming 4.4 mV ( $p < 0.05$ ). Thus, both training load models change the DC in recreational runners. The amount of changes depends on the initial DC before training. **Discussion** It is possible that the body response to training loads is associated with the initial CNS activation level. The role of the 'slow regulatory system of the brain' in short-term adaptation changes after physical loads is discussed [1]. **References** 1. Iliukhina V. ### IS-PM12 Regulation skeletal muscle carbohydrate and fat utilisation in exercise and disease in humans \*

#### LIMITS TO MAXIMAL FUEL UTILISATION IN HUMAN SKELETAL MUSCLE DURING EXERCISE

Jeukendrup, A.

*University of Birmingham*

Carbohydrate and fat are the most important fuels during exercise. The regulation of carbohydrate and fat metabolism has received a lot of attention but is still not completely understood. In the 1960's a theory was proposed by Randle at al referred to as the Randle or glucose-fatty acid cycle. This theory described how an increase in fatty acid availability (fat metabolism), reduced carbohydrate metabolism. However, it later appeared that during exercise, especially at higher exercise intensities this mechanism was not very important. Instead it was demonstrated that carbohydrate metabolism regulated fat metabolism and an increase in glycolytic flux reduced fat metabolism

through several mechanisms. It is known that carbohydrate and fat metabolism are influenced by diet (substrate availability), environmental conditions (heat, altitude), training status of the subject but most of all exercise duration and intensity. As exercise intensity increases fat metabolism increases at first and then decreases. In contrast, carbohydrate metabolism continues to increase as the intensity increases and the demand for energy increases. The increase and then decrease in fat metabolism has been demonstrated by several investigators but is probably best seen when a FATMAX test is applied. This graded exercise test, measures fat oxidation using indirect calorimetry over a wide range of intensities and the intensity at which fat oxidation is maximal can be determined relatively accurately. On average this may occur around 50-55% VO<sub>2</sub>max although intra-individual variation is very large. Only a small percentage of this variation can be explained. Many researchers have been puzzled by this decline in fat metabolism despite an increased demand. The underlying mechanisms that have been proposed include an increase in Malonyl CoA inhibiting CPTI and thus fatty acid transports into the mitochondria, a reduced free carnitine concentration in the muscle, limiting the fatty acid transport capacity and a decrease in pH, which could inhibit CPTI. Evidence for a causal relationship between these potential mechanisms and a reduction in fat metabolism is lacking. In addition to acute changes in the ability to oxidise fat, there are also chronic changes that might occur that increase the fat oxidative capacity. In fact, exercise training has been shown to be the most effective way to increase fat oxidation long term.

### **SKELETAL MUSCLE CARNITINE AVAILABILITY AND THE REGULATION OF FUEL SELECTION DURING EXERCISE**

Stephens, F.B.

*University of Nottingham*

More than 95% of the body's carnitine pool is confined to skeletal muscle where as a substrate for carnitine palmitoyltransferase 1 (CPT1) it translocates fatty acids into the mitochondrial matrix for  $\beta$ -oxidation, and as a substrate for carnitine acetyltransferase (CAT) it buffers excess acetyl-CoA from the pyruvate dehydrogenase complex (PDC) reaction during high glycolytic flux (Stephens et al, 2007). We have demonstrated in a series of studies that insulin stimulates muscle carnitine uptake (Stephens et al, 2007), and that 12-24 weeks of L-carnitine feeding in combination with a carbohydrate beverage in order to stimulate insulin release (1.4 g L-carnitine + 80 g carbohydrate twice daily) can increase the skeletal muscle carnitine store by 20-30% and have some remarkable effects upon fuel selection compared to carbohydrate feeding alone (Wall et al, 2011; Stephens et al, unpublished). For example, the increase in muscle carnitine content in these studies resulted in reduction in muscle glycogen utilisation (Wall et al, 2011), and an increase in whole-body fat oxidation and energy expenditure during low intensity exercise (cycling at 50% VO<sub>2</sub>max; Stephens et al, unpublished). Moreover, the increase in muscle carnitine after 12 weeks of supplementation resulted in a prevention of body fat accumulation associated with daily ingestion of a high carbohydrate beverage, and an adaptive increase in the expression of gene networks involved in insulin signalling, peroxisome proliferator activated receptor (PPAR) signalling, and fatty acid metabolism (Stephens et al, unpublished). Taken together, these findings suggest that increasing skeletal muscle carnitine content can maintain the capacity to oxidise fat in the face of high carbohydrate feeding, which is consistent with the premise that carnitine availability is limiting to CPT1. In contrast, the role of carnitine in carbohydrate oxidation becomes apparent during high intensity exercise (cycling at 80% VO<sub>2</sub>max) where an increase muscle carnitine content results in greater buffering of acetyl groups, and a better matching of glycolytic flux to mitochondrial ATP production as evidenced by increased muscle PDC activation and reduced muscle lactate accumulation. Manipulating both of these metabolic roles of carnitine will have implications for exercise performance. Stephens FB, Constantin-Teodosiu D, & Greenhaff PL (2007). New insights concerning the role of carnitine in the regulation of fuel metabolism in skeletal muscle. *J Physiol* 581, 431-444. Chronic oral ingestion of L-carnitine and carbohydrate increases muscle carnitine content and alters muscle fuel metabolism during exercise in humans. *J Physiol* 589, 963-973.

### **SKELETAL MUSCLE FUEL UTILISATION DURING EXERCISE IN TYPE 2 DIABETES**

Van Loon, L.J.C.

*Maastricht University Medical Centre*

Elevated plasma free fatty acid (FFA) delivery and/or impaired FA oxidation, result in intramyocellular accumulation of triacylglycerol (TG) and FA metabolites (such as fatty acyl-CoA, ceramides, and diacylglycerol), which may induce defects in the insulin signaling cascade, causing skeletal muscle insulin resistance. Insulin resistance can subsequently lead to the development of the hyperglycemic and/or hyperinsulinemic state, which further stimulates IMTG accretion at the expense of IMTG mobilisation and subsequent oxidation. As such, excess IMTG accretion in sedentary, obese and/or type 2 diabetes patients is likely the result of a structural imbalance between FFA uptake, IMTG deposition and its subsequent mobilisation and/or oxidation. However, the proposed relationship between IMTG accumulation and insulin resistance does not appear to be functional, as endurance trained athletes are markedly insulin sensitive, despite substantially enlarged IMTG stores. The latter can be explained by the fact that in the trained athlete, elevated IMTG stores represent one of the many metabolic adaptive responses to endurance training, which enable a greater use of the IMTG pool as a substrate source during exercise. In contrast, the IMTG pool does not seem to represent a readily available substrate source in sedentary, obese and/or type 2 diabetes patients. An elevated IMTG utilisation rate could likely prevent and/or reduce excessive accumulation of intramyocellular TG and/or FA metabolites. Consequently, the turnover of the IMTG pool should form a major therapeutic target in the prevention and/or treatment of skeletal muscle insulin resistance and efforts should be made to develop strategies that stimulate IMTG use.

#### EFFECTS OF A PROGRAM ABOUT ACTIVITIES IN THE WATER ON THE AQUATIC SKILLS OF CHILDREN WITH AUTISM SPECTRUM DISORDER

Nasser, J.P., Zuchetto, A.T.

UNIVERSIDADE FEDERAL DE SANTA CATARINA

**Introduction** The participation in physical activities programs is a challenge for children with Autism Spectrum Disorder (ASD) due to the lowest levels of motor development, low motivation, difficulty in planning, generalization and self-monitoring of activities. The therapeutic effects of water seem to moderate level of excitement and anxiety, and reduce the stereotypic behaviors and self-stimulation. The aim of this study was to analyze the effects of activities in the water and the development of aquatic skills of children with ASD. **Methods** This exploratory and qualitative research had a sample composed of two boys (4 and 5 years old) and two girls of 4 years old. Data was collected from the footages of water activities undertaken twice a week, for 36 weeks, totaling 72 sessions of 1 hour each. The analysis was performed before and after the intervention program through the assessment matrix of aquatic skills (Winnick, 2004), and the form they were developed. **Results** The participants demonstrated improvement in entrances and exits through the access ramp to the pool. First, they refused to do that, and after verbal and gestural instruction, they did it with autonomy and spontaneously entered in the pool. As for the respiratory control, the girls had significant advances in the ability of free diving, and a boy carried it out with physical conduction since the teacher handles his body in order to perform the specified task. In relation to the capacity for moving around the pool by floating, the students evolved in different evaluated skills, each one in his own way. **Discussion** The children not only evolved in the entrances and exits through the ramp of the pool, but also in the respiratory control and fluctuation displacements. The pool, with well-defined physical boundaries, may favor the concentration to the activities and help the students to identify and remember the exercises in each area in order to turn the actions more autonomous (Reid & O'Connor, 2003; Schultheis, Boswell, & Decker, 2000). It also shows positive responses regarding the initial activities of swimming and the improvement in aquatic orientation tasks (Yilmaz, Yanarda, Birkan, & Bumin, 2004). Reid, G., & O'Connor, J. (2003). *Palaestra*, 19(1), 21. Todd, T., & Reid, G. (2006). *Focus Autism Other Dev Disabl*, 21(3), 167-176. Schultheis, SF, Boswell, BB, & Decker, J. #### EFFECT OF COMBINED AEROBIC AND RESISTANCE EXERCISE TRAINING IN ADULTS WITH INTELLECTUAL DISABILITIES

Oviedo, G.1, Javierre, C.2, Álamo, J.2, Delicado, M.C.2, Soto, C.2, Giné-Garriga, M.1, Guerra, M.1

1-FPCEE Blanquerna-Ramon Llull University (Barcelona, Spain); 2-University of Barcelona (Spain)

**Introduction:** Individuals with intellectual disabilities (ID) show lower levels of physical activity (PA). Regular PA is essential for adults individuals with ID. **Purpose:** To investigate the effect of an exercise intervention program on physical fitness in adults with ID and compare it with a non trained group. **Methods:** Two groups of adults with moderate-severe ID participated in this study. The intervention group (IG) (17 women, 22 men; age=40.9±11y; BMI=27.6±5.34kg/m<sup>2</sup>) followed an aerobic and strength training program during 14 weeks, 1 h, 3 times a week. The control group (CG) (13 women; 15 men; age=45.6±12.3y; BMI=28.4±6.64kg/m<sup>2</sup>) did not train. Before and after the PA program, VO<sub>2</sub> peak, isometric strength, systolic and diastolic blood pressure (SBP and DBP) and body fat were evaluated. Independent t-test were used to compare groups. **Results:** After the PA intervention, VO<sub>2</sub> peak was 29.3±7.5 ml/kg/min and 24.4±4.8 ml/kg/min in the IG and CG respectively. IG showed a right handgrip of 22.8±8 kg (IG) meanwhile CG was 18.8±6.2 kg. Left handgrip was 21.1±6.8 kg for the IG and 18±6.7 kg for the CG. IG had legs dynamometry of 42.2±25.1 kg and 41.6±21.5 kg for CG. Resting SBP and DBP were 109.4±14.1/71.1±9.9 mm Hg in the IG and 114.9±17.8/72.6±8.6 mmHg in the CG. Maximal SBP and DBP were 131.9±18.9/67.3±9.8 mmHg in the IG and 134.8±19.2/74.5±13.4 mmHg in the CG. Body fat % was 29.1±10.6% in CG and 32.9±10.5% in IG. IG showed significant increases on VO<sub>2</sub> peak (p<0.05), right hand grip (p<0.05), and maximal workload achieved during the physical stress test (p<0.05). **Discussions:** This study showed the beneficial effects of a combined PA intervention in adults with ID that may also prevent cardiovascular diseases. **References** Bartlo, P., & Klein, P. #### STANDING BALANCE IMPROVEMENTS IN ALCOHOLIC PATIENTS AFTER A SHORT-TERM TREATMENT

Carraro, A.1, Ferri, I.1, Gobbi, E.1, Greguol, M.2, Pavan, P.3

1: FISPPA, University of Padua (Italy); 2: SSD, State University of Londrina (Brazil); 3: DII, University of Padua (Italy)

**Introduction** Alcohol ingestion negatively impacts physical performance, causing worsening of psychomotor skills and reduced balance (Wober et al., 1999). Evidence indicates that exercise-related activities are associated with positive outcomes in the treatment of alcohol misuse disorders (Carraro, 2013; Weinstock, Barry & Petry, 2008). The purpose of the present study was to analyse changes in standing balance after a multidimensional short-term treatment of alcohol misuse, including exercise programs, in a group of chronic alcoholics. **Method** Participants were 32 alcoholic patients (20 men, 12 women; mean age 45.4, SD 9.2 years) consecutively admitted to a residential treatment. They participated to a mean of 15 (SD 3.5) group-based exercise sessions during a 4-week period of hospitalization. Pre- post-measures of standing balance were collected by using a low cost set up based on Nintendo Wii Balance Board (WBB) and administering a Romberg test with opened and closed eyes, with and without a pad-foam on the WBB. A 41 healthy subjects control group was also considered. **Results** Compared with healthy subjects, alcoholic patients revealed at the pre-test reduced standing balance (-44.3%, Co-

hen's  $d = -0.58$ ). Patients reported significant improvements after the treatment in the opened-eyes WBB tests (mean sway area pre vs. post without foam 7.0 vs. 4.1,  $p = .001$ ; with foam 25.8 vs. 15.5,  $p = .048$ ). Significant differences were recorded also in the closed-eyes tests (mean sway area 10.43 vs. 8.10,  $p = .041$ ; 84.6 vs. 59.2,  $p < .001$  respectively). Discussion Findings support the notion that standing balance control seems to be a serious problem for chronic alcoholics. A multidimensional treatment of alcohol misuse, including exercise-related activities, appears as an effective strategy to ameliorate in the short time standing balance control in this population. Further research is needed to evaluate the maintenance over the time of these positive outcomes. References Carraro A (2013). The role of exercise in alcohol dependence recovery. *Edi-Ermes, Milano*. ### ASSESSING PHYSICAL ACTIVITY IN POSTTRAUMATIC STRESS DISORDER: IS SELF-REPORT A VALID MEASURE?

Rosenbaum, S.1,2, Tiedemann, A.1, Sherrington, C.1, van der Ploeg, H.P.3

1 The George Institute for Global Health (Australia) 2 St John of God Healthcare (Australia) 3 EMGO Institute for Health and Care Research, VU University Medical Centre (Netherlands)

**Introduction** Individuals with posttraumatic stress disorder (PTSD) are less physically active (de Assis et al., 2008), and more likely to suffer from poor physical health than the general population (Boscarino, 2004). Physical activity research in this population is hampered by the lack of validated questionnaires. The objective of this study was to validate the International Physical Activity Questionnaire-Short Form (IPAQ-SF) for use among inpatients with PTSD. **Methods** Inpatients of the adult-trauma program at St John of God Hospital in Sydney (Australia) were recruited over a twelve-month period ( $n=59$ , 85% male; 49% police officers). Participants wore an Actigraph accelerometer for seven days, at the end of which participants self completed the IPAQ-SF. Analyses determined the construct validity of the IPAQ-SF against the accelerometer using Spearman rho correlation coefficients. Results The correlation between amount of moderate to vigorous physical activity measured by the Actigraph and total physical activity reported in the IPAQ-SF was 0.46 for the 29 participants with four or more valid days of accelerometer data and available IPAQ-SF data (0.45 for 3+ valid days,  $n=37$ ). Missing data were due to lower than expected compliance with wearing accelerometers ( $n=7$ , 3+ valid days;  $n=17$ , 4+ valid days), non-completion of IPAQ-SF due to early discharge ( $n=4$ ) or both reasons ( $n=3$ ). IPAQ-SF data were excluded from analysis if values were erroneously high (sum of physical activity  $\geq 16$  hours/day) ( $n=8$ ). When stratifying by severity of illness, based on the Health of the Nation Outcome Scale (HoNOS), the Spearman correlation was 0.59 for those with a greater illness severity (HoNOS total  $\geq 21$ ;  $n=14$ , 4+ valid days), and 0.48 for those with lower severity scores (HoNOS total  $\leq 20$ ;  $n=14$ , 4+ valid days). **Discussion** The IPAQ short form self-report questionnaire has acceptable construct validity for estimating physical activity participation of inpatients with PTSD. Poor compliance with wearing an objective activity monitor in this population is a limitation of this study. Clinician-facilitated administration of the IPAQ-SF is recommended to improve reliability in this population. References Boscarino, J. A. (2004). #### SURFACE EMG ACTIVITY OF SUBMENTAL MUSCLES DURING SWALLOWING AND EXPIRATORY MUSCLE TRAINING TASKS IN HUNTINGTON'S DISEASE PATIENTS

Reyes, A., Cruickshank, T., Thompson, J., Nosaka, K., Ziman, M.

*Edith Cowan University*

**Introduction** Huntington's disease (HD) is a neurodegenerative disorder characterised by involuntary movements, cognitive dysfunction and psychiatric disturbances. HD patients also suffer from dysphagia, leading to aspiration pneumonia, which is a major cause of death (1). It seems possible that submental muscles that are crucial for preventing an escape of a bolus into the airway, are affected by HD, but no previous studies have investigated this. Therefore, this study assessed surface electromyography (sEMG) activity of submental muscles during swallowing and expiratory muscle training (EMT) tasks in HD patients in comparison to healthy volunteers. **Methods** Average and peak sEMG activities of submental muscles during saliva, water (50 ml) swallowing, and EMT tasks performed at 25% and 75% of maximum expiratory pressure were recorded and normalised by the sEMG activity during an effortful swallow in which all throat and neck muscles are squeezed maximally. sEMG activities across the tasks were compared between 17 early to mid stage HD patients and 17 healthy volunteers (control) by a two-way repeated measures ANOVA. **Results** No significant differences in absolute and relative sEMG activities were evident between groups for saliva, water swallowing, EMT 25% and effortful swallow. sEMG activity was greater ( $p<0.05$ ) during EMT tasks at 25% ( $58.9 \pm 19.9\%$ ) and 75% ( $76.8 \pm 20.7\%$ ) than saliva ( $36.3 \pm 18.9\%$ ) and water swallowing ( $41.3 \pm 17.5\%$ ), and the activity was greater ( $p<0.05$ ) for 75% than 25% task for both groups. However, HD patients had lower ( $p<0.05$ ) percentage of sEMG activity ( $66.3 \pm 21.1\%$ ) relative to the activity during the effortful swallow compared with the control ( $80.8 \pm 17.3\%$ ) for EMT at 75%. HD patients had fewer ( $p<0.05$ ) swallows ( $4.22 \pm 0.97$ ) for the same amount of water ingestion than controls ( $5.06 \pm 0.98$ ). **Discussion** Decreases in submental muscle activity were not evident at early to mid stage of HD except during EMT at 75%. The between group difference at EMT 75% suggests that some degree of submental muscle weakness is seen only at a high intensity task. It might be that submental muscle function is more affected at later stages of the disease. The fewer number of swallows on the water intake for HD patients compared with controls suggests that the impulsiveness leading to coughing, choking and aspiration of a bolus into the airway is present during deglutition (2). Given that EMT tasks induced significantly greater submental muscle activity than water and swallowing tasks, EMT could be used as a therapeutic and/or prophylactic modality to ameliorate the risk of aspiration pneumonia in HD individuals. **References** 1) Gil JM, Rego AC. *Eur J Neurosci*. 27:2803-20,2008. 2) Heemskerk AW, Roos RA. *Dysphagia*.26:62-6,2011.

## THE SWEDISH PHYSICAL ACTIVITY AND FITNESS COHORT STUDY : THE RELATIONSHIP BETWEEN PHYSICAL CAPACITY AND LUMBO-PELVIC MOVEMENT CONTROL IN MIDDLE-AGED MEN AND WOMEN

Aasa, U., Westerståhl, M.

Umeå University (UA) and Karolinska Institutet (MI)

**Aim** This study investigates whether physical capacity and low back pain are related to movement control in the lumbopelvic region in men and women at the age of 52 years. **Background** Optimal movement patterns ensure that functional tasks can be performed in an efficient way. Further, identifying aberrant movement patterns is fast becoming a cornerstone of rehabilitative neuromusculoskeletal practice since individuals with nociceptive pain often have uncontrolled movements. At present there is, however, little published literature relating uncontrolled movements in the lumbo-pelvic area to pain or to physical performance in a general population. **Subjects and Methods** In 1974 muscular endurance and strength, flexibility, height and weight, were measured in randomly selected 16-year old students (n=425). In 1992 and 2010, the same individuals (1992: men n=157, women n=205, 2010: men n=113, women n=98) were followed up with the same tests. In 2010 the follow-up was supplemented with two tests of lumbo-pelvic movement control: standing Trunk Lean Test (TLT) and supine Double Bent Leg Lower test (DBLLT). These tests assess whether the individual is able to correctly control the movements of the lumbo-pelvic region in flexion and extension, respectively. Univariate logistic regression analyses were performed with TLT and DBLLT as dependent variables and physical performance as independent variables. Chi-square tests were performed to investigate the associations between low back pain during the last 12 months (yes/no) and performance of the TLT and the DBLLT, respectively. The Regional Ethical Review Board in Umeå, Sweden, approved the study. **Results** At the age of 52, significantly more women (65%) than men (44%) performed the TLT correctly (p=0.0039). About 20% of the men and 30% of the women performed the DBLLT test correctly (p=0.073). A higher number of the men without low back pain during the last 12 months, compared to those with back pain, correctly performed the DBLLT (p=0.041). Likewise, women without low back pain during the last 12 months, compared to those with pain, tended to correctly perform the TLT (p=0.068). Among both men and women positive associations were found between lumbar flexion control and hamstrings flexibility, and between extension control and lift strength. Among women, flexion control was also associated with high aerobic capacity and low BMI. A high performance in bench-press in 1974, 1992 and 2010, respectively, was also associated with extension control in 2010. Interestingly, among the men, a high BMI was associated with extension control in a supine position. **Discussion** In a general population of middle-aged men and women, the presence of uncontrolled movements in the lumbo-pelvic area seems to be related to physical performance and having periods of low back pain. Therefore, classifying the site and direction of uncontrolled movements and relating assessment findings to restrictions and disability might be beneficial in rehabilitative neuromusculoskeletal practice.

## EXERCISE HEMODYNAMICS IN PARKINSON'S DISEASE

Low, D.A., Vichayanrat, E., Iodice, V., Mathias, C.J.

Liverpool John Moores University, Imperial College London, National Hospital for Neurology and Neurosurgery, University College London Hospitals

Non-motor features are very common in Parkinson's disease (PD), including autonomic nervous system dysfunction. Cardiovascular autonomic dysfunction can result in precipitous reductions in upright blood pressure (e.g., orthostatic hypotension (OH)) and/or various symptoms, e.g., cognitive impairment, fatigue and fainting. Exercise is a common therapy for PD. Exercise can threaten blood pressure during and/or after exercise however, especially in other autonomic disorders (e.g., Multiple System Atrophy). It is unclear, however, if blood pressure increases appropriately or if exercise accentuates OH in PD patients with autonomic dysfunction. The aim of this study was to examine hemodynamic responses to exercise in PD patients with autonomic dysfunction. Twenty patients (71±7 yr, 7 females) with a confirmed PD diagnosis who were referred to our Autonomic Units during 2008-2012 with suspected autonomic dysfunction performed a supine cycling exercise test (3 min at 25, 50 and 75 watts) with a 5 min stand test pre- and 10 min post-exercise. Blood pressure and heart rate were intermittently recorded using upper arm sphygmomanometry. The group mean supine systolic/diastolic blood pressure was 140±17/77±9 mm Hg, respectively (heart rate; 66±10 beats.min<sup>-1</sup>). Systolic blood pressure (SBP) fell during pre-exercise stand (-34±27 mm Hg, P<0.001), while heart rate (HR) increased (+13±7 beats.min<sup>-1</sup>, P<0.001). The group mean SBP (141±19 vs 161±22 mm Hg, P<0.001) and HR (65±10 vs 94±12 mm Hg, P<0.001) increased during exercise. There was a wide variation in the exercise responses however; SBP increased in 13 patients (INC; +30±14 mm Hg) and either did not change or decreased in 7 patients (DEC -5±7 mm Hg, P<0.001 vs INC). A similar trend was evident for diastolic blood pressure (DBP, +6±12 vs -1±7 mm Hg, P=0.11). The increase in HR was not different between these sub-groups (30±12 vs 25±12 beats.min<sup>-1</sup>, INC vs. DEC, P=0.40). The size of the pre-exercise stand SBP reduction was greater in DEC vs INC (-60±23 (7 out of 7 had OH) vs -19±16 (7 out of 13 had OH) mm Hg, P<0.001). The same was evident for DBP (-21±8 vs -5±6 mm Hg, P<0.001), whereas the HR elevation was not different (13±8 vs 13±5 beats.min<sup>-1</sup>, DEC vs INC, P=0.92). The post-exercise stand SBP reduction for the whole group (-24±26 mm Hg) was not greater (but was in fact smaller) relative to pre-exercise stand (P=0.017). Post-exercise supine SBP/DBP was lower for the whole group compared to pre-exercise supine (133±15/74±10 mm Hg, P<0.05). Similar results were evident for INC and DEC sub-groups. These data indicate that 1) the magnitude of the exercise blood pressure response in PD patients with autonomic dysfunction is related to the severity of their cardiovascular autonomic dysfunction (as indexed by their OH) and 2) exercise does not appear to worsen OH in this sample of PD patients but lowers resting blood pressure. These findings have implications for clinicians and their management of PD patients, as well as therapists using exercise interventions in PD.

## EMG OF PARAVERTEBRALIS MUSCLES IN DIFFERENT EXERCISES AND APPARATUS USED IN THE PREVENTION AND THERAPY OF BACK PAIN

Porta, J., Vallejo, L., Cos, F.

Grup Recerca Ciències de l'Esport: INEFC Barcelona

**ELECTROMIOGRAPHY OF PARAVERTEBRALIS MUSCLES IN DIFFERENT EXERCISES AND APPARATUS USED IN THE PREVENTION AND THERAPY OF DIFFUSE BACK PAIN** **Introduction** The "Diffuse Back Pain" (DBP) is a chronic and unspecific pathology affecting 70-80% of the industrialized countries population. There's a consent to relate the fatigability of the trunk extensors muscles measured with EMG, as an important factor of the DBP. **2,3 Methods** **Subjects:** 4 physical education students, 22.0 ± 2.4 years of age, 75 ± 5.2 kg and 170.4 ± 6.8 cm, volunteered to participate in this study signing an informed consent. **Materials:** to measure the bilateral EMG signal of the muscles: neck extensors, dorsalparaspinal, erectorspinal and multifidus, we utilized the ME 6000 EMG system (Mega electronics, Kuopio, Finland) with surface electrodes (Ag/Ag Cl) and gel conductor (Ambu Blue Sensor, M-00-S, Denmark). **Protocol:** to evaluate the muscles fatigability, the amplitude of the EMG signal was normalized with an isometric contraction force > 30% of the MVC. The exercises studied were: 1/ From

orthostatic position: maximal ankles extension. 2/ Lying facing the floor with flexed knees: trunk extension with extended elbows and hands entwined. 3/ Sitting in the Back EFS with flexed trunk: 45° trunk extension. 4/ Lying facing the floor with flexed knees and belly against the T-Bow: trunk extension with extended elbows and hands entwined. 5/ In the Orthopod, with trunk flexed: 45° extension. Results Except for the multifidus, the EMG signal of the muscles studied in the exercises performed in the T-Bow and Orthopod, was higher ( $p < 0,001$ ). The multifidus EMG signal on exercise 2 ( $190,5 \pm 65,9 \mu\text{V}$  &  $231,2 \pm 85,5 \mu\text{V}$ , left & right) was more intense than the obtained with the T-Bow ( $77,5 \pm 12,4 \mu\text{V}$  &  $33,5 \pm 6,2 \mu\text{V}$ ); Back EFS ( $69,3 \pm 12,6 \mu\text{V}$  &  $73,2 \pm 21,6 \mu\text{V}$ ) and Orthopod ( $63,8 \pm 24,1 \mu\text{V}$  &  $26,2 \pm 8,2 \mu\text{V}$ ). In the exercise 1, the intensity was much lower:  $6,8 \pm 2,5 \mu\text{V}$  &  $15,1 \pm 5,0 \mu\text{V}$ . Discussion/conclusion Despite the DBP is normally only related to the lumbar area, we strongly believe that any muscular/structural problem in the neck, especially in the atlas-axis joint, will worsen this pathology. Therefore, for the prevention and therapy of the DBP is necessary to analyze the action of the different paravertebralis muscles on the different parts of the spine. ### COGNITIVE FUNCTIONAL THERAPY FOR THE MANAGEMENT OF LOW BACK PAIN IN ADOLESCENT MALE ROWERS: A RANDOMIZED CONTROLLED TRIAL

Ng, L., Cañero, J., Campbell, A., Smith, A., O' Sullivan, P.

*Curtin University*

Introduction Contemporary low back pain models propose that the pain is a result of interactions of bio-psycho-social factors, supporting the need for a multidimensional approach for effective management (O'Sullivan, 2011). With research supporting a high prevalence of low back pain in adolescent rowers (Perich, 2011), the aim of this study was to determine the efficacy of cognitive functional therapy to reduce pain and disability in male adolescent rowers. Methods The cognitive functional therapy intervention group (n=19) received an 8-week classification-based program targeting: education regarding pain mechanisms, movement training directed to provide the rowers with alternative movement strategies to minimize pain during rowing (with the use of feedback) and rowing specific conditioning exercises. The control group (n=17) received their usual coaching with no input from the treatment physiotherapist. The primary outcomes of this study were; pain - as measured by Numeric Pain Rating Scale (NPRS) during each minute of a 15-minute ergometer trial pre/post-intervention, and disability - measured by Patient Specific Functional Scale (PSFS) and Roland Morris Disability Questionnaire (RMDQ) pre/post intervention and at 12-week follow-up. The secondary outcomes, measured pre/post intervention, were isometric muscle endurance of the back extensors and quadriceps muscles, and hip, pelvis and trunk kinematic data collected using a 3D electromagnetic device during the 15-minute ergometer row and during static sitting positions. Multilevel linear mixed models were used to estimate group differences in outcomes, adjusting for baseline measures. Results Rowers in the intervention group had significantly less overall pain and less increase in pain compared to the control group over the 15-min ergometer trial following the intervention (NPRS diff for 15th min: -3.6,  $p < 0.001$ ). Furthermore, the intervention group had significantly less disability both immediately post-intervention and at 12 weeks (PSFS diff 12-wks: 4.0,  $p = 0.014$ ; RMDQ diff at 12-wks: -1.4,  $p = 0.013$ ), and also significantly better quadriceps endurance (diff: 20.9,  $p = 0.031$ ). No group differences were found in hip, pelvis and trunk kinematics during rowing, although the intervention group postured their lower lumbar region in more extension in static sitting post-treatment (diff: -9.60,  $p = 0.007$ ). Discussion Adolescent male rowers receiving cognitive functional therapy demonstrated reduced pain and disability, and improvements in quadriceps muscle endurance and habitual sitting posture, in comparison to a control group. However, this study did not detect a treatment benefit for spinal kinematics during rowing. O'Sullivan P (2011). *BJSM* 46 (4), 224-227 Perich (2011). *KSSTA* (19), 20-28

### EFFECT OF TWO-MONTH HOME EXERCISE PROGRAMME ON RANGE OF MOTION, PAIN AND MUSCLE TONE IN PATIENTS WITH HALLUX VALGUS

Aire, A.1, Lenzner, A.2, Gapeyeva, H.1, Pääsuke, M.1

1: *Institute of Exercise Biology and Physiotherapy, University of Tartu (Tartu, Estonia)*, 2: *Department of Orthopaedics and Traumatology, Tartu University Hospital (Tartu, Estonia)*

Introduction Hallux Valgus (HV) is a foot deformity, which causes pain, inflammation and decreased joint mobility in the big toe. There is no universally accepted protocol for treating advanced phase HV (Schuh et al., 2009). The purpose of this study was to assess the effects of two month home exercise programme (HEP) on joint mobility and pain of the first metatarsophalangeal joint (MTP-joint) and muscle tone in calf muscles in women with advanced phase HV deformation. Methods Ten women with mean age ( $\pm$ SD)  $55.5 \pm 2.7$  years with advanced phase HV deformation (first MTP-joint angle more than 20 degrees) who were scheduled for surgery participated in the study. Foot function using modified Foot Function Index (FFI) (Agel et al., 2005) and passive range of motion (PROM) of flexion and extension of the first MTP-joint were assessed. Calf muscle tone (tibialis anterior (TA), extensor digitorum longus, peroneus longus (PL) and gastrocnemius medial head (GM)) was measured in lying and standing position at rest and contraction using hand-held myotonometer Myoton 3 (Müomeetria Ltd, Estonia). All measurements were taken before and after two-month HEP, which consisted of fifteen exercises derived from postoperative and mild phase HV physiotherapy (Schuh et al., 2009, Bayar et al., 2011). Results A 33% increase ( $p < 0.001$ ) in the PROM extension of the first MTP-joint after HEP was noted compared with the joint mobility before HEP, also PROM flexion increased considerably but no significant difference was noted. FFI pain score decreased by 41% ( $p < 0.01$ ) after HEP. Patients demonstrated a significant increase ( $p < 0.01$ ) of GM muscle tone as well as decrease ( $p < 0.05$ ) of TA:GM and PL:GM muscle tone ratio in lying position at rest. Discussion In advanced phase HV two-month HEP was an effective therapeutic approach for increasing first MTP-joint mobility and reducing foot pain. Also, the imbalance of muscle tone in antagonist muscles of the calf was reduced. The exercises in HEP were oriented to improve mobility and proprioception of the foot and to strengthen the muscles of foot and calf. Positive results show the importance of including mobilization and muscle strengthening exercises to HV rehabilitation. #### INFLUENCE OF A FORCE-CONTROLLED BITING TASK ON BODY SWAY AND LOWER EXTREMITY KINEMATICS DURING ONE-LEGGED SQUATS

Ringhof, S.1, Stein, T.1, Potthast, W.2, Schindler, H.J.3, Giannakopoulos, N.N.3, Hellmann, D.3

1: KIT (Karlsruhe, Germany), 2: DSHS (Köln, Germany), 3: UKH (Heidelberg, Germany)

**Introduction** Deficits in postural control represent an important risk factor for falls (Granacher et al., 2010). The risk of sustaining falls is particularly high in seniors. Considering the demographic changes in Europe an increased prevalence of fall-related injuries and higher medical treatment costs must be expected (Stevens et al., 2006). In the recent years numerous studies revealed a neuroanatomical and functional integration of the craniomandibular system (CMS) into the postural control of the human body (Borojerdi et al., 2000). However, the nature of this interrelation could not be clarified yet. Therefore, the aim of this study was to investigate whether force-controlled biting tasks could influence body sway and lower extremity kinematics during one-legged squats, as it was shown for upright bipedal stance (Hellmann et al., 2011). **Methods** To assess the effects of oral motor activity on the balancing behavior, twelve healthy subjects performed one-legged squats under four experimental conditions (biting and non-biting, on the dominant and non-dominant leg, respectively). The bite forces were measured by the use of a hydrostatic system and the current force was visualized in form of a numeric real-time feedback. In addition to common equilibrium parameters (i.e. sway area, length, velocity) various kinematic variables of the lower extremities were calculated via a biomechanical motion analysis. For each condition three valid trials were included in the evaluation. **Results** The results showed that force-controlled biting significantly reduced the COP path length in medio-lateral direction. Furthermore, descriptive statistics revealed smaller values for the other posturographic parameters during the submaximum biting task. Changing the supporting leg had no effects on body sway and joint kinematics. **Discussion** The reduced COP path length in the medio-lateral direction is a further proof of the functional coupling of the CMS and the human postural control. Possible reasons for the lack of additional significant effects might exist in the small sample group and the squat itself, which in comparison to the bipedal stance is a rather voluntary controlled motion and therefore maybe inappropriate for posturographic evaluations. To quantify the influence of dental occlusion on the balance ability and in order to elucidate the efficiency of oral devices to prevent falls further research is necessary. Future studies should concentrate on the assessment of more trivial movement tasks in larger samples. **References** Borojerdi B, Battaglia F, Muellbacher W, Cohen LG (2000). #### BODY BALANCE IN HEALTHY ELDERLY: DIFFERENCES BETWEEN YOUNGER OLD AND OLDEST OLD

Aranda-Garcia, S.1,3, Planas, A.2, Prat-Subirana, J.A.2, Angulo-Barroso, R.3

1: EUSES (Salt, Spain), 2: INEFC-Lleida (Lleida, Spain), 3: INEFC-Barcelona (Barcelona, Spain).

**Introduction** In elderly people body balance is necessary to maintain physical function and to prevent falls. It is widely accepted that body balance deteriorates with age, especially in the last decades of life. Differences between young adults and elderly are more prominent in the medial-lateral direction. However, elderly people comprise a wide range of age and balance between the younger old (YO) and the oldest old (OO) has not been examined to our knowledge. Therefore, the aim of the present study was to compare the body balance by age in healthy elderly participants. **Methods** A sample of 55 participants was divided according to age in YO group (61-71.8 years, n=27) and OO group (72.3-87 years, n=28). We assessed the sway of the centre of pressure (CoP) with a force platform (Dinascan IBV, model 600M) at a frequency of 500Hz. Data were collected across three conditions: quiet standing with eyes open (EO), with eyes closed (EC) and dual task with an additional cognitive task (DT) that consisted in counting backwards by threes. Three 20-second trials were collected per condition. The balance variables were: maximal distance, peak velocity, and trajectory of the CoP in the anterior-posterior (AP) and medial-lateral (ML) directions. All measurements were normalized by the base of support. Two (age groups) by three (balance conditions) ANOVAs were used for all variables. **Results** Balance was better with EO in comparison to EC or DT ( $p < .001$ ) for all variables in both sway directions, and for both groups. When considering all balance conditions together, peak velocity and trajectory was statistically different between age groups only in the AP direction ( $p < .05$ ). The OO group presented higher AP peak velocity (22%) and AP trajectory (32%) than the YO group. However, there were no differences between age groups in any of the ML direction variables. **Discussion** Our results are consistent with existing findings that reported worse balance with eyes closed or dual task than eyes opened in the elderly. Unlike ML direction defining balance difference between young adults and elderly or between elderly fallers and elderly non-fallers (Rogers and Mille, 2003), our findings showed that AP discriminates between the YO and the OO. Similar findings with dynamic balance were observed when comparing new-walkers with experienced-walkers in toddlerhood (Looper et al., 2006). We suggest exercise interventions focused on the oldest old should include exercises to improve body balance in the AP direction. **References** Looper J, Wu J, Angulo Barroso R, Ulrich D, Ulrich BD (2006). #### INFLUENCE OF EXPERTISE AND PLAYING POSITION ON POSTURAL CONTROL OF YOUNG AND ADULT ELITE SOCCER PLAYERS

Pau, M., Ibba, G., Leban, B., Scorcu, M.

University of Cagliari (Cagliari, ITALY) and Cagliari Calcio S.p.A.

**Introduction** In soccer, balance represents a key factor to achieve an optimal performance level and reduce the risk of lower limb injuries. In particular, it has been demonstrated that soccer players exhibit, due to the specific training, superior postural control in unipedal stance conditions with respect to either untrained subjects or athletes of other disciplines (Matsuda et al, 2008, 2010). Nevertheless, the effects of playing position and expertise have been scarcely investigated (Bizid and Paillard, 2006, Paillard et al., 2006). Therefore, the aim of this study was to assess the possible changes in postural control performances in young and adult elite soccer players according

to their age (and thus expertise) and playing position. Methods A total of 83 adult and young athletes who compete in national tournaments, were recruited for the study. In particular we tested players of Italian first league (Serie A, n=23) and youth leagues (Under 19, n=19, Under 17, n=26, Under 15, n=15). Using a pressure platform, time series of center of pressure (COP) position were acquired under bipedal (BP) and unipedal (UP) conditions. Data processing allowed to calculate Sway Area (SA), COP Path Length, COP displacements in Antero-Posterior (AP) and Medio-Lateral (ML) directions, as well as COP velocity. Results Under BP conditions, no statistically significant differences were observed between the teams or different playing positions. For the single leg stance, no effect of limb was detected, while playing position influenced all the considered variables except COP velocity in ML direction, and team was responsible for changes in SA only. In particular, post-hoc analysis revealed that midfielders achieved the best performances and defenders the poorest. Also, youngest players of Under 15 team were characterized by SA values significantly higher than both Under 19 and Serie A team. Discussion An interesting result of this study is represented by the superior balance performance exhibited by the midfielders, probably due to their habit to handle the ball for longer times during a match. It is also noticeable that the effect of age on postural control is evident only in UP stance, being the youngest athletes characterized by the worst postural control. Our data also suggest that BP tests might not be sensitive enough to investigate balance in soccer players. Consistently with previous studies, no differences in postural sway were found between dominant and non-dominant limb. References Matsuda S, Demura S, Uchiyama M. ## AGE-RELATED NEUROMUSCULAR FUNCTION AND DYNAMIC BALANCE CONTROL DURING SLOW AND FAST DYNAMIC BALANCE PERTURBATIONS

Piirainen, J.M., Linnamo, V., Avela, J.

*University of Jyväskylä*

INTRODUCTION It has been shown previously that static postural control in man is connected to efficient synaptic transmission between afferent and efferent pathways (H-reflex) at spinal level (Koceja et al. 1995). There is also evidence that fast force production capability is related to good balance control (Piirainen et al. 2010). Therefore, the purpose of this study was to investigate whether H-reflex response, measured during standing balance perturbation and isometric rapid force production are connected to dynamic balance control in young and elderly males. METHODS Totally 19 healthy young (Y; N=9, 27±3 years) and elderly (E; N=10, 68±3 years) males participated in this study. Standing balance perturbation was measured using custom build balance measurement device in SLOW (max velocity 15cm/s) and FAST (max velocity 25cm/s) conditions, in anterior and posterior direction and in horizontal plane. H-reflex (H/M20%) was measured 30ms after the onset of anterior and posterior perturbations in both SLOW and FAST conditions. Rapid torque production (peak torque at 200ms) was measured during maximal isometric knee extension. RESULTS In SLOW perturbation E showed larger peak displacement after anterior perturbation (15%, p<0.05), whereas in FAST no differences were observed. However, in FAST Y showed a trend (37% p=0.086) for faster recovery after the perturbation. No differences were observed in posterior direction on either velocity. H/M20% was significantly lower in E during FAST perturbation (anterior, -50% p<0.05; posterior, -51% p<0.05). In SLOW, only a trend for age-related (anterior, -40% p=0.069; posterior, -37% p=0.098) differences were observed. E showed significantly lower isometric rapid knee extension torque (Y 310±31 Nm; E 176±46 Nm, p<0.001). When both groups were combined, rapid torque production (r=-.536 p<0.05; r=.494 p<0.05) and H/M20% (r=-.510 p<0.05; r=-.580 p<0.05) correlated negatively with anterior SLOW peak displacement and positively with anterior FAST peak recovery, respectively. DISCUSSION According to these results age-related differences in balance control were more evident in anterior than in posterior direction perturbations. Decreased H-reflex sensitivity in E may be caused by lower activity from sensory receptors or increased pre-synaptic inhibition (Koceja & Mynark, 2001). Correlation analysis revealed that both rapid torque production and high reflex sensitivity are important factors for good dynamic balance control. REFERENCES 1. ## CHANGES IN POSTURE AND BALANCE PERFORMANCE DURING FIVE DAYS OF WOBBLE BOARD TRAINING

Granerud, E., Federolf, P.

*Norwegian School of Sport Sciences*

CHANGES IN POSTURE AND BALANCE PERFORMANCE DURING FIVE DAYS OF WOBBLE BOARD TRAINING Granerud, E. & Federolf, P. Norwegian School of Sport Sciences, Oslo, Norway Introduction Human postural control is facilitated through postural movements such as ankle-, hip-, or multi-joint strategies (Winter, 1995). Principal component analysis (PCA) applied to kinematic marker offers a novel approach study the structure of postural movements by identifying and quantifying correlated segment motion (Federolf et al. 2012, in press). This study investigated if the structure of the postural movements changes as subjects learn to master a balance task (standing on a wobble board). It was hypothesized that the relative contribution of principal components quantifying the main types of body sway (e.g. ankle strategy) to the whole postural movements would decrease as subjects improved in performance, while the contribution of higher-order movement components might increase. Methods Eleven healthy male volunteers (age 25.1±1.7, weight 77.2±5.8 kg, height 1.80m±0.07) conducted a total of 25 120-second quiet stance trials on a wobble board, 5 trials per day during 5 consecutive days. The subjects' postural movements were recorded with a standard 3D-camera system (ProReflex, Qualisys INC., Gothenburg, Sweden) using 45 reflective markers distributed over all major body segments. For each timeframe, a 135-dimensional posture vector was defined that included all marker coordinates. The posture vectors of all trials of a subject were normalized and assembled into an input matrix for the PCA. The structure of a subject's postural movements were then characterized by calculating the relative contribution (RC) of the first 10 principal movement components (PCs) to the entire postural variation in one trial. For each trial, a "balance score" was calculated by totalling the standard deviation of the vertical position of 4 markers placed on the wobble board. A repeated measures ANOVA (Sidak correction) was conducted to determine differences in RC or balance score between trials. Results Balance performance on the wobble board improved over the first 2-3 test days with the balance score decreasing from 52.1±11.0 in the first trial to levels below 34.2±6.1 in all trials of the 4th and 5th day (mean±stdev). This change was significant (F(1,24)=11.17, p<0.001). However, no changes were observed in the structure of the postural movements as quantified by the first 10 PCs: F(1,24)<1.42, p>0.98 in the RC calculated for the first 10 PCs. Discussion The hypothesis was not confirmed. The results of this study suggest that the improvement in performing the wobble-board balance task was not related to changes in the structure or organization of postural movements as quantified by PCA-RC. **NEUROMOTOR CONTROL IN CHILDREN WITH AND WITHOUT CEREBRAL PALSY WHILE HOLDING A LOAD**

Puig-Diví, A.1, Medina-Casanovas, J.2, Ripoll-Ramis, J.2, Angulo-Barroso, R.M.3

1:EUSES, (Salt, Spain), 2: GUTTMANN (Badalona, Spain), 3: INEFC (Barcelona, Spain).

Introduction Spastic cerebral palsy (CP), the result of an insult to an immature central nervous system, has a primary adverse effect on neuromotor control and movement patterns characterized by slow and stiff movements. The upper extremities (UE) are more involved in postural control in CP than children with typical development (TD). However, little is known about the effects of UE holding a load on neuromotor control in children with CP and with TD. Methods 43 children participated in the study, 21 with spastic diplegic cerebral palsy (SDCP) (9,37±2,90 yr) and 22 with TD (9,11±2,55 yr). Both groups were matched for age and sex. The total sample also was subdivided into 3 age groups (5-7; 8-10; 11-13 yr). Children were instructed to maintain quiet stance for 30 seconds in 3 different conditions: Arms free or baseline (B); Holding a tray (T); Holding a load equivalent to 4% of body weight (W). 3 valid trials were registered per condition. The center of pressure (CoP) was computed with a force platform (Kistler 9286BA) and BTS systems software, sampling at a frequency 140Hz and filtered with a cutoff frequency of 10Hz. The variables analyzed were the position (POS), path length (LEN) and peak velocity (PkV) of the CoP in the anterior/posterior (AP) and medial/lateral (ML) directions. 2 (SDCP, TD) x 3 (age groups) x 3 (conditions) ANOVAs with repeated measures in conditions were conducted. Results A significant group effect was found in 5 of the 6 variables (all  $p < .05$ ), indicating that POS was more anterior and to the left in SDCP than TD group. Furthermore, PkV in AP and ML, and LEN in AP, were larger in SDCP than TD group. Significant or tendencies to significant age effect were also found in 5 of the 6 variables (all  $p \leq .08$ ), with POS in AP becoming more anterior, and LEN and PkV in AP and ML decreasing with age. For condition, only POS in AP had a tendency to be more anterior in W compared to B conditions ( $p = .06$ ). None of the group x condition interactions was significant. Discussion Our data confirmed that neuromotor control is worse in children with SDCP than TD but we provided the new knowledge of no differential group effects in the CoP characteristics when the upper extremities held up to an equivalent load of 4% of body weight. As expected, data confirmed the developmental progression of neuromotor control regarding CoP characteristics. Based on these results, we suggest that rehabilitation intervention including bimanual activities holding a load up to 4% of the body weight may be adequate in SDCP, since this manipulation had no impact in the neuromotor control of their static balance control. However, possible conditions effects should be examined at the cinematic and muscular pattern level.

**08:30 - 10:00****Oral presentations****OP-PM39 Rehabilitation [RE] 2****MOMENT-KNEE ANGLE RELATIONS AND GAIT ANALYSIS IN FEMALES 10 YEARS POST TOTAL KNEE ARTHROPLASTY**

Ullrich, B., Pelzer, T., Raab, J., Stening, J.

*Olympic training and testing centre of Rheinland-Pfalz/Saarland; Sports medicine section, diakonie hospital Bad Kreuznach, Germany*

Introduction The implantation of total knee arthroplasty (TKA) is a standard clinical procedure at the final stage of gonarthrosis (McClelland et al., 2007). Despite the clinical success of TKA, profound limitations of neuromuscular capacities and biomechanical gait patterns were reported in patients several months post TKA (Valtonen et al., 2009). However, limited information exists about possible long-term reductions of neuromuscular capacities in TKA patients. Methods Ten years post surgery 9 female TKA patients (64 years, mobile-bearing knee inlay, LINK, Germany) and 10 age-matched controls were tested in this study. The unilateral maximal voluntary isometric knee angle relations of knee extensors and flexors and the EMG knee angle relation of m. vastus medialis and m. vastus lateralis were studied using an isokinetic dynamometer with synchronized surface EMG. Lower extremity sagittal plane kinematics during treadmill-walking at 2km/h were recorded using an active-infrared motion analysis system (Lukotronic-Gaitlab AS 200, Steinbichler GmbH, Innsbruck, Austria). Plantar pressure distribution was analyzed at individual walking speeds using a pressure-platform (zebris-FDM, zebris Medical GmbH, Isny), Germany). Results Compared with controls, TKA patients reached significant lower absolute and body mass normalized knee extension and knee flexion moments at all tested knee angle positions. However, no significant group effects were detected in the normalized [% Max.] moment knee angle relations for both muscle groups. The normalized [% Max.] EMG-knee angle relation of the knee extensors was also without significant group differences. Compared with controls, TKA patients demonstrated several functional reductions of their biomechanical gait pattern and significant alterations of their plantar pressure profiles. Discussion The current findings indicate that 10 years post surgery, TKA patients demonstrate significant reductions in maximum voluntary force production capacities and biomechanical gait parameters. Long-term controlled strength training might be important in the rehabilitation process with TKA patients. References McClelland, JA, Webster, KE, Feller, JA. (2007). The Knee, 14, 253-263. **DUAL-TASK EXERGAMING IMPROVES BALANCE AND GAIT IN PATIENTS WITH MULTIPLE SCLEROSIS AS MUCH AS CONVENTIONAL BALANCE TRAINING**

Kramer, A., Dettmers, C., Gruber, M.

*University of Konstanz*

Background: Multiple sclerosis (MS) normally entails various restrictions of the patients' everyday life and quality of life. One of these restrictions is the increased fall risk due to balance problems. Conventional balance training rehabilitation programs usually improve balance scores in the short run. However, long-term improvements can seldom be achieved due to a lacking adherence to the exercise program outside the physiotherapy or rehabilitation clinic. In addition, the results of recent studies suggest that balance training with an additional cognitive or motor task – so-called dual-task (DT) training - might be more relevant than conventional single-task (ST) training, as DT situations have a much higher fall risk (Granacher 2010). The aim of the present study was to assess if a balance training based on DT and serious gaming would increase compliance and improve balance and gait in MS patients more than ST training. Methods: 63 MS patients were divided into 3 training groups; the first group took part in conventional balance training (CTG), the second group underwent

a DT serious gaming program (playing exergames on an unstable platform)(DTG), and the third group performed exercises on the same unstable platform without exergames (STG). All participants trained for 3 weeks, with a total of 9 training sessions lasting 30' each. Before and after the training period, they performed 11 balance tests (7 on a force plate and 4 on the unstable surface) and a gait analysis under ST and DT. In addition, after the training period they were asked to fill out a questionnaire about the training program. Results: All three groups showed improved balance and gait scores ( $p < 0.05$ ), but there was no significant group x time effect. However, in contrast to the other two groups, the DTG reported that they would have trained longer than 30' per training session and that they intended to continue the training at home. Conclusions: Playing serious games on an unstable surface improved balance and gait as much as ST balance exercises on an unstable platform or a conventional balance rehabilitation program. Although the group x time interaction effect did not reach significance level, the DTG scored higher in most of the DT balance and gait tests than the STG and the CTG, suggesting that DT exergaming might indeed be beneficial in DT situations, but that this effect was masked by the high day-to-day performance variability observed in MS patients. Provided that the increased compliance with the training program translates to a higher adherence, the integration of serious games should be beneficial for the long-term effectiveness of rehabilitation programs. References: Granacher U et al. (2010). *Int J Sports Med*, 31, 353–358.

### THE PSYCHOLOGICAL RESPONSE TO COMBINED STRENGTH AND AEROBIC TRAINING IN A GROUP OF CARDIAC PATIENTS.

Skaug, A.1, Hanssen, K.E.1, Sveen, O.1, Johansen, E.2, Jensen, J.2

1.Østfold College, Faculty of Education 2.Norwegian School of Sport Sciences

Abstract ECSS, Barcelona 2013 The psychological response to combined strength and aerobic training in a group of cardiac patients. Introduction Combination of strength and endurance training has recently been suggested to be superior to endurance training to improve health in elderly subjects. The effect of training with combined endurance and strength training has mainly focused on physiological health parameters. However, psychological wellbeing is also an important aspect of quality of life. Aim: The aim of this study was to investigate the hypothesis that intensified training, consisting of two strength training session with heavy loads and two high intensity spinning interval weekly, would improve psychological wellbeing more than a moderate training consisting of two endurance training sessions and one circuit training session weekly. Methods: Twenty nine coronary patients (aged: 50-72 years; 23 males and 6 females) were recruited from Fredrikstad Cardio-Club (Club for cardiac patients after hospital treatment) and stratified to intensified training or continuation of normal training. One group performed intensified training (INT) exercised four days a week: two aerobic exercises (spinning) of 60 minutes and two days of strength training during 10 weeks. The control group (CON) exercised 45 minutes aerobic training two days a week and one day of strength circle training. Questionnaire based on self-determination theory was used to evaluate psychological wellbeing. Results Both groups reported subjective improvement in physical capacity. This agrees with objective measurements of increase in maximal oxygen uptake and muscle strength. The group performing intensified training reported higher motivation, satisfaction and happiness. Furthermore, the group performing intensified training reported higher score on health benefits of training than the group who conducted moderate intensity training. Discussion: Both groups reported improved physical capacity on questionnaire, which agreed with the objective measurements. It is of note that the cardiac patients who conducted four training sessions reported higher satisfaction and subjective than the group continuing with moderate intensity training. Both the control and intervention group increased maximal oxygen similarly. However, the group with intensified training increased muscles strength in leg muscles more than CON. The ability to complete very intense training sessions was satisfying, and we speculate that participation in high intensity training and increased muscles strength improved self-confidence. Conclusion: Intensified training and inclusion of strength training may be beneficial for psychological wellbeing in middle-aged and elderly cardiac patients.

### SKILLING-UP EXERCISE FOR DECONDITIONED NURSING HOME DWELLERS

Rogan, S.1, de Bruin, E.D.2

Discipline Physiotherapy

1: Discipline Physiotherapy, Bern University of Applied Sciences Bern, Switzerland 2: Institute of Human Movement Sciences and Sport, ETH Zurich, Zurich, Switzerland. Introduction Because frail older adults have often been excluded from research little is known about the effects of exercise in these individuals [1]. Frailty and impaired muscle functioning are closely associated [2]. Dynapenia describes age-associated loss of muscle strength and power leading to increased risk for functional limitations and disability [3,4]. The nervous system's ability to fully activate skeletal muscle voluntarily seems impaired in dynapenia, which might be trained through vibration exercise [5] and video games [6]. This study determined the effects of an 8 weeks stochastic resonance whole-body vibration (SR-WBV) and video game training in nursing home dwellers. Methods 29 frail elderly ( $87.1 \pm 8.7$  years) randomly assigned to intervention (INT) and control (SHAM). INT performed 5 sets SR-WBV lasting 5 minutes, with 1 minute rest between sets (base frequency 3 Hz up to 6 Hz, Noise 4) during 5 weeks. From weeks 5 to 8 a video dance game 3 times per week was added. SHAM performed a five-set SR-WBV program lasting five minutes, with 1 minute rest (1 Hz, Noise 1). From week 5 to 8 trampoline exercise 3 times per week was added. Outcomes were the Short physical performance battery (SPPB). A two (groups) x three (time points) ANOVA with Bonferroni correction, with repeated measures on the last factor, was used for analysis ( $p \leq 0.05$ ). Results The within subject test indicated a significant time effect for the SPPB parameter:  $F(2,46) = 16$ ,  $p < 0.001$ . The between groups test indicated that the variable Training reached significance in SPPB  $F(2,46) = 21.23$ ,  $p < 0.001$ . Where SHAM remained unchanged with SPPB values pre/post =  $4.1 \pm 1.8 / 3.9 \pm 1.3$  points INT shows large improvements  $2.8 \pm 1.5 / 6.8 \pm 3.5$  points. Conclusions The findings of this study contrast previous reports showing that physical exercise programs for frail older people are less effective on disability outcomes [7]. These findings encourage further examination of the effect of strength exercise training types that specifically focus on aspects of neuromuscular functioning in frail elderly. **08:30 - 10:00****Oral presentations****OP-PM34 Physiology [PH] 11****ACUTE AND CHRONIC EFFECTS OF RESISTANCE TRAINING COMBINED WITH VASCULAR OCCLUSION OR HYPOXIA ON HORMONAL RESPONSE.**

Hamlin, M.J.1, Manimmanakorn, A.2, Manimmanakorn, N.2, Draper, N.3, Billaut, F.4, Shearman, J.P.5

*1:Lincoln University (Christchurch, NZ), 2:Khon Kaen University (Thailand), 3:University of Canterbury (Christchurch, NZ), 4:Institut national du sport du Québec (Canada), 5:CPIT (Christchurch, NZ)*

**Introduction** Low-load resistance training (20-50% of one repetition maximum, 1-RM) combined with vascular occlusion or hypoxia produces similar performance gains as traditional high-intensity resistance training (70-85% 1-RM), however, the underlying physiological mechanisms behind such improvements are controversial. Therefore, the aim of this study was to investigate the hormonal response to acute and chronic low-load resistance training combined with either vascular occlusion or normobaric hypoxic exposure. **Methods** In a randomised controlled trial, 30 well-trained team-sport athletes took part in a 5-week training of knee flexor/extensor muscles in which low-load resistant exercise (20% 1-RM) was combined with either a) an occlusion pressure of ~230 mmHg (KT, n = 10), b) hypoxic air to generate an arterial blood oxygen saturation of ~80% (HT, n = 10), or c) no additional stimulus (CT, n = 10). The training was of the same intensity and amount in all groups. Serum growth hormone (GH) was measured before and after (1-2, 15, 30 min post) the first and last training bouts. Strength (3-s maximal voluntary contraction [MVC3]) and cross-sectional area (CSA) of the quadriceps and hamstrings were measured before and after training. **Results** Compared to CT, both HT and KT showed a substantial increase in GH release 1-2 min after the first training bout (by approximately 3- to 4-fold). GH release continued to be substantially elevated in the KT group compared to CT and HT groups up to 30-min post the first training bout. After 5 weeks of training, however, the release of GH post exercise was substantially reduced and similar in all groups. Relative to CT, KT and HT increased MVC3 ( $11.0 \pm 11.9\%$  and  $15.0 \pm 13.1\%$  respectively, mean  $\pm$  90% CI) and CSA ( $7.6 \pm 5.8$  and  $5.3 \pm 3.0\%$ ) by the end of training. **Discussion** Performance gains (in particular strength and hypertrophy) from low-load resistance training combined with vascular occlusion or hypoxia are likely related to the heightened acute release of growth hormone found after such training. Importantly, the training must be continuously adapted to the improvement in strength as growth hormone release diminishes over time with similar intensity training bouts.

**INFLUENCE OF SMOKING STATUS ON MUSCULOSKELETAL INJURY RISK IN BRITISH ARMY INFANTRY TRAINEES**

Siddall, A., Bilzon, J., Thompson, D., Izard, R., Greeves, J., Stokes, K.

*University of Bath*

Cigarette smoking is the most widely reported independent risk factor for training-related injuries in military personnel (Knapik et al., 2001). Despite this, smoking prevalence in military populations is typically higher than in the general population (Klesges et al., 2001). We examined injury incidence during British Army infantry training to determine whether habitual smoking influences injury risk. After obtaining written informed consent, a lifestyle questionnaire was administered to trainees (aged 18-33) at entry to training (n=1810) to determine current smoking behaviours. Data on lower limb and lumbar spine injuries over 26 weeks of training were obtained retrospectively from military medical records. Injury type, anatomical site and training time lost were recorded for all training-induced injuries and categorised as either traumatic or overuse in nature. The sample comprised 49% smokers (>1 cigarette•day<sup>-1</sup>) and 33% non-smokers with the remainder either former or occasional smokers. Training-related injury incidence for the sample was 58% and time-loss training injury incidence was 32% where median (IQR) training days lost was 14 (43) days per time-loss injury. Odds ratios (95% CI) for training injury (1.22 [1.12-1.34]), time-loss training injury (1.23 [1.06-1.44]) and overuse training injury (1.38 [1.11-1.72]) showed greater risk in smokers (p<0.01). Smokers exhibited higher incidence (95% CI; p<0.01) of training injuries (60 [57-63]% vs. 55 [51-59]%), time-loss training injuries (34 [31-38]% vs. 30 [26-34]%) and injuries attributed to overuse (22 [19-25]% vs. 17 [14-20]%), but not traumatic training injuries. Additionally, average duty days lost (95% CI) to time-loss training-injuries per 1000 trainee-days was significantly greater in smokers (132 [120-144]) than non-smokers (104 [92-116]; p<0.01). The most prevalent training-related and time-loss injuries were non-specific soft tissue injury (51% of injuries) and the most common anatomical sites were knee (25%), foot (24%) and ankle (17%), with injuries to the lower leg comprising >75% of all lower body injuries, with similar patterns observed for smokers and non-smokers. Smokers have a greater risk of training-related injury than non-smokers in this British Army infantry training population, though univariate analyses cannot demonstrate that smoking per se is the cause of this difference. The greater number of training days lost per 1000 trainee-days suggests that smokers either suffer more severe injuries and/or may not recover from injuries as quickly or effectively as non-smokers. **Introduction** Skeletal muscle is a dynamic tissue with a remarkable regenerative capacity. The critical role of macrophages (MPs) and the corresponding inflammatory response associated to the muscle repair process has been recently highlighted<sup>1</sup>. Although it has been well acknowledged that Hypoxia Inducible Factors (HIF) act as an oxygen sensor, recent studies have demonstrated that HIF-1 $\alpha$  could play a key role in inflammation<sup>2,3</sup>. On that basis, one could expect an impaired or delayed muscle regeneration process as a result of HIF-1 $\alpha$  deletion in MPs. We aimed at investigating strictly noninvasively, using multimodal Magnetic Resonance Imaging (MRI) including T2 mapping and Diffusion Tensor Imaging (DTI), the effects of an acute injury in a mouse model specifically deleted for HIF-1 $\alpha$  in MPs<sup>2</sup>. **Methods** Acute muscle injury was induced by the i.m. injection of the myotoxin cardiotoxin (CTX) in the tibialis anterior muscle. MRI experiments were performed in a mouse model specifically deleted for HIF-1 $\alpha$  in MPs (i.e., *LysM-Cre;HIF-1 $\alpha$ /fl*; n=7)<sup>2</sup> and the wild-type littermates (WT; n=6) mice before and 1, 2, 3, 7 and 21 days after CTX injection. Ultra-high field MR experiments were performed on a 11.75 T vertical MRI system. DTI metrics, including diffusivities ( $\lambda_1$ ,  $\lambda_2$  and  $\lambda_3$ ), and T2 values were measured. **Results** Both DTI metrics and T2

values were significantly modified as a result of CTX injection.  $\lambda_2$  and  $\lambda_3$  peaked at D1 (+38-57%) and remained elevated at D2 (+32-53%) and D3 (+7-18%). These parameters were further reduced at D7 (-11-13%) and returned to the baseline values at D21.  $\lambda_1$  increased at D1 (+14%) and D2 (+11%) and returned to the baseline values at D3. T2 values were significantly elevated at D1 (+98%), peaked at D2-D3 (+126-133%), remained elevated at D7 (+34%) and recovered at D21. Interestingly, all these MRI changes were similar for both WT and LysM-Cre;HIF-1 $\alpha$ /fl mice. Discussion We demonstrated that CTX injection led to similar MRI changes in both LysM-Cre;HIF-1 $\alpha$ /fl and WT groups, suggesting that HIF-1 $\alpha$  is not involved in the muscle regeneration process resulting from an acute injury. Interestingly, the CTX injection affected the MRI parameters i.e. DTI metrics and T2 values with a different time-frame, thereby indicating that the corresponding indices likely reflect different physiological processes. Multimodal MRI might be considered as a suitable diagnostic tool for monitoring skeletal muscle injury and repair processes. References 1. Arnold L, Henry A, Poron F et al. ### MUSCLE DISUSE REDUCES POST-PRANDIAL MUSCLE PROTEIN SYNTHESIS RATES IN YOUNG MEN

Wall, B.T., Snijders, T., Verdijk, L.B., Senden, J.M.G., Dolmans, J.D., Gijsen, A.P., Van Loon, L.J.C.

*Maastricht University*

Muscle disuse leads to a substantial loss of skeletal muscle tissue and, therefore, numerous negative health consequences. While it has been established that muscle disuse atrophy is mechanistically underpinned by a decline in basal (post-absorptive) muscle protein synthesis rates, it is currently unclear whether a parallel reduction in postprandial muscle protein synthesis also occurs. In the present study, we assessed post-prandial muscle protein synthesis rates before and after a period of disuse in humans. Twelve healthy, young (23.8 $\pm$ 1.0 y) men underwent a 14 day period of one-legged knee immobilization by way of a full leg cast. Before and after the immobilization period, quadriceps cross sectional area (CSA), muscle strength and skeletal muscle protein synthesis rates were assessed. Continuous infusions with L-[ring-2H5]phenylalanine were applied to assess mixed muscle protein fractional synthetic rates (FSRs) following the ingestion of 20 g dietary protein. Immobilization led to an 8.4 $\pm$ 2.8 % (P<0.001) and 22.9 $\pm$ 2.6 % (P<0.001) decrease in quadriceps muscle CSA and strength, respectively. Post-prandial muscle protein synthesis rates declined by 31.0 $\pm$ 12.5 % following immobilization (0.046 $\pm$ 0.004 to 0.032 $\pm$ 0.006 %·h<sup>-1</sup>; P<0.05). In conclusion, this is the first study to demonstrate that muscle disuse atrophy is accompanied by a reduced muscle protein synthetic response to the ingestion of a meal like amount of dietary protein. Anabolic resistance to nutritional stimuli contributes to the loss of muscle tissue during a period of disuse.

### REGULAR PHYSICAL ACTIVITY FAVOR SKELETAL MUSCLE REGENERATION AFTER TOXIC INJURY

Teixeira, E.I, Fonseca, H.I, Moreira-Gonçalves, D.I, Carvalho, A.I, Duarte, J.I

*I- CIAFEL, Faculty of Sports, University of Porto*

Introduction Skeletal muscle regeneration (SMR) is a highly complex process that involves coordinated recruitment of a wide range of cells, meticulous interactions with the inflammatory system and ends either with proper regeneration of fibres or fibrotic tissue (FT) formation[2]. The aim of this experiment was to determine the possible preventive role that physical activity (PA) may play in the skeletal muscle post-injury regeneration. Methods Twelve male Wistar rats, 2 months old, were either housed in cages with running wheel (RW)(Ex;n=6) or in cages without RW (Sed;n=6) during 8 weeks. At the end of this protocol the right tibialis anterior (TA) muscle of all rats was injected with 30 $\mu$ L of 20 $\mu$ M cardiotoxin (CTX). Three animals from each group were sacrificed 7 days (Ex7 and Sed7 groups) after CTX injection and the remaining following 15 days (Ex15 and Sed15 groups). Skeletal muscle fibres cross-sectional area (CSA), percentage of central nucleated fibres (CNF), and FT were analyzed, within the area classified as damaged or regenerating[1], by histomorphometry following H&E and Picrosirius Red staining, respectively. Results During the 8 weeks the Ex group registered a mean running distance of 3.2Km per day. The mean fibre CSA in Ex7 (240 $\pm$ 92  $\mu$ m<sup>2</sup>) was smaller than the Sed7 (308 $\pm$ 150  $\mu$ m<sup>2</sup>), p<0.01. However, the mean fibre CSA in Ex15 (677 $\pm$ 367  $\mu$ m<sup>2</sup>) was higher than the Sed15 (337 $\pm$ 219  $\mu$ m<sup>2</sup>), p<0.01. The percentage of CNF in Ex7 (35.2%) and Sed7 (33.7%) fibres did not differ. Nonetheless, CNF in Ex15 (5.2%) were less abundant than in Sed15 (27%), p<0.01. Both Ex7 (24.6 $\pm$ 4.6 mm<sup>2</sup>) and Ex15 (11 $\pm$ 4.3 mm<sup>2</sup>) had less FT area than Sed7 (37.6 $\pm$ 11 mm<sup>2</sup>) and Sed15 (21.4 $\pm$ 5.5 mm<sup>2</sup>), respectively, p<0.01. Discussion Evidence that augmented contractile activity during SMR may have a therapeutic effect in the full recovery of muscle mass has been verified by others[3]. Our results suggest that physical inactivity may negatively influence the SMR towards a more dysfunctional phenotype, i.e., increasing FT deposition and compromising the overall SMR. Our data, although preliminary, seems to indicate that voluntary RW PA may be effective in enhancing the SMR process. ### EFFECT OF ECCENTRIC VERSUS CONCENTRIC TRAINING ON METABOLIC MEASURES FOLLOWING ECCENTRIC EXERCISE INDUCED MUSCLE DAMAGE

Hughes, J., Johnson, N., Brown, S., Sachinwalla, T., Stannard, S.

*University of Gloucestershire*

Introduction Repeated eccentric based exercise initiates a protective adaptation so that replicating the same eccentric exercise at a later date results in reduced symptoms of damage compared to the initial bout (Clarkson et al., 1992). Following an acute initial bout of eccentric exercise, an increase in the muscle Pi / PCR occurs (Hughes et al. 2010), but it is not known if this indirect measure of intracellular metabolism is attenuated by repeated exposure to eccentric exercise. Methods Using 31P-MRS the purpose of this study was to examine the effect of a bout of EEIMD on intramyocellular phosphate metabolism in skeletal muscle which had been concentrically (ConTr) versus eccentrically (EccTr) trained. Six participants (35  $\pm$  7 yrs mean  $\pm$  SD; 174.5  $\pm$  7.2 cm and 70.9  $\pm$  7.1 kg body mass) performed six training sessions on an isokinetic dynamometer (5 x 10 reps) on each leg; one leg was trained eccentrically and the other concentrically. Following the training period participants undertook a bout of eccentrically biased exercise, which had previously been shown to induce EEIMD. This involved 300 unilateral, maximal, isokinetic, eccentric contractions (EE) (30°·s<sup>-1</sup>) using the quadriceps of both legs on an isokinetic dynamometer. Unlocalised 31P-MRS was used to assess resting quadriceps [PCr], [Pi], [ADP], pH, and MRI utilized to measure muscle volume. Results Significant increases in isometric MVC (P < 0.05) were evident following both training conditions (pre 231  $\pm$  43Nm to post 265  $\pm$

45Nm; pre  $235 \pm 58$ Nm to post  $276 \pm 64$ Nm in ConTr and EccTr respectively), though the ConTr leg experienced a significant decrease in MVC after EE ( $276 \pm 64$  to  $197 \pm 21$ Nm). A main effect of trial was evident for muscle volume, which was significantly greater following EE in the ConTr leg compared to the EccTr leg ( $P = 0.045$ ). Pi / PCr was greater than 0.19 in both ConTr and EccTr at both time points, which is consistent with EEIMD in both legs. However, there were no significant differences in resting [PCr], [Pi], [ADP], pH or Pi / PCr between ConTr or EccTr conditions following EE (all  $P > 0.05$ ). Discussion These findings indicate that increases in skeletal muscle phosphate metabolism typically associated with muscle damage are not attenuated by prior exposure to repeated bouts of EE. Therefore, decrements in force generating capacity of muscle due to EEIMD may be mediated by more central factors. Further, prior eccentric exercise attenuates the muscular swelling which occurs in the period after unaccustomed eccentric exercise. References Clarkson, Nosaka & Braun. (1992). *Med Sci Sport Ex*, 24, 512-520. Hughes, Johnson, Brown, Sachinwalla, Walton, & Stannard. (2010). *Eur J Appl Physiol*, 110(6), 1135 - 1141.

##### VARIATIONS IN NEUROMUSCULAR ACTIVITY OF THIGH MUSCLES DURING WHOLE-BODY VIBRATION IN CONSIDERATION OF DIFFERENT BIOMECHANICAL VARIABLES

Perchthaler, D., Horstmann, T., Grau, S.

*University Clinic Tuebingen*

**Introduction** In the last ten years, whole-body vibration (WBV) has become a steadily increasing field of interest in sports science and research. In fact, previous studies have shown that WBV exercises have positive effects in men (Cardinale&Wakeling, 2005). However, limitations of previous studies are different training procedures with regard to the biomechanical variables (vibration frequency, vibration amplitude, and joint angle) affecting the intensity of neuromuscular activation. Few studies have investigated the responsiveness of different muscles in different exercises during vibration stimulus, only regarding two of three biomechanical variables (e.g. Roelants et al., 2006; Cardinale&Lim, 2003). The intention of this study was to systematically analyze the impact of all biomechanical variables on thigh muscle activity during exposure to WBV. **Methods** 51 healthy men and women (age  $54.9 \pm 8.1$  years) voluntarily participated in the study and were randomly allocated to five different vibration-frequency groups. Each subject performed 9 static squat positions (3 amplitudes x 3 knee angles) on a side alternating vibration platform (Galileo Fitness, Novotec Medical GmbH, Pforzheim). Surface electromyography (EMG) was used to record the neuromuscular activity of the quadriceps femoris and hamstring muscles. Maximal voluntary contractions (MVCs) were performed prior to the measurements to normalize the EMG signals. Results WBV exercises lead to an increase in quadriceps femoris and hamstring muscle activity. Depending on the biomechanical variables, EMG muscle activity ranged between 18.2 and 74.1 % MVC in the quadriceps femoris muscle and between 5.2 and 27.3 % MVC in the hamstring muscles during WBV. Especially in the quadriceps femoris muscle, a frequency of 30 Hz and an amplitude of 4 mm led to a significant increase in muscle activity compared to the other tested frequencies and amplitudes. However, it seems that knee angle is only relevant for the quadriceps femoris muscle. **Discussion** The highest levels of muscle activation were found at high frequencies and large amplitudes, which also correspond to the findings of Krol et al. (2011). Roelants et al. (2006) investigated leg muscle activity during different squat exercises with subjects standing on a synchronous vibrating platform. They showed an increase in muscle activity during WBV while increasing the knee angle as we confirmed for the quadriceps femoris in our present study. The results of our study should give more information for developing individual training protocols in consideration of all biomechanical variables for WBV treatment in different practical applications. **References** Cardinale, M, Lim, J (2003). *J Strength Cond Res* 17: 621-624. ##### EFFECT OF PROGRESSIVE-OVERLOAD WHOLE BODY VIBRATION TRAINING AS PART OF OFF-SEASON STRENGTH TRAINING IN FEMALE ATHLETES

Jones, M.T.

*George Mason University*

**Introduction** Use of whole body vibration (WBV) as an intervention method for athletic development in trained women has been inconclusive. Bodyweight WBV (Jones et al., 2011) and externally loaded WBV (Preatoni et al., 2012) training in conjunction with conventional strength training (ST) showed the inclusion of WBV had no apparent benefit over ST, yet there was little change in the protocol. Therefore, the aim of this study was to analyse the effect of a periodized, progressive-overload WBV+ST protocol on strength and power. **Methods** Lacrosse athletes ( $n=18$ ,  $19.6 \pm 1.2$  yr,  $167.37 \pm 8.34$  cm,  $66.10 \pm 7.13$  kg) with  $> 1$  year of ST, but no prior WBV training, completed the 15-week (wk) study. Random assignment to Group 1 (GP1) or 2 (GP2) followed pre-tests (wk1) of seated medicine ball throw (SMBT), single leg hop for each leg (LSLH, RSLH), countermovement vertical jump (CMVJ), 3-RM front squat (FS), pull-up (PU), bench press (BP), and %body fat (BF). WBV was two 3-wk phases of dynamic and static-hold bodyweight exercises administered 2 days/wk in team ST sessions. The 15-wk training included Phase I (wk2-4): WBV1+ST1 (GP1) or WBV1sham+ST1 (GP2), Phase II (wk5-7): WBV1+ST1 (GP2) or WBV1sham+ST1 (GP1), post-test 1 (wk 8), Phase III (wk9-11): WBV2+ST2 (GP1) or WBV2sham+ST2 (GP2), Phase IV (wk12-14): WBV2+ST2 (GP2) or WBV2sham+ST2 (GP1), and post-test 2 (wk15). WBVsham+ST and WBV+ST were identical exercise protocols minus the WBV. Total WBV exposure was 6 min broken into 30-sec bouts with 60-sec rest for a 1:2 work relief ratio. Exercises, frequency and amplitude progressed in intensity from the first 3-wk (Phase I,II) to the second 3-wk (Phase III,IV) training phase. Five  $2 \times 3$  repeated measures analyses of variance (ANOVA) were used to analyze SMBT, CMVJ, LSLH, RSLH and FS, and three  $2 \times 2$  repeated measures ANOVAs were used for %BF, PU and BP. Alpha level was set at  $p < 0.05$ . Results FS (38%), LSLH (12%), and RSLH (15%) increased ( $p=0.001$ ) from pretest to post-test 2. FS (9%) increased from post-test 1 to post-test 2. %BF (4%) decreased ( $p=0.04$ ) and PU (27%) increased ( $p=0.008$ ) from pretest to post-test 2. SMBT (3%) and BP (4%) showed a trend of increased performance from pretest to post-test 2 ( $p=0.10$ ). **Discussion** Two 3-week phases of periodized, progressive-overload WBV+ST training elicited gains in upper- and lower- body strength (FS, PU), power (LSLH, RSLH), and %BF during a 15-wk off-season program in trained female athletes. No differences existed between GP1 and GP2, indicating the timing of WBV (Phase I,

Phase III (GP1) or Phase II, Phase IV (GP2)] had no effect. Greatest improvements in performance tests occurred in the initial WBV phase. References Jones, MT, et al. (2011). *J Strength Cond Res* 25(9), 2434-2441. Preatoni, E, et al. (2012). *J Strength Cond Res* 26(9), 2495-2506.

### HIGH-INTENSITY, VELOCITY, ACCELERATION, AND DECELERATION RUNNING EFFORTS DURING TENNIS MATCHES IN YOUNG MALE PLAYERS

Hoppe, M.W., Baumgart, C., Bornefeld, J., Pieper, S., Sperlich, B., Freiwald, J.

*Research Center for Performance Diagnostics and Training Advice, University of Wuppertal, Germany*

**Introduction** In field sports, a new definition of high-intensity running incorporates both running with high-velocity and/or high-acceleration (Dwyer & Gabbett, 2012). Since tennis players perform a lot of running with high-deceleration (Fernandez-Fernandez et al., 2009), the aim of this study was to analyze the high-velocity, high-acceleration, and high-deceleration running efforts during tennis matches in young male players. **Methods** 20 young male tennis players (13±1 years, 7±2 years tennis experience) performed a training match (two winning sets with a match-tiebreak) on clay courts. Running velocity was measured via global positioning system at 10 Hz (Catapult Innovations, MinimaxX S4, Melbourne, Australia). The acceleration and deceleration data were calculated from the measured velocity data. The thresholds for high-velocity, high-acceleration, and high-deceleration running efforts were 3 m/s, 2 m/s<sup>2</sup>, and -2 m/s<sup>2</sup>, respectively. All running efforts were expressed as relative values per minute match play (1/min). Descriptive data (mean±SD) were calculated after checking for normality with the Kolmogorov-Smirnov Test. Pearson-product-moment correlation coefficients were used to determine the common variance (R) between the different high-intensity running efforts. Statistical significance was set to p<.05. Results Per minute match play, young male tennis players performed 0.2±0.1 1/min high-velocity, 0.6±0.2 1/min high-acceleration, and 0.6±0.2 1/min high-deceleration running efforts. The common variance between the high-velocity, high-acceleration, and high-deceleration running efforts was R=.27 (p>.05), R=.24 (p>.05), and R=.66 (p<.01), respectively. Discussion During tennis matches, young male players perform threefold more high-acceleration and high-deceleration than high-velocity running efforts. The common variances revealed that high-acceleration and high-deceleration are independent from high-velocity running efforts, and therefore, obtain additional information. Based on these observations, high-intensity running should be defined using velocity, acceleration, and deceleration data. This approach should be included when assessing high-intensity running efforts in young male tennis players. References Dwyer, D.B. & Gabbett, T.J. (2012). ### EASY METHOD FOR QUANTIFYING FATIGUE IN HANDBALL TEAM PLAYERS

Galdeano Llinares, P.1, Suárez-Parra, I.1, Alarcón-Torrecillas, S.1, Barba-Moreno, L.1, González-Hernández, J.M.2, Cuadrado-Peñafiel, V.3, Ortega-Becerra, M.A.4

1: Catholic university of San Antonio, Murcia, España 2: UAX (Madrid, Spain), 3: UJA (Jaen, Spain), 4: Pablo de Olavide University (Seville, Spain)

**Introduction** In handball team, the possession or not of the ball it determines the own player's behaviors, existing a constant relation offensive - defense that takes place during the game. This correlation implies that the actions players realize are characterized by rapid direction changes, accelerations, sprints, jumps and throws, all of them performed to high intensity and opposite to an opponent what implies that the handball team players develop high degrees of fatigue specially in muscles' legs (Ronglan, Raastad, & Borgesen, 2006). Therefore the aim of this study is acquiring more specific knowledge regarding development of fatigue following real handball matches. Such sport specific knowledge may facilitate the adjustment of more adequate training and competition procedures within elite handball. **Methods** Sixteen male players from Spanish First Division (age 25.6 ± 4.4 yr, body mass 86.3 ± 7.9 kg, height 184.4 ± 14.6 cm; body fat 12.7 ± 8.2%) participated in this study. They performed 5 countermovement jumps (CMJ) and 10-m sprint test just after finishing warm-up and before match, these measures were repeated at the half time of match and at the end of match. Results CMJ height and 10-m sprint time were collected during four official matches. CMJ height loss pre-post session were significant for all matches (p<0.001) and 10-m sprint time loss was significant too (p<0.01). Speed losses produced presented a high relation with CMJ height losses (r=0.83). Furthermore, these differences also were found between first and second half of matches. Discussion Habitual actions in elite handball (rapid direction changes, accelerations, sprints, jumps and throws) induce a fatigue degree that can be evaluated with some usual tests (Ronglan, Raastad, & Borgesen, 2006). Therefore, in this study, the high correlation found between mechanical (speed and CMJ height losses) measures of fatigue highlight the utility and validity of using CMJ to monitor training load. Thus, it is possible to conclude that the use of the CMJ and 10-m sprint time are valid and reliable tools for estimating the neuromuscular fatigue produced (Jiménez-Reyes et al, 2012). ### EFFECTS OF 1 YEAR OF WHOLE BODY VIBRATIONS TRAINING IN POSTMENOPAUSAL WOMEN.

Tillaar, R.

*University College of Nord Trøndelag*

**Introduction** As the world population is getting older, occurrence of osteoporotic fracture is an increasingly important public health problem. Increase in strength, balance and power can help older women against falling and thereby against possible osteoporotic fractures. Therefore the aim of our study was to investigate the effect of 1 year of whole body vibration (WBV) training in postmenopausal women on strength, balance and power. **Methods** 98 postmenopausal women (age 61.5 ± 6.3 years, mass 69.1 ± 11 kg, height 1.67 ± 0.05 m) participated in this study. Static and dynamic strength of the knee extensors and flexors was tested as peak force in a dynamometer. Balance was tested while standing on 1 and 2 legs over 10 seconds on a force plate. Power was measured by peak jump velocity and height during a CMJ with and without arm swing. After the pretest, two groups trained WBV training. The first group (n=27) trained on a WBV platform that only conducted horizontal vibrations (Nordic Vibroplate II, Nordic Fitness AS, Norway), while second group (n=55) trained on a tilting WBV platform (Galileo Fitness, Novotec Medical GmbH, Germany). The third group was a control group (n=16) that did not train WBV. Each training group trained 3 times per week, 8\*1 minute squatting per session on their platform according to the principle of overload. Results Both training groups increased their peak force significantly in flexion (11.4 %) and extension (4.3%) of the knee and in the isometric strength (11.2%) of the knee extensors, while the control group had a decrease in extension (-12%) and isometric strength (-

11%). No significant difference between the two training groups was found. No significant ( $p > 0.05$ ) changes in jump height and peak velocity (power) and balance were found after 1 year of training. However, post hoc comparison showed that the control group significantly decreased peak velocity, while the training groups did not. Discussion The increased strength after WBV training in our study was in line with earlier studies (e.g. Bogaert et al., 2007; 2009). However, no changes were found in balance and power as in these studies. This was probably caused by the used protocol. To stimulate the different body properties (Rittweger, 2010) we used different frequencies (5-6, 12-14, 18, 22-26 Hz) and a lower amplitude (2-4mm) than in earlier studies. Due to this, the impact on the muscles was not high enough to stimulate balance and power enough. It could only help to minimise the natural decrease in power. It was concluded that both horizontal and tilting induced WBV training can help postmenopausal women with increasing their leg strength but not balance and power. References Bogaerts AC. et al. (2007). *J Gerontol A Biol Sci Med Sci*, 62, 630-635. Bogaerts AC. et al. (2009). *Age Ageing*, 38, 448-454. Rittweger J. (2010). *Eur J Appl Physiol*, 5, 877-904.

#### OP-SH02 Physical Education and Pedagogy [PP] 1

##### THE ROLE OF SELF MOTIVATION IN THE AFFECTIVITY OF HUNGARIAN STUDENTS AGED 11-18 FOR PHYSICAL EDUCATION AT SCHOOL

Hamar, P.1, Versics, A.1, Volák, A.1, Karsai, I.2, Soós, I.3

*1Semmelweis University Budapest, HU, 2University of Pécs, HU, 3University of Sunderland, UK*

**Introduction** An important factor of school education is motivating and motivation (Csapó, 2000; Szabó, 2004). During this presentation, rather than considering it as a primarily psychological phenomenon, we are going to investigate motivation as a pedagogical question of school teaching and learning as well as that of physical education at school. By using self motivation questionnaires familiar from psychological tests we are endeavouring to find a reinforcement to our first hypothesis that during the process of acquiring physical education at school a dominant role is played by factors which motivate students such as achievement orientation, determination, perseverance, reliability, love of comfort, a desire to relax, the search for entertainment and avoiding risks as well as to our second hypothesis that the aforementioned factors are interrelated. A further hypothesis of ours states that the abovementioned motivation factors, which play a significant role during physical education classes, manifest themselves typically in relation to sex and age. **Methods** The sample tested comprised 2840 students between the ages of 11-18 with an approximately equal distribution between the sexes: 1367 boys and 1473 girls. The method of the cross-section testing was a survey based on questionnaires. The questionnaire on self motivation consisted of 36 questions, in which the subjects tested had to assess the statements in the questions in relation to themselves on a five-level Likert-scale. The 36 questions in the questionnaire were used to form six factors (F). Following basic statistical calculations we made a two-sample analysis of variance ( $2 \times 4$  between – subjects ANOVA) and we used the Bonferroni Post Hoc test to examine the differences between the sexes (female, male) and age groups (students in the age groups of 11-12, 13-14, 15-16, 17-18). To investigate the distribution of factor values (Fv, Fc, Fs, Fp, Fr and Fbr) among the individual groups we used the Kolmogorov Smirnov test while homogeneity among groups was determined with the Leven's test. **Summary** Our test hypotheses have been validated because during the process of acquiring physical education at school a dominant role is played by the factors examined by us and they are interrelated. In addition, motivating factors playing a significant role in physical education classes manifest themselves typically in relation to sex and age. To illustrate this, the youngest age group deviates from older age groups in nearly every respect. **References** Csapó, B. ##### DOES ENHANCED PHYSICAL ACTIVITY INCREASE COGNITIVE PERFORMANCE AMONG YOUNG PEOPLE?

Collard, D.C.M., Scholten, A.M., Schokker, D.F., Preller, L., Wisse, E.A., Sabel, J., Alpay, L., van Empelen, P.

*Mulier Institute*

**Introduction** Various reviews report positive associations between physical activity and cognitive performance in youth. These findings are generally based on correlational data. Previous review studies do not provide clear answers on the causal relationship between physical activity and cognition in youth. Therefore, we aimed to conduct a systematic review of studies that investigated the causal relation between physical activity and cognition among the general population of young people (4-18 years). Key questions that were addressed are 'Does current evidence support a causal positive relationship between physical activity and cognition?' If so, 'can the effect be related to type, quality or setting of the intervention studies?'. **Method** Eligible intervention studies, published between 2007 and 2012, were identified through the PubMed and PsycINFO database. Other eligible articles published before 2007 and after 1990 were selected from (systematic) reviews published between 2010 and 2012, which evaluated the relationship between physical activity and cognitive performance in youth. Relevant articles, published between 1990 – 2012, were examined against the inclusion criteria. Finally, 22 articles were included and divided in school-based interventions and experiments. Data were extracted and methodological quality was rated. All outcome variables in the studies were coded as 'positive', 'negative' or 'none' based on their relation between physical activity and cognition. **Results** The twenty-two selected intervention studies were described. The studies varied widely in terms of study quality, sample size, type and number of cognitive tests reported. In total 94 cognitive indicators were examined. Of those 94 indicators, 30 indicators (32%) showed favourable changes, 62 indicators (66%) did not change, and 2 indicators showed negative changes in cognitive performance as a result of the physical activity intervention. Only in 6 (27%) studies the number of positive effects outweighed the number of non-effects. **Discussion** In agreement with earlier findings we conclude that physical activity does not harm cognitive development of young people. However, the results of the review neither support popular (policy) beliefs about a positive causal relation between physical activity and cognitive performance among youth. More final conclusions are still seriously hampered by low quality and small sample sizes of the studies.

**THE EFFECTS OF AN INTERVENTION IN PHYSICAL EDUCATION ON CHILDREN'S EXECUTIVE FUNCTIONS**

Schmidt, M.1, Jäger, K.2, Conzelmann, A.1, Roebers, C.2

*University of Bern*

Introduction Executive functions (EF) are understood as an individual's ability to initiate, adapt, regulate, monitor and control information processes. They are very important in everyday life and they are predictive for academic and professional achievement (Blair & Diamond, 2008). Physical activity seems to be one potential factor which can affect EF throughout lifespan, as existing studies indicate short-term as well as long-term effects of physical activity on EF for adolescents, adults and elderly people (Chang et al., 2012). However, empirical findings in children's population are rare. According to Best (2010), cognitively-engaging exercise at a moderate level appears to be the most promising intervention type for enhancing children's EF-performance through physical activity. Therefore, the aim of the present study was to investigate the acute effects of a specifically designed sport lesson on the EF of primary school children. Methods A total of 100 second grade primary school children (M=7.98 years, SD=.39) from 9 classes participated in the study. The intervention group (n=50) underwent a specifically designed intervention (20 min) integrating cardiovascular-stimulating tasks with executive demands. Meanwhile, the control group (n=50) listened to a storybook. Before and after the intervention, respectively control condition, an n-back task to measure updating and Flanker task to measure inhibition and cognitive flexibility was used. In order to determine the effects of the intervention on children's EF, methods for the analysis of variance (with repeated measures) were used, as usual in experimental designs. Results The significant interaction between time and group ( $F(1,98) = 5.56, p = .01, \eta^2 = .05$ ) indicates that the investigated physical education intervention had a positive effect on the inhibition of primary school children. In working memory and cognitive flexibility, however, no effects could be found. Discussion Overall, results support the assumption that physical activity in the school setting can positively affect cognitive performance in children. Specifically, an intervention in PE, integrating cardiovascular and executive demanding tasks, seems to be suitable to enhance inhibition. Whether the improvement in inhibition is caused by the physical activity, the cognitive load of the intervention or the combination of the two components needs to be examined in further studies. **THE HORSE AS AN "ENABLER" IN HORSEBACK RIDING – THE HISTORY OF THERAPEUTIC HORSEMANSHIP**

Hedenborg, S.

*Malmö University*

The purpose of this paper is to explore and analyse the history of therapeutic horsemanship in Sweden. Sports used as therapy have a long history. This paper will focus on therapeutic horse riding since WW2 up until today. Therapeutic riding started in Sweden in the late 1950's, influenced by the Olympic rider Liz Hartel (Hedenborg 2009). Today therapeutic riding is the largest sport for disabled. The number of horse has grown significantly in recent years (Hedenborg 2011). The growth can be connected to the fact that horses are important in new ways related to the unique partnership forged between horses and humans. In this paper exploring questions like when were the organisation for therapeutic riding established; how many people have been and are members of the organisations, who - sex, age and social class - is a member; and what kind of activities are offered in the organisations will be posed and the results will be analysed from a gender perspective as well as a perspective in relation to disability research and the post human turn.

**08:30 - 10:00****Oral presentations****OP-SH13 Sport Management [SM] 1****THE TRANSFORMATION OF CHINA'S NATIONAL FITNESS POLICY: FROM A MAJOR SPORTS COUNTRY TO A WORLD SPORTS POWER?**

Tan, T.C.

*National Taiwan Normal University*

Introduction The paper locates the transformation of the PRC's 'national fitness policy' after an official speech addressed by the president of the PRC, Hu Jintao who, for the first time, mentioned about getting "from a major sports country to a world sports power" after 2008 Beijing Olympic Games. Thus, in this study, we try to combine the five policy indicators (including organization, statutes, budget, personnel, and media) developed by Hogwood and Peters (1983), as well as Zhuang (2003) to assess the extent of China's national fitness policy change. Besides, through elite theory, we explore the motivation and driving force behind the governing elites taking part in the national fitness policy making process. Methods Data were collected from a number of sources including official government documents, news media, and a series of 23 interviews from China's sport administrative system including General Administration of Sport (GAS), three national sport associations and 7 Chinese sports academics from inside and outside China in 2011 and 2012. Results As regards the extent of China's national fitness policy change, it has been reflected in 1) establishing new department in GAS, 2) promulgating "Regulations on National Fitness" by the State Council, 3) increasing funding from national and local level, 4) raising the seniority of leaders in charge of national fitness policy, and 5) increasing interest in the media, especially from the media owned by GAS. There are two driving forces to push sport for all further up the agenda, which are external and internal forces. As for the external one, China was feeling the pressure to look for models in those successful Olympic countries which have relevantly high-levels of sport participation. Regarding the internal one, the national fitness policy is part of the economic motives about stimulating domestic consumption and reducing national medical cost. Discussion To a large extent, Chinese governing elites seemed to be a rebalancing of the policy after Beijing Games in 2008, not necessary a rejection of the elite sport, but a great priority given to sport for all. The evidences of the scale of change could be illustrated by the five dimensions mentioned above and the changing the law being the most obvious one. From this research, it seems

like those Chinese governing elites were pushing by both external and internal forces to fulfill their new collective goal, "from a major sports country to a world sports power", by transforming China's National Fitness Policy. ### EVALUATING THE DEVELOPMENT OF ELITE SPORTS POLICY IN TAIWAN

Chen, S., Bairner, A.

*LOUGHBOROUGH UNIVERSITY, SPORT, EXERCISE AND HEALTH SCIENCES*

**Introduction** Over the last few decades, the value of international sporting success has attracted the attention of many national governments. This has led to an increasing interest in countries such as Australia, Canada, China, Japan and the UK in the development of elite sport systems. It is recognized by some academics that the elite sports systems of sporting superpowers converge towards similar models but with local variations. Thus, it is interesting to evaluate whether the elite sports systems of countries such as Taiwan which are less successful in international sporting events share similarities in terms of sport policy formulation. **Objectives** The main aim of the current study is to explain and evaluate elite sport policies over time in three sports (baseball, taekwondo and tennis) through the application of the Advocacy Coalition Framework (ACF). **Research Methods** The study adopts a qualitative case-study approach based on documentary analysis and semi-structured interviews. The selection of semi-structured interviewees has involved purposive and snowball sampling and is based on the ACF which refers to potential policy actors within the policy sub-system from five different domains. In total, 26 interviews were conducted. The data were transcribed and thematic coding method adopted. **Results & Discussion** The initial research results are as follows: First, successive Taiwan governments have been aware of the value of international sporting success and in particular potential political benefits. Although the government had strongly intervened in the development of elite sports since the 1950s, this became more obvious after the establishment of the Sports Affairs Council (SAC). However, it does not invest sufficient amounts of money in development. Second, the development of sports policy conforms to the institutional features of a welfare regime. Third, important influences and constraints affect the actors within the sports policy subsystem. Fourth, the relationships between the SAC and the NGBs are top-down as the former provides funding to the latter. Fifth, the study reveals that the elite sports systems of the three selected sports are converging towards a model similar to that which operates in other countries, including the development of elite level facilities, identification of sports talent, the provision of competition opportunities for elite athletes both domestically and internationally, the provision of coaching and sports science support, the emergence of full-time athletes, and support for elite athletes' post-career. However, there are local variations. **References** Esping-Andersen, G. (1990). *The Three Worlds of Welfare Capitalism*. Cambridge: Polity Press. Green, M. and Houlihan, B. ### SPORT POLICY FACTORS LEADING TO SPANISH INTERNATIONAL SPORTING SUCCESS. ATHLETES' AND MANAGERS' PERCEPTION

Inglés, E., Marín, A., Vilanova, A.

*INEFC*

**Introduction** This study is part of an international project that aims to compare sports policies from different countries to determine their factors leading to international sporting success. 14 countries are involved. The analysis is based on the theoretical model of De Bosscher et al. (2006) that classifies its influential factors in 9 pillars. Our aim is to show the comparison between the perception of top-level athletes and sports federations managers in Spain (Vilanova, 2011) in relation to the following factors: financial support (P1), sports policy organization and structure (P2), talent identification and development system (P4), athlete support (P5), national and international competitions (P8). **Methods** The method used were standardized surveys to athletes and managers. The sample of athletes was determined based on the National Sports Council (CSD) database (universe=528). By means of systematic probabilistic sampling and using the calculation for finite population (<100,000) our sample consisted of 166 athletes (confidence level 95%, p=q=0.5, max. error 6.5%). Furthermore, a different survey was submitted to 28 managers. **Results** P1. Investment in sports from the government (CSD) is 0.04% of the total national budget. 60.1% of athletes consider that the amount they receive is enough to live and 23.5% consider that it is insufficient. Federations assign 66.6% of its budget to top-level sport. P2. The organization of sports policy in Spain is complex because of its multilevel structure, and the information comes to the athletes by the federations (30.2% of them consider that it is insufficient). P4. Athletes admit to be satisfied with the support received from their clubs (45.1%), while a 26,8% consider the support received from the federations as good. 30.7% of managers consider that their system of talents identification is worse than the one from the leading countries in their sport. P5. The PROAD (Program for the attention to high-level sportspeople) offers individualized attention to athletes. 22.6% consider that the support they receive is excellent, and 17.6% consider that it is insufficient. P8. Most of the top level athletes consider that the frequency of international sports events hosted in Spain is insufficient (72.3), whilst a 61.54% of managers consider that it is satisfactory. **Discussion** We consider that it is crucial to know athletes' and managers' opinion about the current situation, because they are its direct actors. The combination of the perception of athletes and managers with the analysis of the real situation allowed us to make a precise diagnosis of the sports policy system in Spain. **References** De Bosscher, V., De Knop, P., Van Bottenburg M, Shibli, S. (2006). A conceptual framework for analysing Sports Policy Factors Leading to international sporting success. In *European Sport Management Quarterly*, 6 (2), 185-215. Vilanova, A. (Dir.) (2011). *Memoria Científico-Técnica. Factores de la política deportiva española que conducen al éxito deportivo internacional*. Madrid: Consejo Superior de Deportes.

### PROFILING RECREATIONAL AND SPORTING USERS IN NATIONAL AND NATURAL PARKS AND WILDERNES AREAS IN CATALUNYA - SPAIN

Farias Torbidoni, E., Monserrat-Revillo, S.

*Consultoria Socioambiental Ecogestion - INEFC (GISEAFE)*

**Introduction** Natura 2000 areas play an important role in tourism, sport and recreation in addition to their primary purpose of nature conservation. Researchers haven't paid much attention to study what are the most important factors relating the use of these protected areas by different segments of the population. In this study we analyse the results of a survey made in eight different natural areas in Catalonia, all of them included in Natura 2000 net, in order to gain a better understanding of the use of this natural spaces and especial-

ly their physical or sporting use. Methodology This study was carried out in eight Natura 2000 natural areas, specifically in one National Park, one Natural Park and six Wilderness Areas belonging to Catalunya Fundation – La Pedrera, along 11 years, from 2001 to 2012. The data used in this study is based on a total of 3676 on-site structured interviews distributed proportionally in all natural areas. Results The results obtained revealed that the profile of the visitors were: male (65.5%), with an average age of 43.1 years (54.2% between 32 and 51 years old), had finished university (46.3%), currently lived in Barcelona area (58.4%). More than 80% had high level of knowledge about the protection status of visited area. They were not staying in any accommodation during their trip (47.8%) and were visiting the protected area as their first time (38.7%). They went with friends (31.6%). More than 73% were visiting the natural area for half a day (from 30' to 6 hours) and about the 69% of visitors do some physical activities in the protected areas: recreational hiking - walking more than ½ hour - (16.8%), hiking - walking more than 1 hour - (38.1%), snow activities (5.1%), mountaineering (4.9%), climbing (3.9%) and mountain biking (4%). These figures show an increase of 10% comparing to previous research (Fariás 2005 and 2011) Discussions The analysis of 3676 questionnaires indicates that users of recreational areas in Catalonia have a higher average of education and knowledge of Natura 2000 net than European and Spanish population (Eurosat, 2012). Natural areas users were typically enthusiastic about some particular outdoor activities or sporting recreation, like hiking and mountaineering. According to previous studies carried the results obtained in this study can be used to promote physical or sporting activities in protected areas, improving the experience of the visitors and also optimising resources in the Park. ### ASKING QUESTIONS ABOUT ATHLETE WELFARE: PIUTTING THE PERSON BACK TOGETHER

Saunders, J., Pink, M.

*Australian Catholic University*

Introduction The growth of sport science within professional sport in Australia has been characterised by an emphasis on seeking competitive advantage through optimising physiological, technological and to a far lesser extent psychological potential. Such approaches have been largely taken in isolation from each other. The overall outcome has been to view the athlete as a quantifiable commodity. However from an ethical perspective an increasing number of people have shown concern for the value of considering the athlete as a person within a longer term perspective. The study reported here is part of an ongoing initiative sponsored by the AFL research board aimed at increasing understanding of the value in supporting and encouraging the continuing personal development of players away from the competition field. Methods This case study of an individual club involved over two weeks of immersion in the club environment. Data compiled included observations, interviews and document analysis Findings A conceptual framework was developed drawing on Schein's model for organisational culture to provide a basis for understanding players' non-football engagements and their relationship to their football performance. Seven dimensions of the club environment were identified as influencing non-football engagements. Six types of engagement were reported and five criteria which contributed to the quality of those engagements as perceived by the players Discussion Findings about the relationship of players' off-field engagements with respect to their performances as footballers can only be interpreted in the context of the individual and the characteristics of the setting provided by his club. This case study involved a club that provided institutional support for players' lives off the field through a player development department. At least two of the dimensions of the club environment were directly related to this formal level of support provided. The importance of personal relationships with respected staff of the club is just one element that will be evaluated further in the ongoing enquiry. However, it reinforces the need to consider the experience of the individual within the culture of his own club before meaningful conclusions can start to be drawn about player behaviour. The significance of this larger project and the support it is receiving from sections of the football community can be taken as heartening evidence of increased awareness of the value of seeing the athlete as a whole person. References Pink, M (2013) The relationship between off-field engagement and on-field performance among elite Australian Rules football players. PhD study in progress. ### PROMOTING PARTICIPATION: IS ELITE SPORT A REMEDY OR AN OBSTACLE?

Seguí, J., Inglés, E.

*INEFC-Lleida*

Introduction The relationship between elite sport and sport-for-all is an important and very topical subject. Policy practice and academic literature is full of examples of the role of elite sport on the promotion of sport participation. This assumption is based on the so-called double pyramid theory, in which a trickle-up and trickle-down effect exists between sport-for-all and elite sport (IOC, 2000). The trickle-up effect assumes that the broader the base, the greatest number champions. In the other side, the trickle-down effect assumes that successful elite sport performances stimulate people's participation: "viewing" leads to "doing" (Wan, 2000). The assumption of the reliability of these effects, in many cases, legitimates governments to invest in the elite sport policies (top of the pyramid) or in the sport-for-all policies (base of the pyramid), to make the opposite side of the pyramid improve, respectively. The trickle-down hypothesis has been rarely rigorously tested. So the aim of our study is to verify the existence of the effects of the double pyramid in the case of Spain. Methods The method of our study has been the analysis of content of the existing documentation on: a) the sports licenses of the 66 Spanish sports federations since 1980; and b) the participation and success of the national teams in world championships and Olympic Games during this period. The rigorous empirical study consisted of the comparison of the evolution of those data in each of the analyzed sports and its correlation. Based on this correlation (evolution of sports licenses – top-level sporting success), we are able to verify the existence or non-existence of the trickle-down effect in the Spanish case. Results Results show that there's not a general correlation between the sporting success in world championships or Olympic Games and the growth in the number of sports licenses. We can observe some cases where a great national sporting success has led into a growth in the number of sports licenses of this discipline, but these are only punctual cases and not a general tendency. Discussion As some other previous studies in other countries have shown (Van Bottenburg, 2002), we can confirm that, in some punctual cases, the trickle-down effect exists, but we can not define it as a general tendency in the Spanish sports participation since 1980. Therefore, elite sport can not be considered a "magical" remedy nor an obstacle for sport participation promotion. Consequently, we think that the public investment on elite sport development with the aim of promoting participation is not totally justified. In the Spanish case, "viewing" do not necessary lead to "doing". References IOC (2000). Sport for All/Sport pour Tous, Lausanne: International Olympic Committee. Van Bottenburg, M. (2002). ### OP-PM54 Training and Testing [TT] 8

#### **PREDICTING AND MONITORING CYCLING PERFORMANCE IN TRAINED TO ELITE CYCLISTS; PRACTICAL IMPLICATIONS FOR USING THE LSCT.**

Lamberts, R.P.

*University of Cape Town*

Complaints of painful and powerless legs due to hard training are common in professional cyclists. Although that most of these symptoms can be explained by a high training load, in some cases these symptoms are caused by iliac blood flow restrictions. Being able to predict, monitor and reflect pathologies such as restricted iliac blood flow are important to optimize training adaptation. The main aim of this study was to establish the predictive value of a novel submaximal cycle test (LSCT) for Peak Power Output (PPO), VO<sub>2</sub>max and 40km time trial (40-km TT) performance (n=82, VO<sub>2</sub>max range: 46.5-74.8 ml/min/kg). In addition, actual and predicted cycling performances (LSCT) in a professional cyclist with bilateral iliac blood flow restrictions, before and after surgical intervention, were compared to the dataset of the 82 symptom free cyclists. Good correlation were found between the LSCT and PPO (r=0.96), VO<sub>2</sub>max (r=0.92) and 40km TT time (r=0.96), in the 82 symptom free cyclists. Meaningful differences were found between predicted and actual 40km TT time in the 2 tests before the surgical intervention (2:51 and 2:55 (min:s), respectively), which disappeared after the surgical intervention (0.02 (min:s)). No differences were found between predicted and actual PPO and VO<sub>2</sub>max. This finding suggests that kinking of the iliac artery is likely to mainly impair endurance capacity and not PPO and VO<sub>2</sub>max. In conclusion, the LSCT can accurately predict cycling performance in trained to well-trained and elite cyclist. Discrepancies between actual and predicted cycling performance shows potential as an early screenings tool for deteting iliac bloodflow restrictions.

#### **SECULAR TRENDS OF PHYSICAL FITNESS IN JUNIOR AUSTRIAN COMPETITIVE SKI RACERS: A COMPARISON BETWEEN 1996-2003 AND 2004-2011 TIME PERIODS**

Raschner, C., Starker, T., Patterson, C., Platzer, H.P., Mueller, L., Hildebrandt, C.

*University Innsbruck*

**Introduction** There is evidence that physical fitness of young people has declined across all age groups during the last decades. Limited scientific information is available concerning secular trends of junior athletes and no research has assessed physical fitness of junior ski racers over time. Therefore the aim of this study was to compare fitness data from adolescent ski racers from 1996 to 2003 (group 1) with those from 2004 to 2011 (group 2). **Methods** Through cooperation with the Skigymnasium Stams all 14-18 year old female (F) and male (M) ski racers underwent anthropometric measurements (body height and weight) and fitness tests (Coopertest, isometric leg extension strength, counter movement jump, drop jump and agility) annually (Raschner et al. 2012). Group 1 included 807 athletes (F=352, M=455), group 2 712 athletes (F=317, M=395). Group differences of 14, 15, 16, 17 and 18 year old ski racers were calculated separately with the Mann-Whitney U-test. Statistical significance was set at p<0.05. **Results** For anthropometric data, significant differences between group 1 and group 2 were found in body weight. F (14-16 years) and M (14, 15 and 17 years) ski racers of group 2 were heavier compared with the age matched athletes of group 1. F and M ski racers of group 2 had significantly lower endurance (F: 15-18 years, M: 14-17 years), isometric leg extension strength (F: 15-18 years, M: 14-18 years) and jump height (F: 15-18 years, M: 14-18 years) compared to athletes of group 1. Reactive strength and agility results were statistically better in group 2 for all age groups except 14 year old M athletes. **Discussion** Strength, power, agility, and aerobic/anaerobic training (with varied emphasis) have been included in age-appropriate training programs of young Austrian ski racers for decades. Due to the constant evolution of ski equipment and environmental factors training focus has changed. For example young slalom ski racers must be more agile and reactive between the gates now, so more time is spent with agility and reactive strength training. High volume endurance training and strength endurance training were emphasized in group 2. In spite of this, the decline of endurance, strength and power performance is in line with results of secular trends of high school pupils. Ski racing demands a multitude of physical abilities but there is still no one single physiological variable that can determine success (Turnbull et al. 2009). **References** Raschner C., Platzer HP., Patterson C., Werner I., Huber R., Hildebrandt C. #### **THROWING PERFORMANCE PRIOR TO OLYMPIC FEMALE WATER POLO COMPETITION**

Freeston, J., Smith, S., Rooney, K., O'Meara, D.

*The University of Sydney*

**INTRODUCTION:** Throwing ability is critical to successful water polo performance, requiring a high degree of speed and accuracy (Vila et al, 2011). Despite its importance, throwing speed and accuracy of elite female water polo players has not yet been described in detail, nor examined under different game-like conditions. Furthermore, changes in throwing performance over time have not been described for any throwing population. Consequently, the aim of this study was to provide a detailed description of shooting performance in elite female water polo players under a range of different shooting conditions, on multiple occasions in the lead up to Olympic competition. **METHOD:** Ten Olympic female water polo players were tested eight, six and four months prior to Olympic competition for maximal throwing speed and accuracy towards three different target locations, with and without a goalkeeper present. **RESULTS:** Maximal throwing speed remained consistent (p = 0.41), while Hit Percentage improved (p < 0.001) across the three testing sessions. No overall location effects were observed, such that throwing speed and accuracy were similar across the different target locations however, throwing speed (p < 0.05), hit percentage (p < 0.05) and horizontal accuracy (p < 0.05) were reduced in the presence of a goalkeeper. **DISCUS-**

SION: These athletes consistently demonstrated elite levels of throwing performance in the lead up to Olympic competition, achieving higher maximal throwing speeds than any values previously reported for female water polo players (Elliott & Armour, 1988), with an average error of just 20.7 cm. Despite the elite nature of the playing group however, speed and accuracy were reduced in the presence of a goalkeeper. We attribute this to differences in technique (baulking) and strategy (decision-making in response to GK movements). While maximal speed remained consistent, accuracy (Hit %) improved significantly over time. The mechanism for this is unclear however; we propose that future investigations should explore the effect of training volume on throwing performance. CONCLUSION: Elite female water polo players demonstrated a high degree of throwing speed and accuracy, yet suffered reduced performance with a goalkeeper present. We recommend that water polo testing and training should simulate game-like conditions where possible, in order to minimise this negative goalkeeper effect. Elliott, B. C., & Armour, J. (1988). ### THE OFFENSIVE AND DEFENSIVE DEMANDS OF COMPETITIVE AMATEUR BOXING: A COMPARISON OF ELITE AND NON-ELITE PERFORMANCES

Thomson, E., Lamb, K., Nicholas, C.

*University of Chester*

**Introduction** Whilst performance analysis has been applied to several combat sports, little attention has been paid to amateur boxing. The limited research to-date has considered performance (in terms of offensive and defensive actions) with respect to contest outcome (win/lose) only (El-Ashker, 2011; Davies et al., 2012), failing to address differences that may exist owing to other factors, such as ability level and contest duration. Thus, the purpose of the study was to elucidate the offensive and defensive demands of competitive amateur boxing with respect to boxer ability and contest duration. **Methods** With ethical approval, 42 boxing contests (3 x 3 minute Elite (E) contests: n = 17; 3 x 2 minute Non-elite (NE) contests: n = 25) across 11 weight categories (48 – 91+ kg) were recorded and analysed for 47 offensive and 53 defensive performance indicators using Dartfish TeamPro (Version 4.0, Switzerland). **Results** Analysis revealed that the absolute offensive demand was higher in the E than the NE contests (mean  $\pm$  95% Confidence Limits: Punches performed: E: 218  $\pm$  30 vs. NE: 166  $\pm$  14; standardised ES: -0.47; Duration attacking: E: 98  $\pm$  13s vs. NE: 73  $\pm$  6s; standardised ES: -0.48) across each round of boxing. However, expressed relative to the contest duration, most differences in offensive performance were reduced or rendered unclear (Punches performed (per min): E: 25  $\pm$  3 vs. NE: 26  $\pm$  2; standardised ES: 0.27; Duration attacking (per min): E: 11  $\pm$  1s vs. NE: 12  $\pm$  1s; standardised ES: 0.24). Similarly, E contests were characterised by a higher absolute defensive demand (Defences performed: E: 88  $\pm$  10 vs. NE: 64  $\pm$  6; standardised ES: -0.6) in each round. However, differences in defensive performance were rendered unclear when expressed relative to the contest duration (Defences performed (per min): E: 10  $\pm$  1 vs. NE: 10  $\pm$  1; standardised ES: 0.09). Differences in technical performance (% of offensive/defensive actions deemed successful/unsuccessful) were also declared unclear (standardised ES: -0.19 to 0.37). **Discussion** The findings highlight a higher absolute offensive and defensive demand in Elite compared to Non-elite boxing contests, indicating the need for enhanced levels of conditioning. However, the demands of each minute of competition and technical performance were analogous, implying it is the ability to maintain comparable efforts for longer (9 min vs. 6 min) that distinguishes Elite from Non-elite contests. Coaches and boxers should adopt tailored training regimes cognisant of this ability disparity in contest demands. **References** Davies, P., Wittekind, A. Beneke, R. ### CROSS-COUNTRY SKIING: SPECIFIC STRENGTH TRAINING FOR ENDURANCE SUCCESS

Shishkina, A., Tarbeeva, N.

*Urals Federal University*

**Introduction** Strength training in elite sports has to provide a hypertrophy of muscles providing competitive activity (principle of specificity) and biomechanical sportive technique compliance and be aimed on necessary type of strength abilities. **Methods** For specificity: the determination of skiing sports technique important elements allowed to define leading muscles groups and to pick up strength exercises for their enhancement. For biomechanical proximity: the order of performance of strength exercises corresponded to sequence of inclusion of muscles in work (1), angular and dynamic characteristics agree with those in skiing classical and/or skating styles. For the proper orientation of x-country skiers strength training: for increasing of actually strength abilities (a hypertrophy of slow muscular fibers) low intensive strength training (2) with the principle of the isolated training (one group of muscles –in one training day) was chosen. Thus, 4 independent strength complexes of 4 basic exercises in each for skiers-racers were formed: for muscles of arms, for a press and a back, 1 for legs in classical style and 1- for legs in skating style. The strength training session for E-group (10 males and 5 females highly skilled skiers aged 17-23) was distributed as 1-1-3-4-4 series per week with 3 sets in each. 3 different complexes (arms, press+back, legs) were fulfilled once a week. Rest period between complexes was 5-7 days, between series was 10 min, between sets 30 s. Members of C-group (10 males and 5 females) were trained three times a week according to the classical scheme of strength training. Before and after 5 weeks strength session strength and physical workability were tested by step increasing speed roller skiing with Garmin Forerunner 305 monitoring. **Results** The analysis of results of ski roller testing of E-group allowed to define decreasing of heart rate at low speed roller skiing (V=8 km/h), increasing of physical working capacity (speed at HR=170 beats per min) and the maximum speed of skiing while the results of C-group were opposite. It proves effectiveness of strength complexes both for strength and for endurance. Moreover, the research of athletes hemodynamic changes after low intensive strength session revealed a considerable growth of cardiac output (from 95,8 $\pm$ 14,7 to 135 $\pm$ 17,8 ml), increasing of minute blood volume from 5,7 $\pm$ 0,34 to 7,4 $\pm$  0 ,74 l and final diastolic volume from 174,1 $\pm$ 8.9 to 226.3 $\pm$ 15,4 ml. All above mentioned hemodynamic changes were caused by specifics of low intensive strength training and connected with endurance. **References** 1. Godic M (1980). ### CHANGES IN PRO/ANTIOXIDANT BALANCE IN PROFESSIONAL MALE PLAYERS THROUGHOUT A SOCCER SEASON

Le Moal, E., Groussard, G., Chaory, K., Plantet, K., Pincemail, J., Zouhal, H.

*Movement Sport Sciences and Health Laboratory (M2S)*

**Introduction** Physical exercise is associated to an increase of reactive oxygen species (ROS) production by skeletal muscle. Exercise-induced ROS production presents beneficial effects by up-regulating antioxidant enzyme activity. However, intense training can be asso-

ciated to oxidative stress occurring when ROS production exceeds antioxidants defenses (Machefer et al 2007). There are few data concerning the longitudinal follow-up of pro/antioxidant balance in highly trained soccer players and, to our knowledge, no one have been associated to training period. The aim of this study was to analyze changes in pro/antioxidant balance related to training period in professional soccer players. Methods Eight professional soccer players (18.3±0.6 years, 179.4±6.2cm, 73.0±6.2kg) participated in this study. They performed six training sessions and one game a week. Five blood samples were collected throughout the season: in July (T1), September (T2), December (T3), January (T4) and May (T5). These time-points allowed us to frame crucial periods of training during the season: the preseason training (T1-T2), the championship period (T2-T3 and T4-T5), and winter break (T3-T4). Several markers of the pro/antioxidant balance (Vitamin E, Beta-carotene; activity of glutathione peroxidase (GPx), superoxide dismutase (SOD) and GSH/GSSG ratio) have been measured. Dietary intakes were also assessed. Results GSH/GSSG ratio was increase significantly in T4 compared to other time-points suggesting that winter break allows restoring GSH/GSSG after an intense period of competition ( $p<0.05$ ). The activity of GPx showed a significant down-regulation toward the end of the season (T5) compared to other time-points ( $p<0.05$ ). In contrast, SOD activity presented a large increase after winter break and toward the end of the season (T4 and T5) compared to other time-points ( $p<0.05$ ). Furthermore, there were no changes concerning vitamin E and dietary intakes throughout the season. Discussion These results show changes in pro/antioxidant balance throughout a season. These changes can be related to training periods. No changes were observed according to preseason training period consisting in large volume of aerobic moderate to high intensity running. A large increase in GSH/GSSG ratio observed in T4 suggests that winter break is important in order to encompass deleterious effects associated to intense training. Surprisingly, antioxidant enzymes activities present a different pattern during the second part of the season (T4 & T5). To conclude, training periods (preseason vs. championship) induce changes of pro/antioxidant balance throughout a season in male professional soccer players. ##### THE IMPACT OF MAINTAINED AND INCREASED PLASMA VOLUME ON CARDIAC FUNCTION FOLLOWING PROLONGED EXERCISE

Stöhr, E.J.1,2, Low, D.A.2,3, Eldridge, L.2, Nicholas, G.1, Newcombe, D.1,4, Stembridge, M.1, Bassett, K.1, Nio, A.Q.X.1, Shave, R.1,2

1: Cardiff Metropolitan University; 2: Brunel University; 3: Imperial College London; 4: Oxford Brookes University

Introduction Acute reductions in cardiac function, including left ventricular (LV) twist and strain ('LV mechanics'), have been reported following prolonged exercise. However, previous findings may have been influenced by dehydration and a consequential reduction in plasma volume impacting upon preload of the heart. To date, a controlled laboratory study examining the influence of altered plasma volume during prolonged exercise on post-exercise cardiac function is missing. The aim of this study was to manipulate fluid intake during prolonged exercise, to either maintain or increase plasma volume, and thus examine the effects of hydration status upon post-exercise cardiac function. Methods Eight healthy male cyclists (age 31±4 years) completed two 6-hour cycling challenges at 20% below lactate threshold (power output= 169±26 Watts). During one cycling challenge, dehydration was prevented by regular ingestion of 500 ml / hour of a carbohydrate-electrolyte fluid (EUHY), during the other cycling challenge hydration status was matched to maintain body mass (measured hourly), a method which is known to acutely increase plasma volume (EXPANS). Venous blood samples were taken before and during exercise to monitor changes in plasma volume. Before, immediately after and 24 h post-exercise a comprehensive cardiac ultrasound examination was performed for assessment of LV volumes, diastolic function and LV mechanics (i.e. strain and twist). Data were analysed with two-way repeated measures ANOVA. Statistical significance was accepted at  $p<0.05$ . Results Plasma volume was maintained during EUHY cycling and increased during EXPANS cycling (Main hydration effect:  $p=0.006$ ). Similar to previous reports, cardiac filling decreased as evidenced by reduced end-diastolic volume and early filling velocity ( $p<0.0001$ ). This was accompanied by a significant reduction in SV ( $p=0.0009$ ). Circumferential strain at the base was mildly reduced following 6h cycling but all other strain and twist indices were maintained following prolonged EUHY exercise ( $p>0.05$ ). All post-exercise changes in LV function returned to baseline 24 h later. There were no differences in any cardiac parameters between EUHY and EXPANS ( $p>0.05$ ). Conclusions Following prolonged exercise with maintained plasma volume LV twist and strain are maintained, suggesting that reduced filling and stroke volume may be caused by peripheral factors. Plasma volume expansion through enhanced fluid ingestion during prolonged exercise does not appear to further alter post-exercise cardiac function.

##### COMPARISON OF CARDIOVASCULAR STRUCTURE AND FUNCTION IN ATHLETES WITH AND WITHOUT MYOCARDIAL INFARCTION

Maessen, M., Eijsvogels, T., Dijk, A., Hansen, R., Korte, C., Thijssen, D., Hopman, M.

Radboud University Nijmegen Medical Centre

Background Although regular exercise training protects against future cardiovascular events, occurrence of myocardial infarction (MI) has been reported in apparently healthy, life-long athletes. Possibly, differences in cardiovascular structure and function may contribute to the development of MI. The aim of this study was, therefore, to compare cardiovascular structure and function between post-MI life-long male athletes and their healthy peers. We hypothesize that post-MI athletes have a lower cardiovascular structure and function compared to a healthy control group. Methods A cross-sectional design was used to compare cardiovascular characteristics between post-MI ( $n=11$ , 61±4 years) and healthy controls (C) ( $n=12$ , 64±8 years). All subjects were life-long athletes (>20 years >6 h/week moderate-to-high intensity endurance exercise). A maximal cycling test was performed to determine physical fitness level. Echocardiography measurements included the assessment of ejection fraction (EF), cardiac output (CO), left ventricular end-diastolic (LVEDM), and end-systolic mass (LVESM). Radial and circumferential strain of the carotid and superficial femoral artery were assessed using multiple beam steered angles. Strain was quantified using 2D cross-correlation based coarse-to-fine estimation strategy. Results We found no differences be-

tween post-MI and C in peak oxygen consumption (MI  $40.4 \pm 6.2$  vs. C  $43.2 \pm 10$  mL/min/kg), workload (MI  $260 \pm 35$  vs. C  $288 \pm 54$  Watt), heart rate (MI  $167 \pm 12$  vs. C  $161 \pm 15$  bpm), and exercise history (all  $p > 0.05$ ). Echocardiography revealed no difference between post-MI and C for EF (MI  $59 \pm 7$  vs. C  $60 \pm 6\%$ ), CO (MI  $3.7 \pm 0.7$  vs. C  $3.4 \pm 1.0$  L/min), LVEDM (MI  $158 \pm 20$  vs. C  $161 \pm 30$  gr), and LVESM (MI  $160 \pm 22$  vs. C  $159 \pm 25$  gr) (all  $p > 0.05$ ). Post-MI showed significantly lower radial strain of the carotid (MI  $12.0 \pm 6.7\%$  vs. C  $22.0 \pm 11.9\%$ ) and femoral artery (MI  $11.7 \pm 4.9\%$  vs. C  $18.0 \pm 11.5\%$ ) compared to C ( $p = 0.005$ ). Circumferential strain in the carotid artery (MI  $-22.3 \pm 8.2\%$  vs. C  $-31.7 \pm 12.2\%$ ) and femoral artery (MI  $-19.5 \pm 8.3\%$  vs. C  $-28.8 \pm 13.2\%$ ) was significantly decreased in the post-MI group compared to C ( $p = 0.006$ ). Conclusion Whilst both groups demonstrate similar fitness levels and cardiac structure and function, post-MI life-long athletes demonstrate an impaired conduit artery function in both carotid and femoral artery compared to their healthy peers. Although speculative, these differences between both groups may have influenced the development of atherosclerosis and cardiovascular diseases.

### HEART RATE COMPLEXITY CHANGES DURING BICYCLE ERGOMETRY

Berskiene, K.1, Navickas, Z.2, Vainoras, A.3

*Lithuanian University of Health Sciences*

Introduction Over the past decade, the non-linear dynamics methods based on deterministic chaos and the complex system theories to analyse the complex physiological systems have been introduced. The traditional methods based on self-regulation and statistics appear to be insufficient for the analysis of non-linear and non-stationary signals generated by the living organism. The main feature of the physiological systems – their complexity is ‘hidden’ in the biomedical signals. Human body adaptation to physical load is an actual task of sports and clinical medicine. During bicycle ergometry work we can evaluate the functionality of the human body. The main task was to find the complexity measure for ECG RR interval, which could integrally evaluate body reaction to physical load. Methods There were used the standard stress test method of provocative incremental bicycle ergometry work. For evaluation of cardiovascular system reactions the ECG analysis system “Kaunas – Load” was used. The investigated contingent consisted of 21 asymptomatic women (20-50 years old), participating in aerobics exercise program. We divided these group according age (20-30 years old group, 11 women, and 31 – 50 years old group, 10 women), analyzed load and recovery data separate. We used RR intervals (ms) during every cardio-cycle, divided data to the same size intervals and calculated averages and variances. We hypothesized that the algebraic form of the dependence variance (average) is the power function. All our data satisfied this hypothesis ( $p < 0.05$ ). The relation between averages and variances is called allometric. The slope of logarithmic dependence we called the allometric complexity measure. According to Bruce J. West, we hypothesized, that if the absolute value of the slope is less than 1, the complexity of the process is low and body reaction to load is inadequate, if more than 1 – the complexity is high- the higher value of complexity means better adaptation to physical load. Results For all tested women RR interval allometric complexity absolute value was higher than 1 ( $p < 0.05$ ). We showed that RR interval complexity for young women was significant higher ( $p < 0.05$ ). It means, that young women body adaptation to physical load is better. Comparing the results during load and recovery, complexity measures were higher during recovery for young women ( $p < 0.05$ ), but the values didn’t differ for another group. Discussion We can conclude, that the slope of ECG RR interval allometric relation could be the complexity measure, which defines all body adaptation to physical load. This generalized complexity measure is suitable for long signal (algorithm needs no less than 100 points). It was estimated, that RR interval complexity measure was higher ( $p < 0.05$ ) of healthy and better physical state persons. References Bruce, J. W. Where Medicine Went Wrong. Rediscovering the Path to Complexity. Studies of Nonlinear Phenomena in Life Science. World Scientific, 2006. 335 p.

### SIGNIFICANT IMPROVEMENT IN HEMODYNAMIC RESPONSES TO METABOREFLEX ACTIVATION AFTER ONE YEAR TRAINING IN SPINAL CORD-INJURED HUMANS

Crisafulli, A.1, Milia, R.1, Roberto, S.1, Marongiu, S.1, Olla, S.1, Sanna, I.1, Angius, L.1, Bassareo, P.2, Pinna, M.1, Tocco, F.1, Concu, A.1

*university of Cagliari*

Introduction Spinal cord injured (SCI) individuals show an altered control over the circulation during the muscle metaboreflex (Crisafulli A. et al. 2009). This altered control is due to the absent peripheral vasoconstriction below the level of the spinal lesion, which reduces the capacity to vasoconstrict the arterial and the venous vessels and impair cardiac pre-load and after-load. Exercise training was found to enhance circulating catecholamines in response to exercise in SCI subjects (Bloomfield SA et al. 1994). Therefore, training would result in an enhanced capacity to vasoconstrict the circulation. This study aimed at testing the hypothesis that one year training improved the hemodynamic response to the metaboreflex in SCI patients. Methods Nine SCI patients took part in this study. They underwent a metaboreflex activation test at the beginning of the study (T0) and after one year training consisting in three to five hours/week of arm-cranking at 60% of maximum (T1). Hemodynamics were assessed by impedance cardiography and echocardiography at both T0 and T1. Results Results show that there was an increment in cardiac output gain due to metaboreflex activity at T1 as compared to T0 ( $545.4 \pm 683.9$  ml•min<sup>-1</sup> vs.  $220.5 \pm 745.4$  ml•min<sup>-1</sup>). Moreover, ventricular filling rate gain was higher at T1 ( $51.7 \pm 50.1$  ml•s<sup>-1</sup>) than at T0 ( $15.1 \pm 35.3$  ml•s<sup>-1</sup>). Similarly, end diastolic volume gain were increased after training ( $7.2 \pm 22.2$  ml at T0 and  $25.7 \pm 19.3$  ml T1 respectively). Discussion Data from the present investigation provides evidence that in SCI subjects a period of training, together with an increased physical capacity, can also successfully improve the hemodynamic response to the muscle metaboreflex activation. In fact, after the training period there was a higher cardiac output during the metaboreflex with respect to baseline. This result was likely the consequence of an ameliorated ventricular filling rate and end-diastolic volume, which were probably due to an improved capacity to vasoconstrict the venous beds, thereby reducing venous pooling and increasing venous return. It remains to be elucidated if this cardiovascular adaptation to training was to be ascribed to an augmented level of circulating catecholamines or it was due an enhanced myogenic response to transmural pressure at venous level or to both phenomena. ### CARDIOPROTECTION AFFORDED BY BETA-BLOCKADE IS MAINTAINED DURING ISOMETRIC MUSCLE CONTRACTIONS

Thomas, D.P.1, Ng, A.V.2, Sissons, M.3, Nagle, F.3, Rockey, S.1, Conviser, J.M.4

*1: U. Wyoming (USA) 2: U. Marquette (USA) 3: U. Wisconsin (USA) 4: JMC Healthcare & Assoc. (USA)*

Introduction Whether or not the cardio-protective effect of beta<sub>1</sub>-, or beta<sub>1,2</sub>-adrenergic blockade on rate-pressure product (RPP), a widely accepted measure of myocardial oxygen consumption (MVO<sub>2</sub>), is retained during static exercise has not been evaluated. Therefore the purpose of this study was to measure the hemodynamic and metabolic responses during isometric contractions involving hand-

grip (HG), single leg-extension (LE) and two-legged dead-lift (DL) under placebo control, beta1(ATEN) and beta1, beta2 (PROP) conditions. Methods Eleven male subjects performed HG, LE, or DL at 30 percent of maximal voluntary isometric contraction (MVC) for 3 min during which time HR, SBP, DBP, RPP, cardiac output (Q), SV (stroke volume) VO<sub>2</sub>, VCO<sub>2</sub>, and TPR were either measured directly or calculated under control, ATEN or PROP conditions. Results While not preventing the pressor response normally seen with isometric exercise, both ATEN, and PROP adrenergic blockade similarly and significantly reduced HR, SBP and their product, RPP during 30% MVC. This cardio-protective effect was more pronounced with the largest muscle mass involvement (DL), and highest HR, SBP and RPP measured. Discussion Most importantly this protection exists under exercising conditions that normally increase oxygen requirements for the heart by some three-fold compared to the resting state. #### IS-PM05 Obesity, diabetes and exercise: new developments \*

##### EFFECTS OF EXERCISE AND DIET ON MUSCLE FAT METABOLISM AND INSULIN ACTION

Horowitz, J.

*University of Michigan*

Insulin resistance is among the most pervasive metabolic complications associated with obesity, and it is linked with the development of chronic diseases, such as type 2 diabetes and cardiovascular disease. Weight loss is known to attenuate and even reverse insulin resistance, and adding an endurance exercise training program to a calorie restricted diet has been proposed to augment the improvements in insulin action. However, differentiating the effects of exercise training from the effects of weight loss can be rather challenging. As such, the precise mechanisms that mediate improvements in insulin sensitivity after a combined weight-loss/exercise training intervention are poorly defined. It is well known that excessive systemic fatty acid availability, a hallmark of obesity, can induce insulin resistance. Within skeletal muscle, accumulation of fatty acid intermediates (e.g., long-chain acyl-CoA [LCACoA], diacylglycerol [DAG], and ceramide) and subsequent activation of pro-inflammatory pathways (e.g., c-jun N terminal kinases [JNK] and nuclear factor- $\kappa$ B [NF- $\kappa$ B]) are thought to be a major contributor to obesity-related insulin resistance. This presentation will focus primarily on the effects of exercise and weight loss on changes in muscle lipid metabolism, the activation of pro-inflammatory pathways, and the subsequent effects on insulin action.

##### EXERCISE TREATMENT OF TYPE 2 DIABETES

Van Loon, L.J.C.

*Maastricht University Medical Centre*

Estimates of global diabetes prevalence indicate that type 2 diabetes has reached epidemic proportions. The latter can only partly be attributed to changing population demographics, as epidemiological data show diabetes incidence to increase particularly in the young and middle-aged. The latter implies that type 2 diabetes related complications will be experienced more frequently at a much earlier age. Postprandial hyperglycemia forms a direct, independent risk factor for the development of type 2 diabetes complications. Continuous glucose monitoring (CGMS) shows that type 2 diabetes patients experience hyperglycemia (blood glucose >10 mmol/L) throughout the greater part of the day. The latter despite the fact that such patients receive standard primary care and use oral, blood glucose lowering medication and/or exogenous insulin therapy. Clearly, additional therapeutic interventions are warranted to lower post-prandial blood glucose excursions. A single bout of moderate-intensity exercise lowers the prevalence of hyperglycemia by more than 40% during the subsequent 24 hour period. In accordance, regular physical exercise is now generally prescribed for the prevention and treatment of type 2 diabetes. However, more detailed information on the preferred type, intensity, duration, and/or frequency of exercise to maximize the benefits of exercise on glycemic control is presently unavailable. This lecture will define some of the characteristics that constitute the most effective and applicable exercise regimen to improve glycemic control in type 2 diabetes. Based on our current work more practical guidelines will be formulated to assist healthcare professionals and their type 2 diabetes patients to implement exercise interventions as an effective and applicable tool in the prevention and treatment of type 2 diabetes.

##### EXERCISE ADAPTATIONS IN MUSCLE LEPTIN SIGNALING.

Guadalupe Grau, A.

*University of Las Palmas de Gran Canaria*

Leptin is a 16 kDa hormone primarily released from adipocytes and the systemic levels increase in direct proportion with increasing adiposity. Leptin has been highlighted as a promising anti-obesity therapeutic target because of its central role in food intake and body weight control. Pleiotropic effects have also been attributed to leptin due to the expression of leptin receptors (OB-Rs) in several peripheral tissues, such as skeletal muscle. In addition to its locomotive function, skeletal muscle accounts for the majority of the basal metabolic rate and is the primary tissue responsible for whole body glucose metabolism. Leptin stimulates fatty acid oxidation, reduces the accumulation of intramuscular fat and increases glucose uptake and energy expenditure in skeletal muscle, but the intracellular mechanisms leading to these effects are not completely understood. Therefore, the aim of this talk will be to address the research on the effects of different life styles (i.e. long term training, obesity, physical inactivity) on the amount of leptin receptors as well as its intracellular pathways in human skeletal muscle. We will focus on mechanisms leading to intramuscular leptin resistance, as well as on acute interventions that induce activation of leptin signaling in human skeletal muscle, like severe acute energy restriction and exercise.

## IS-PM10 Dietary nitrate as an ergogenic aid \*

**MECHANISTIC BASES FOR DIETARY NITRATE AS AN ERGOGENIC AID**

Bailey, S.

*University of Exeter*

Dietary supplementation with inorganic nitrate has been shown to improve exercise tolerance during severe-intensity constant-work-rate exercise and incremental exercise tests, and to improve cycling time trial performance over 4 km, 10 km and 16.1 km. Recent data also demonstrate that dietary nitrate supplementation might be effective at improving intermittent exercise performance. The purpose of this presentation is to discuss the potential mechanistic bases for the improved exercise performance after dietary nitrate supplementation. Ingested inorganic nitrate is transported, via the entero-salivary circulation, to the salivary glands for secretion into the oral cavity. Lingual anaerobes reduce salivary nitrate to nitrite, which is swallowed and can be reduced to nitric oxide and other reactive nitrogen intermediates within the acidic environment of the stomach. However, it is also clear that ingested nitrite increases the circulating nitrite stores. Nitrite can undergo a one-electron reduction to nitric oxide in a reaction that is independent of oxygen and potentiated by acidosis. The increase in nitrite and/or nitric oxide bioavailability after nitrate supplementation is believed to be responsible for eliciting physiological responses conducive to exercise performance enhancement. Initial studies showed that dietary nitrate supplementation might be ergogenic by lowering the oxygen cost of exercise. Further studies have shown that nitrate can improve exercise efficiency by lowering the ATP cost of muscle force production and increasing the mitochondrial P/O ratio. A blunting in muscle phosphocreatine hydrolysis and lower accumulation of intramuscular [inorganic phosphate] and [adenosine diphosphate], and extracellular [potassium], might also contribute towards the improved exercise performance after nitrate treatment. Recent animal experiments have suggested that nitrate supplementation might preferentially enhance physiological responses in type II muscle fibres; specifically, contractile force, rate of force development and calcium release were improved only in type II muscle fibres in mice supplemented with nitrate, while nitrate supplementation was shown to increase muscle blood flow with a greater blood flow distribution to type II muscle fibres in rats. Therefore, while the mechanistic bases for the ergogenic effects of nitrate supplementation have not been completely resolved, it appears that the step-wise reduction of nitrate to nitrite and then nitric oxide augments a number of physiological responses that converge to enhance exercise performance. Indeed, improvements in excitation-contraction coupling, muscle perfusion and the efficiency of oxidative metabolism, and a blunting in muscle metabolic perturbation, are likely candidate mechanisms for the enhanced exercise performance after nitrate treatment.

**APPLICATION OF DIETARY NITRATE AS AN ERGOGENIC AID IN ATHLETES**

Cermak, N.

*Maastricht University Medical Centre+*

Chronic supplementation (3-15 d) of dietary nitrate, using nitrate-rich beetroot juice (6-8 mmol NO<sub>3</sub><sup>-</sup> per dose) has been demonstrated to reduce pulmonary oxygen uptake during submaximal exercise, reduce the metabolic cost of force production and improve exercise tolerance during more intense work rates. As such, these works proposed that dietary nitrate may contain ergogenic properties, prompting the direct investigation of the effect of dietary nitrate supplementation on exercise performance. Six days of supplementation with dietary nitrate-rich beetroot juice (8 mmol NO<sub>3</sub><sup>-</sup>·d<sup>-1</sup>) significantly improved 10 km time trial performance in trained cyclists, and acute supplementation (6.2 mmol NO<sub>3</sub><sup>-</sup> 2.5 h prior to exercise) significantly improved 4 and 16.1 km cycling time trials. These findings suggest that dietary nitrate ingestion can be applied as a potent ergogenic aid. However, in follow-up studies, no improvements in longer (1 h and 50 mile) time trial performances were observed after acute supplementation (6.2-8.1 mmol NO<sub>3</sub><sup>-</sup> 2.5 h prior to exercise). Consequently, the ergogenic properties of nitrate supplementation may be dependent on the duration and/or intensity of the exercise, the supplementation period and/or the elevation in plasma nitrite. Recently, dietary nitrate supplementation (28.7 mmol NO<sub>3</sub><sup>-</sup> consumed intermittently over ~30 h prior to exercise) significantly improved intermittent-type running exercise, supporting the suggestion that some ergogenic effects may be intensity driven. Moreover, data from rodents indicate that dietary nitrate supplementation improves vascular control and elevates skeletal muscle oxygen delivery during exercise in predominantly type II muscles. In this presentation, the evidence for nitrate supplementation as an ergogenic aid will be discussed and practical questions that need to be addressed in future research will be defined.

**APPLICATION OF DIETARY NITRATE AS AN ERGOGENIC AID IN CLINICAL POPULATIONS**

Allen, J.D.

*Duke University*

Athletes use ergogenic aids to enhance an already elevated performance level and gain a competitive advantage. In clinical populations performance enhancement is usually an attempt to minimize a deficit and hopefully address an acute or chronic maladaptation. This talk will mainly focus on the role of dietary nitrate in the vaso-occlusive condition of peripheral artery disease (PAD). PAD is a form of cardiovascular disease caused by atherosclerosis which leads to arterial obstruction and decreased blood flow to the lower extremities. The most frequent clinical symptomatic manifestation of PAD is intermittent claudication defined as, pain in 1 or both legs during exercise that is relieved with rest. This inability to match oxygen delivery to tissue demands during physical activity severely debilitates subjects with PAD such that approximately 1/3rd have pain ambulating in their home. These patients suffer a markedly impaired quality of life and a high perception of disability. Although measures of conduit vessel and gross limb blood flow are used to diagnose PAD, they show a poor relationship with functional capacity. It appears that the key to increasing functionality in IC patients may lie at the resistance arteries, arterioles and capillaries that serve the skeletal muscle tissue distal to the site of stenosis. These are the vessels which are responsible for much of the oxygen delivery and become hypoxic during the increased demands for perfusion accompanying physical exertion. In this talk we discuss the role of endogenous and exogenous nitrate, nitrite, and nitric oxide pathways and their impact to; (a) acutely improve

oxygenation to areas of ischemia and; (b) chronically increase vessel growth to these ischemic areas. This promising therapy may allow for greater exercise tolerance, ease the burden of exercise compliance and facilitate greater improvements in function and quality of life in PAD patients.

#### IS-BN10 Evidence Based Sports Physiotherapy: Core stability in sports – myth or reality

##### FUNCTIONAL ASSESSMENT OF CORE STRENGTH

Zemkova, E.

*Faculty of Physical Education and Sport, Comenius University*

The importance of function of core musculature for stabilization and force generation in many sports activities is being increasingly recognized. Despite of widespread use of core exercises in sport training, their efficiency in improvement of performance is questionable. This may be corroborated by no significant correlations between core stability and functional movement variables indicating no strong predictor of performance. One explanation for moderate to weak correlations may be the use of isometric and isokinetic measures of strength and isometric tests of muscle endurance for the core strength assessment, whereas the performance involves dynamic movement. Therefore, there is a need for new valid tests of core strength that assess multiple aspects of function and correlate well to sport performance. Particularly, transverse and rotational movements are often neglected in the assessment of core musculature in spite of the fact that many sports involve movements in the sagittal, frontal, as well as transverse planes. Additionally, maximal strength is usually evaluated, whereas power represents better characteristic of muscle contraction in dynamic movements. To avoid these drawbacks, one should use functional tests close to sport specific movements for the assessment of strength capabilities and efficiency of core training. Introduction of novel methods for functional assessment of core strength and their application in sport practice will complement the presentation.

##### MYTH OR REALITY - DOES IT MATTER?

Verhagen, E.

*EMGO-Institute/VU University medical center*

Core stability has been a trending topic in sports and sports medical research in recent years. Core stability is currently a generally accepted training principle to increase performance, prevent injury and rehabilitate from various musculoskeletal complaints. Parallels can be drawn with the stretching trend that started few decades ago, another athletic common good surrounded by controversy. When it concerns core stability though, there are a lot of important factors still ill described. Amongst these there is yet no uniform definition of core stability. Let alone, that we agree upon which muscles adjoin to core stability, what the optimal strategy is, or how to even measure the concept core stability. In the absence of consensus the core stability notion remains elusive. Yet, does it matter we are not fully clear on what core stability is? Instead of looking from the top down we may be able to build our ideas bottom up. Are there any clinical benefits when we train the 'core' according to current standards and beliefs? If so, these clinical outcomes may provide valuable clues to solve ruling puzzles around core stability.

##### THE EFFECT OF CORE EXERCISES ON LUMBAR RANGE OF MOVEMENT AND CORE STABILITY

Solana-Tramunt, M., Cabedo, J., Morales, J.

*Ramon Llull university, research group on health, physical activity and sport*

Introduction: Core exercises are often used to improve core strength or related on core stability in many of the general strength programmes in sport. It's accepted that these have to respect the functional characteristics of the technical movement that we would like to improve (Lederman, 2009), but not all core exercises performance the same joints position or movement. Although core exercises pretend to increase core stability by core muscle stiffness it doesn't contribute to other soft tissue stability function, related on its proprioception (Hodges et al., 1997,2003; Lephart and Fu, 2000; Tsao and Hodges, 2008). The purpose of this study was to determine the effect of 3 core exercises in sagittal plane on lumbar range of movement (ROM) in the same plane on professional swimmers. Methods: A sample of 37 professional swimmers, 21 males and 16 females (20.7±3.3 yrs), participated in the study. They were randomly divided in 21 swimmers for the experimental group (EG) and 16 swimmers for the control group (CG). EG fulfilled 3 core exercises, 6 days a week during 11-weeks. All subjects underwent the same type of training in parallel with the experimental group intervention and signed informed consent. The exercises consisted of performing maximum lumbar extension and recover underwater gliding body position, repeated at slow pace of 10 breaths. ROM was measured by an electrogoniometer attached on the skin, its cranial arm over T12-L1 spinous process, line up to L3 level, and lower arm over S1-S3 surface. The evaluation consist of measuring lumbar ROM from maximal flexion to maximal extension degrees, in 3 consecutive trials separated by 20s, sitting over a Swiss ball keeping hips and knees between 80° and 90° of flexion, the back straight, the sight to the front and both hands over the knees on a relaxed position. The test position allowed easy lumbar movements on sagittal plane. It has been measured the mean of each flexion and extension trial and calculated the total ROM from the maximal extension mean to maximum flexion mean degrees. ROM comparisons between pre-test and post-test were made using paired samples t-Test. The results are expressed by the mean, SD and significant differences (p<0.05) before and after the experimental period. Results: Lumbar ROM changed on EG from 34.4±12.9° to 44.7±14.3° (p=0.000) and on CG from 34.7±11.9° to 35.9±12.5° (p=0.22). Conclusions: The results suggest that to repeat maximal lumbar extension movement increase its ROM in sagittal plane, changing the soft tissue stiffness and its proprioceptive sensibility. Accordingly, not all kind of core exercises contribute positively on core stability.

## Oral presentations

### OP-BN08 Biomechanics [BM] 8

#### THE USE OF SPRINGS IN SPORTS FOOTWEAR, THE NEXT BIG THING OR REINVENTING THE WHEEL?

Richards, J., Lindley, S., Sutcliffe, M., Selve, J.

*University of Central Lancashire*

**Introduction** It has been estimated that up to 70% of runners will sustain an overuse injury during any one year period (Caspersen et al, 1984). Repetitive and abnormal loading of the lower limb with high loading rates has been shown to increase the occurrence of overuse injuries, such as tibial stress fractures (Milner et al, 2006). Therefore much emphasis has been placed upon achieving optimum shock absorption through specially designed running shoes. The introduction of springs in footwear is not a new idea, however the recent development of micro-spring technology now allows a higher density spring configuration. This study explored the effectiveness of high density micro-springs in reducing impact forces and vertical loading rates during running. **Methods** Three-dimensional kinematics and kinetics were recorded from 11 healthy recreational heel striker runners during overground running in a Movement Analysis Laboratory. Two versions of a branded running shoe were tested; one pair remained unmodified and the other was modified with 30 high density micro-springs. Test conditions were blinded and randomised. Each subject completed 5 running trials of approximately 20 m under each test condition at a self-selected speed. A paired t-test was conducted to determine the changes in biomechanics between the two conditions. **Results** No significant differences were seen in the peak vertical ground reaction force, the anterior push off force or the contact time. However, the introduction of the high density micro-springs showed a significant reduction in the vertical loading rate of 7.3 body weights per second or 10.4% ( $p=0.02$ ) compared with the unmodified shoe and a significant reduction of 0.048 N/BW or 18% in the peak posterior ground reaction force at impact ( $p=0.012$ ). **Discussion** The similarity in the contact time and the peak vertical loading force indicate similar propulsion performance. However the reduction in the vertical loading rate and posterior ground reaction forces acting with the high density micro-springs may make clinically important differences which could help runners who report overuse running injuries. The balance between the spring stiffness and surrounding damper materials of the sole is worthy of further exploration for different sports and recreational footwear. **References** Caspersen CJ, Powell KE, Koplak JP, Shirley RW, Campbell C, Sikes RK. (1984). #### LUMBAR KINETICS IN THE ELITE ADOLESCENT MALE TENNIS SERVE: A LINK TO LOW BACK PAIN

Reid, M.1,3, Campbell, A.2, O'Sullivan, P.2, Elliott, B.3, Straker, L.2

*1. Tennis Australia, 2. Curtin University, 3. University of Western Australia*

**Introduction** Male tennis players are at significant risk of developing low back pain (LBP) coincident with lower lumbar pathology, with data verifying that 37.5% of the 2012 elite Australian players, who missed training owing to LBP, also had L4 or L5 stress reactions (Tennis Australia, 2012). Anecdotal evidence points to a mechanical aetiology, yet lumbar spine kinematics/kinetics have not previously been explored. This study aimed to quantify and compare lumbar region kinetics in kick and flat serves performed by elite, adolescent male players with and without a history of LBP. Lumbar region kinematics, as well as racquet velocity and the position of the ball at impact, were described to facilitate kinetic data interpretation. **Methods** Twenty Tennis Australia adolescent male players participated; 7 with a history of disabling LBP and confirmed L4/L5 injury, and 13 controls matched for age, height, mass and performance. Racquet, upper limb, trunk and lumbar movement were recorded using a VICON motion analysis system during three 'flat' and three 'kick' serves. A customised mathematical model calculated lumbar region kinetics/kinematics, racquet velocity and ball position at impact and were reported as if all players were right-handed. A series of 2x2 mixed model analyses of variance were utilised to compare between pain/no pain and kick/flat serves. **Results** There was no significant difference in racquet velocity or ball position at impact between pain groups or serve types. Midway through the drive phase of the tennis serve the lumbar region reaches simultaneous peak extension/lateral flexion, whilst absorbing large peak left lateral flexion (2–4\*bodyweight) and compression forces (10\*bodyweight). The players with a history LBP/injury reported significantly greater peak left lateral force than the control group (mean difference: 1.5 N.kg<sup>-1</sup>). **Discussion** The lumbar region undergoes substantial loading during both the kick and flat tennis serves, including lateral flexion forces up to 8 times those experienced during running. Both large lateral flexion forces (Ferdinands et al., 2009) and coupled movements (Glazier, 2010) have each been reported in populations where LBP is similarly pervasive. Given that the pain group reported left lateral flexion forces that were approximately 50% greater than the control group, and these were demonstrated to occur concurrent to peak compression force, extension and right lateral rotation, this may represent an important mechanism for low back pain mechanism in this population. **References** Ferdinands R, Kersting U, Marshal R. *J Biomech.* (2009), 42, 1616–21. Glazier P. *Sports Med.* (2010), 40, 809–815. Tennis Australia. Unpublished Musculoskeletal Injury Reports. (2012).

#### THE USE OF GLOBAL POSITIONING SYSTEM TRACKING DEVICES TO ASSESS MOVEMENT DEMANDS AND IMPACTS IN UNDER-19 RUGBY UNION MATCH PLAY

Opperman, E., Opperman, S., Venter, R.E.

*Stellenbosch University*

**The use of Global Positioning System (GPS) tracking devices to assess movement demands and impacts in under-19 rugby union match play** **Introduction** In order to develop specific conditioning programs and recovery strategies for rugby players, it is essential to have a thorough understanding of the unique demands of different playing positions. This is now possible by tracking players during matches by the use of portable global positioning system (GPS) devices. The aim of the study was to use GPS technology to determine movement patterns, as well as impacts from collisions, in elite under-19 rugby union forward and back players. **Methods** Seventeen under-19 semi-professional male rugby players were studied during five Super League A (SLA) rugby matches. The players were divided into four groups

based on the assumption that they have the same on-field requirements (Duthie et al., 2003). Participants were tracked using GPS devices (SPI Pro; GPSports Systems, Canberra, Australia). Data used included distance, speed and player impacts as measured in "g" force. Data from the first 30 minutes of each half were analyzed. Results Players covered on average  $4469.95 \pm 292.25$  m during the games. Players spent  $72.32 \pm 4.77\%$  of the total game time either standing or walking. Of the total game time, the outside backs spent on average significantly more time walking ( $60.34 \pm 3.92\%$ ) ( $p < 0.05$ ) than the front row forwards ( $42.1 \pm 9.99\%$ ). Back row forwards had the highest total amount of impacts during the games ( $683.4 \pm 295.04$ ). The inside backs experienced the highest amount of severe impacts ( $>10g$ ) ( $12.16 \pm 3.18$ ) per match. Discussion Similar to our study, Cuniffe et al. (2009) reported that players were standing or walking 72% of the total time. Cuniffe et al. (2009) also found that forwards spent less time standing and walking than backs ( $66.5$  vs.  $77.8\%$ , respectively). Props and locks spent more time jogging than the outside backs. This might be as a result of the nature of the game where forwards are continuously moving to get into position (Bompa & Claro, 2009), while the backs are typically walking, standing or waiting for the ball to be delivered from the contest (Duthie et al., 2003). While back row forwards had the highest total amount of impacts during the games, the inside backs experienced the highest amount of severe impacts. To our knowledge, this is the first study to quantify impacts from collisions between players. Results thus emphasized the need for individualized conditioning and recovery programs, based on position-specific movements and impacts. References Duthie, G., Pyne, D. & Hooper, S. (2003). Sports Medicine, 33(13), 973-991. Cuniffe, B., Proctor, W., Baker, J. S. & Davies, B. (2009). J Strength Cond Res, 23(4), 1195-1203.

### ACUTE EFFECTS OF SMALL CHANGES IN SADDLE HEIGHT ON PEDALLING EFFICIENCY AND LOWER LIMB KINEMATICS

Ferrer-Roca, V.1,4, Bescós, R.2, Roig, A.1, Galilea, P.1, Valero, O.3, García-López, J.4

1:GIRSENE, Centre Alt Rendiment (CAR), Barcelona, Spain. 2:INEFC-Barcelona, UB, Barcelona, Spain. 3:Servei d'estadística aplicada, UAB, Barcelona, Spain. 4: FCAFD, IBIOMED, ULE, Leon, Spain.

Introduction Proper bicycle configuration reduces aerodynamic drag, improves cycling efficiency and may prevent overuse injuries (Bini et al. 2011). Saddle height is an important factor in correct bike fitting. The aim of the present study was to assess the acute effects of small changes in bicycle saddle height on pedalling efficiency and lower-limb kinematics. Methods Well-trained cyclists ( $n=14$ ) performed three randomized sets of 6 min with the preferred saddle height, 2% higher and 2% lower at submaximal pedalling intensity ( $\sim 70$ -75% of the  $\dot{V}O_{2max}$ ) and at constant cadence (90 rpm). Physiological parameters were continuously measured breath-by-breath by a computerized gas analyser (Jaeger Oxycon Mobile, Germany). A two dimensional video analysis system (Peak Motus, Version 9.2.0; Vicon Motion System; Centennial, USA) was used for video recording, digitizing, processing and analysing the lower limb kinematics. Results Gross efficiency (GE) was significantly lower when raising the saddle ( $GE = 19.9 \pm 1.5\%$ ) than when lowering it ( $GE = 20.4 \pm 1.3\%$ ). A significant effect of the small changes in saddle height on lower limb kinematics was observed ( $p < 0.05$ ). The differences between lower and higher saddle positions, in hip, knee and ankle joints were an increase of extension ( $\sim 4$ , 7 and  $8^\circ$ , respectively), a decrease of flexion ( $\sim 3$ , 4 and  $4^\circ$ , respectively) and, consequently, an increase of the range of movement ( $\sim 1$ , 3 and  $4^\circ$  respectively). Discussion Findings of the present study may have a certain relevance because it is well known that variation in GE explains  $\sim 30\%$  of the variation in power output during cycling time-trials (Jobson et al; 2012). Previous studies showed differences in cycling efficiency and lower limb kinematics due to greater modifications in saddle height, between 4 to 10% of trochanteric height. Nevertheless, these modifications are too wide to be applied by experienced cyclists. Conclusions The results indicate that small changes in saddle height ( $\sim 1.5$  cm) affected GE and lower limb kinematics. The observed changes in lower limb kinematics could justify, in part, the GE changes. Further research should evaluate long-term effects of these small modifications in the seat height on GE and lower limb kinematics. References Bini R, Hume PA, and Croft JL. Effects of Bicycle Saddle Height on Knee Injury Risk and Cycling Performance. Sports Med 41: 463-476, 2011. Jobson SA, Hopker JG, Korff T, and Passfield L. Gross efficiency and cycling performance: a brief review. J Sci Cycling 1: 3-8, 2012.

### CHANGES IN THE APONEUROSIS WIDTH INDUCED BY RESISTANCE TRAINING: IMPLICATIONS FOR A HYPERTROPHIC MODEL OF PENNATE MUSCLE

Wakahara, T., Ema, R., Miyamoto, N., Kawakami, Y.

Waseda University

Introduction Muscle fibers of a pennate muscle attach to the aponeurosis at a certain angle (pennation angle). The pennation angle has influence on the force transmission from muscle fibers to tendon (Alexander & Vernon 1975). It has been shown that the pennation angle increases after resistance training (Kawakami et al. 1995). The increase in the pennation angle has been considered as a strategy for more contractile materials to be packed for a given attachment area of aponeurosis. On the other hand, the attachment widths and areas of the aponeuroses of hypertrophied muscles are larger than those of normal muscles (Abe et al. 2012). This cross-sectional observation points to a possibility that the attachment area of aponeurosis increases with resistance training, which prompts us to reconsider the hypertrophic model of pennate muscle. The purpose of this study was to examine longitudinally the changes in the aponeurosis width and muscle architectural parameters induced by resistance training. Methods Eleven young men completed a resistance training program of unilateral knee extension for 12 weeks. Before and after the training program, the aponeurosis width and muscle anatomical cross-sectional area (CSA) were measured with magnetic resonance imaging, and the pennation angle and fascicle length were determined with ultrasonography at the belly of the vastus lateralis. By using the relative changes in CSA and the pennation angle before training, a theoretical change in pennation angle by resistance training was calculated on an assumption of constant aponeurosis width, and compared with experimentally determined value. Results and Discussion There were significant increases in the aponeurosis width, CSA and pennation angle after the training, whereas no significant change was found in the fascicle length. The increase in the aponeurosis width supports the previous finding (Abe et al. 2012). The relative change in aponeurosis width ( $1.9 \pm 3.1\%$ ) was significantly smaller than the square root of relative change in CSA ( $5.2 \pm 3.6\%$ ). In addition, the experimentally determined pennation angle after the training ( $19.9 \pm 2.5^\circ$ ) was not significantly different from the corresponding value calculated with the constant aponeurosis width ( $19.9 \pm 2.3^\circ$ ). These results indicate that, although the aponeurosis width is increased by resistance training, it does not substantially affect on the training-induced increase in the pennation angle. ## THE INFLUENCE OF ACUTE VARIABLE RESISTANCE LOADING ON SUBSEQUENT FREE-WEIGHT MAXIMAL SQUAT PERFORMANCE.

Mina, M.A.1, Giakas, G.2, Blazevich, A.J.3, Kay, A.D.4

1: UoD (Derby, UK), 2: UoT (Thessaly, Greece), 3: ECU (Perth, WA), 4: UoN (Northampton, UK)

**Introduction** Elastic bands attached to a loaded barbell during a squat exercise create a variable resistance (VR), thus changing the mechanical loading and stress placed through the musculoskeletal system. Preconditioning the neuromuscular system using near-maximal or maximal voluntary contractions (MVC) can induce a phenomenon known as post-activation potentiation (PAP) to enhance performance to 'supramaximal' levels. However, the potentiating effects of VR on subsequent free-weight resistance (FWR) squat performance have not been examined. Thus, the aim of the present study was to examine the influence of VR exercise using elastic bands on subsequent FWR squat performance. **Methods** Sixteen recreationally active men (age =  $26.0 \pm 7.8$  yr, height =  $1.7 \pm 0.2$  m, mass  $82.6 \pm 12.7$  kg) experienced in squatting (>3yr) volunteered for the study after giving written informed consent; ethical approval was granted from the University of Northampton. Subjects' 1-RM were determined then on two subsequent days either a 3-RM FWR (control) or a 3-RM VR (experimental) squat exercise was performed at 85% 1-RM (35% of the load generated from band tension in the VR condition). Five minutes later, motion analysis recorded knee joint kinematics during a subsequent FWR 1-RM squat, with vastus medialis, vastus lateralis, rectus femoris and semitendinosus electromyograms (EMG) simultaneously recorded. Paired t-tests were used to determine significance, accepted at  $p < 0.05$ . **Results** A significant increase in 1-RM (7.7%;  $p < 0.01$ ) and a decrease in peak and average eccentric (16-19%;  $p < 0.05$ ) and concentric knee velocities (12-21%;  $p < 0.05$ ) was found in the VR condition compared to the FWR condition. No change in knee flexion angle (1.8%;  $p > 0.05$ ) or EMG amplitude (5.9%;  $p > 0.05$ ) occurred. No subjects increased 1-RM in the FWR condition, however 13 of 16 (81%) increased 1-RM by ~10% following VR. **Discussion** Preconditioning the neuromuscular system using VR significantly increased 1-RM without changes in knee extensor muscle activity or knee flexion angle, however eccentric and concentric velocities were reduced. Thus, VR can potentiate the neuromuscular system to enhance subsequent maximal lifting performance. The lack of change in EMG suggests that changes in muscle activity were small or non-existent, which may be explained by force-velocity effects (slower movement = larger forces). Alternatively a greater activation of hip musculature (not measured in the present study) may allow a greater total lower limb force to be developed. Regardless, as 1-RM increased greater lower-limb loading occurred, thus VR potentiated the neuromuscular system and could enhance training stimuli.

#### MENTAL IMAGERY AND MOVEMENT OBSERVATION OF BALANCE TASKS: ACUTE EFFECTS ON BRAIN ACTIVITY AND FUNCTIONAL LONG-TERM ADAPTATIONS

Keller, M.1, Leukel, C.1,2, Mouthon, M.2, Annoni, J.M.2, Taube, W.1

1: SMS (Fribourg, Switzerland), 2: IFS (Freiburg, Germany)

**Introduction** Immobilization is often related to impaired postural control and increased risk of falling (1). Therefore, alternative training regimes are needed as countermeasures during long periods of immobilization when no physical training is possible. Mental imagery and movement observation may constitute such countermeasures. Therefore, the present study evaluated its effects twofold: In Experiment 1, brain activity was assessed by means of fMRI during imagination as well as active and passive observation of different postural tasks. In Experiment 2, long-term behavioral effects on postural control of non-physical balance training were analyzed before and after 4 weeks of training. **Methods** Experiment 1: fMRI data were recorded in 16 healthy subjects ( $27 \pm 4.8$  years). The experiment contained three different parts: a) active observation, b) passive observation, and c) mental imagery. In contrast to passive observation, subjects were instructed to interpret the acting person in the video in a first person perspective during active observation. In each of the three conditions, two tasks were evaluated: i) static standing on solid ground and ii) medio-lateral perturbation on an instable surface. Experiment 2: Balance performance and H-reflexes were measured before and after a training program of 4 weeks. Subjects ( $n=35$ ) were assigned either to a mental (MBT) or an active observational balance training (OBT) group or served as controls. **Results** Experiment 1: Our results indicate that I) motor imagery and active motor observation activate brain regions important for balance control (Putamen, Cerebellum, Supplementary and pre-motor Area), II) subjects displayed higher brain activation in the more challenging (dynamic) postural task, III) passive observation was not able to induce significant activity in brain areas responsible for balance control. Experiment 2: After training, we observed a significant interaction of TIME \* GROUP. Post-hoc tests revealed significant reductions in sway path for both the mental and the observational group. No changes were observed for the H-reflex. **Discussion** Experiment 1 suggests that motor imagery and active but not passive movement observation represent suitable tools to activate brain regions, which are associated with postural control. This assumption was indirectly confirmed in Experiment 2, showing improved postural control after MBT and OBT. As the training was purely non-physical, it seems unlikely that spinal circuitries were activated during training. Therefore, one might suggest that the improved postural control is a result of supraspinal adaptations. **References** (1) Visschedijk J et al (2010). J Am Geriatr Soc 58, 1739-48

#### FACTORS INVOLVED IN THE ADOPTION OF A PREFERRED GAIT AROUND THE WALK-RUN TRANSITION: EFFECTS OF LEARNING RACEWALKING

Heugas, A.M., Majed, L., Siegler, I.A.

Univ Paris-Sud, UR CIAMS, EA4532, Orsay, France

**Introduction** Why do humans shift between walking and running at a preferred transition speed (PTS)? Many theories have been put forward. Among them, the metabolic optimization theory, transition is believed to occur when a critical metabolic level is reached. Hreljac (1995) has pointed out the role of mechanical constraints in transition triggering. Recently, Ziv and Rotstein (2009) showed that racewalkers have a higher PTS than a control group. The aim of this study was to better understand the factors underlying gait transitions

by studying the effect of learning racewalking on PTS and its metabolic aspects. **Methods** Nine participants ( $22.9 \pm 5.2$  years) with a good aerobic fitness performed two tests of PTS determination; before (pre-test) and after (post-test) 7 sessions of a racewalking learning protocol (Majed et al., 2012). A gas analyzer (Cortex Metamax 3B, Germany) was used to determine metabolic cost of transport (MCT expressed in  $\text{mlO}_2 \cdot \text{kg}^{-1} \cdot \text{km}^{-1}$ ). Kinematic data (60 Hz) were recorded (VICON370, Oxford Metrics, UK) to determine stride frequency (Sf) and amplitude of the vertical displacement of the upper body (Dz). **Results** During the post-test, 77.8% participants used racewalking between walking and running therefore delaying the transition to running ( $9.53 \pm 0.61 \text{ km} \cdot \text{h}^{-1}$  vs  $8.04 \pm 0.73 \text{ km} \cdot \text{h}^{-1}$  during pre-test). At these speeds, racewalking shared the same Sf as running, significantly higher than that used in walking. Furthermore, racewalking produced significantly lower Dz compared to both running and walking. However, the walk-racewalk transition resulted in a significant increase in MCT compared to the walk-run transition. **Discussion** At the post-test, racewalking was spontaneously adopted by a majority of participants as an intermediate gait, replacing running at the slowest running velocities (between 7.4 and 8.7  $\text{km} \cdot \text{h}^{-1}$ ). The new learned pattern did not seem to exhibit any advantages on a metabolic level at the tested speeds around transition. However, racewalking seemed more advantageous on a mechanical level, possibly allowing participants to improve mechanical efficiency and/or to stabilize head in space. These two factors could play an important role in triggering the walk-run transition rather than metabolic factors. **References** Hreljac A. (1995). *Hum Mov Sci*, 14, 205-216. Ziv G, Rotstein A. ### EXAMINING THE ASSOCIATION BETWEEN HYPOTHESIS-TESTING AND WORKING MEMORY DURING MOTOR LEARNING

Buszard, T.1, Farrow, D.1, Reid, M.2, Zhu, F.F.3, Masters, R.S.W.3

1: Victoria University, 2: Tennis Australia, 3: University of Hong Kong

**Introduction** Traditional motor learning theories suggest that hypothesis testing is a necessity for learning. However, implicit motor learning theory argues that acquiring motor skills without testing hypotheses is not only possible but leads to performance advantages (Masters & Poolton, 2012). Hypothesis testing uses working memory, the system responsible for storage and manipulation of task-related information in the mind (Baddeley, 2012). We hypothesized that the likelihood of hypothesis testing during skill acquisition would be associated with the amount of working memory capacity available to the learner. Two experiments were conducted to examine the relationship between working memory and hypothesis testing when performing a basic tennis skill task. **Methods** The first experiment investigated hypothesis testing in children (6 – 11 y), whereas the second investigated young adults (17 – 26 y). Both experiments employed the same methodological design. Two measures of hypothesis testing were used: (1) the number of alterations made to technique, and (2) the number of task-related rules or hypotheses reported. Working memory capacity was assessed using the Automated Working Memory Assessment (Alloway, 2007). This measured both verbal and visuospatial components of working memory. **Results & Discussion** Regression analyses indicated that hitting accuracy and verbal working memory capacity were the most significant predictors of hypothesis-testing in both children and adults. People with lower hitting performance and larger verbal working memory capacity tested more hypotheses. The number of alterations to technique and the number of task-related rules reported were significantly correlated with each other; although, young children (6-7 years) had greater difficulty than older children (10-11 years) verbalising the alterations that they made to their technique. **Conclusion** The findings increase our understanding of hypothesis testing in the context of motor learning, and provide support for implicit motor learning approaches that seek to inhibit working memory engagement during practice by limiting the commission of errors (i.e., poor performance). **References** Alloway, T. ### PROMOTING OBJECT CONTROL SKILLS BY SUPPRESSING ERRORS DURING LEARNING INCREASES PHYSICAL ACTIVITY ENGAGEMENT OF CHILDREN WITH DISABILITY

Capio, C.M.1, Poolton, J.M.1, Eguia, K.F.2, Sit, C.H.P.3, Masters, R.S.W.1

1: University of Hong Kong; 2: KU Leuven, Belgium; 3: Chinese University of Hong Kong

**Introduction** Fundamental movement skills (FMS), consisting of locomotor and object control skills, contribute to accrual of sufficient physical activity (PA) in children (Barnett et al., 2008). Developmental disability impairments generate a negative impact of FMS proficiency on PA participation (Wrotniak et al., 2006). This research tested a reduced-errors approach to remediation of object control skills in children with disability, with the aim to promote greater PA engagement. **Methods** In Study 1, a training program that either reduced outcome errors (error-reduced) or allowed errors to freely accumulate (error-strewn) was implemented to train the object control skill of overhand throwing in children with intellectual disability. In Study 2, an error-reduced training program targeted three skills (overhand throwing, catching, kicking) in children with cerebral palsy. A control group of children with cerebral palsy underwent their usual physiotherapy program. Using a pretest-posttest study design, product-oriented measures (e.g., throwing accuracy) and process-oriented assessment (Test of Gross Motor Development-2) evaluated object control proficiency. The impact on PA was inferred from the frequency of overhand throwing in free play (Study 1), and from PA monitoring using an accelerometer (Study 2). **Results** Children with intellectual disability in the error-reduced program improved process-oriented FMS proficiency to a greater extent than the error-strewn program. Error-reduced learners also maintained throwing accuracy when engaged in a secondary cognitive task. Moreover, the error-reduced program facilitated a greater increase in free play throwing activity. Children with cerebral palsy in the error-reduced program displayed improved object control proficiency while those in the control group did not. No changes in weekday PA were found but increased moderate to vigorous physical activity and decreased sedentary time during weekends was found in the error-reduced group. **Discussion** The findings support the use of a reduced errors approach in remedial movement training of children with disability, suggesting that such approach improves performance and heightens movement engagement in free play. The findings also contribute to the growing evidence base that suggests improved FMS proficiency contributes to PA engagement in children with disability. **References** Barnett LM, Van Beurden E, Morgan PJ, Brooks LO, Beard JR. ## THE EFFECT OF STIMULUS INTENSITY ON RESPONSE TIME AND ACCURACY IN DYNAMIC, TEMPORALLY CONSTRAINED ENVIRONMENTS

Causer, J.I, McRobert, A.P.1, Williams, A.M.2

1: LJMU (Liverpool, UK); 2: Brunel University (London, UK)

**Introduction** The ability to make accurate judgments and execute effective skilled movements under severe temporal constraints are fundamental to elite performance in a number of domains including sport, military combat, law enforcement, and medicine. The speed and accuracy of these judgments can be affected by the strength of sensory information available (Klein, 2001). Researchers (cf. Klein, 2001) have reported high stimulus strength to facilitate a decrease in response time and an increase in response accuracy in laboratory-based tasks. Conversely, low stimulus strength has been demonstrated to increase response times and response accuracy. In two experiments, we examine the effect of stimulus strength on response time and accuracy in a temporally constrained, real-world, decision-making task. **Method** We examined the effect of low stimulus intensity (black) and high stimulus intensity (sequin) uniform designs, worn by teammates, to determine the effect of stimulus strength on the ability of soccer players to make rapid and accurate responses. In both laboratory- (experiment 1) and field-based (experiment 2) scenarios, professional soccer players viewed developing patterns of play and were required to make a penetrative pass to an attacking player. Results Significant differences in response accuracy between uniform designs were reported in laboratory- (black = 77.1%; sequin = 90.6%) and field-based (black = 77.1%; sequin = 88.5%) experiments. Response accuracy was significantly higher in the sequin compared with the black uniform condition. Response times only differed between uniform designs in the laboratory-based experiment (black = 2597.58ms; sequin = 2288.68ms). **Discussion** This novel approach to investigating decision making and performance by manipulating uniform designs provides a valuable insight into the application of increasing stimulus strength to increase performance and paves the way for future research in the area. The data presented extends the theory behind stimulus intensity and its relationship to stimulus-driven attentional control into an ecologically valid, dynamic task. The results demonstrate the effectiveness of stimulus strength as a method of increasing the ability of performers to pick up visual cues, which may subsequently facilitate improvements in response time and accuracy. These findings highlight the practical utility of using manipulations to playing uniform design to positively influence performance in sport and other fields of activity. **References** Klein, S. A. (2001). Percept Psychophys, 63 (8), 1421–1455.

## VECTOR SUMMING IN THE CONTROL OF MULTI-SEGMENT UPPER LIMB MOVEMENTS

Han, J., Adams, R., Waddington, G., Anson, J.

University of Canberra

**Introduction** In overhead sports, proprioception plays a crucial role in accurate catching and releasing when visual information about the hand is not available. However, the mechanism for using proprioceptive information in multi-segment upper limb movement control remains unclear. Although it has been hypothesised that movement is controlled by proprioceptive information arising from specific receptors, it is possible that a higher-order form of control exists whereby each vector of a complex movement is summed by an automatically-executed algorithm, in a process known as vector summing (Franklin & Wolpert, 2011). Thus multiplanar movements to overhead targets could either worsen final hand position accuracy by an overload of proprioceptive information from multiple joints, or be accurately culminated by vector summing. The aim of this study was to compare uniplanar and multiplanar arm raising to an overhead target in terms of accuracy of judgment of the final hand position. **Methods** Sixteen healthy young adults (8M, 8F, mean 21 years of age, range 19 to 24) volunteered. The Active Movement Extent Discrimination Apparatus (AMEDA) for the shoulder was employed to generate the end positions for arm-raising to 5 different overhead targets to be identified (Whiteley et al., 2008). Standing against the overhead-positioned AMEDA, participants used two different arm raising patterns to get to the overhead targets: uniplanar arm flexion in the sagittal plane, or arm unfolding upwards in 3 dimensions. To obtain separate movement discrimination scores for the two arm movement patterns, the mean pair-wise Area Under the Curve (AUC) were obtained using SPSS software. The two movement patterns were compared using ANOVA, and Pearson correlations between the discrimination scores were determined. **Results** A significant positive correlation between the scores for the two patterns was observed ( $r = 0.70$ ,  $p = 0.003$ ) however there was no significant difference between them in terms of discrimination accuracy ( $F(1, 15) = 0.50$ ,  $p = 0.49$ , partial  $\eta^2 = 0.03$ ). **Discussion** Vector summing for movement control is supported because multiplanar movements were performed as accurately as uniplanar arm movements to overhead targets. The significant relationship between performances with the two techniques suggested that the same computational mechanism for tracking a limb through space to an unseen target could have been used for both arm-raising patterns. **References** Franklin, D. ### IS-SH07 Sport sciences to improve dance performance and participation, an interdisciplinary proposal

#### QUALITY OF PARTICIPATION AND DANCER'S HEALTH

Quested, E., Woodcock, C., Norfield, J., Cumming, J., Duda, J.L.

University of Birmingham

It is well established that social-psychological factors play an important role in nurturing high quality participation and optimizing health among those that engage in performance-related pursuits. In 2002, the application of psychology techniques in the context of dance was described as in its' infancy (Hays, 2002). However, in the past decade the field has witnessed a notable growth in studies that have applied theories and research evidence from sport psychology for the benefit of dancers. This presentation will give an overview of our multi-method and multi-approach research that has contributed to the knowledge base concerning the social and psychological pro-

cesses operating in vocational dance contexts. One dominant line of work has been the role of motivational processes in accounting for differences in health-related outcomes among dancers. Studies have consistently supported the self-determination theory (Deci & Ryan, 2000) based hypothesis, that when dancers feel a sense of autonomy, competence and relatedness with regard to their participation, their state emotional (e.g., anxiety) and biological (e.g., cortisol) responses and enduring indicators of optimal vs. compromised functioning (e.g., self-evaluative tendencies, burnout) are likely to be more adaptive. Research findings with elite and recreational samples have highlighted the important role of the teacher in creating an adaptive motivational climate, conducive to basic need satisfaction. The field has also progressed with regard to our understanding of dancers' use of psychological skills and techniques, and the correlates of such usage. Findings highlight dancers use such skills and techniques and value their importance. Importantly, results also indicate that the systematic use of effective psychological techniques and skills does not develop naturally. Rather, as we have seen in sport, psychological skills training programmes for the dancers and their instructors are required. This body of work highlights the great potential for theory and evidence based intervention studies in dance. In the case of teachers, it would be advantageous to explore whether it is possible to modify the motivational climate created by teachers via systematic training. In the case of dancers, intervention research could identify the effectiveness of embedding psychological skill and technique training within the dance curriculum. With respect to both complimentary lines of work, it would be prudent to examine whether interventions also impact upon the health, well-being and sustained engagement in dancers as well as the quality of their performances. ### EXPERT LOOKING: PERCEPTUAL, PSYCHOPHYSIOLOGICAL, AND NEURAL RESPONSES TO DANCE BY DANCERS

Christensen, J.1, Calvo-Merino, B.2

<sup>1</sup> University of the Balearic Islands; <sup>2</sup> Complutense University of Madrid and City University of London

**INTRODUCTION** Dancers are a special type of motor experts. They are trained both in highly athletic motor actions, and in endowing their movements with artistic quality. Due to the requirement of this complex set of skills, recently, Cognitive Neuroscience has started to explore how dance expertise modulates neural, perceptual and psychophysiological processes in the dancer's brain. Neuroimaging studies show that dancers have a stronger motor resonance in the so-called mirror neuron system when viewing dance movements of their area of expertise. Behavioral research suggests different perceptual strategies (configural/analytical) when dancers watch dance, as compared to non-dancers. In a series of studies, we have now further investigated the perceptual and psychophysiological responses of dance experts to dance, and interestingly, these responses were related to the aesthetic experience associated to dance appreciation. **METHOD** Two groups, expert dancers and non-dancers, carried out two visual tasks. An initial task measured which processing strategy (configural/analytical) was adopted while viewing dance positions. To do this, participants performed a computerized match-to-sample task, where picture-pairs were presented one after the other. After each pair, participants had to state whether the two pictures were the same or different. Importantly, in half of the total number of trials, the stimuli were presented upright and in the other half, the same stimuli were presented up-side-down. To assess which processing strategy is adopted, psychologists calculate the inversion effect. The inversion effect is the difference in performance (accuracy) between upright vs. inverted displays. As stimuli, we used 24 pairs of dance positions and 24 pairs of control stimuli (scrambled). In a second task, participants stated their personal aesthetic preference for each stimulus on a visual analogical scale, by mouse-clicking on a bar between 0 (not at all) to 100 (a lot). **RESULTS** Accuracy in the perceptual task showed a main effect of stimuli. Accuracy was higher for upright dance positions than for inverted displays, while no such difference was found for the control stimuli. Moreover, correlational analyses were performed on the accuracy data and the subjective aesthetics ratings. These analyses revealed that the more configurally a stimulus was processed, the more it was liked. This confirms conjectures of cognitive ergonomics in that we find visually pleasing what is easy to process for our visual system. **CONCLUSION** We relate these findings to previous literature on dance expertise, and draw future avenues of research on the relation between visual processing, expertise and aesthetic appreciation.

### THE BEAUTY OF KINEMATIC DANCE PARAMETERS

Morey-Klapsing, G.1, Castañer Balcells, M.2, Torrents Marín, C.2, Jofre Marín, T.1

1. INESCOP, 2. INEFC

**Introduction** This presentation approaches the beauty of kinematic dance parameters from two different perspectives. Part A - When analysing art in general and particularly contemporary dance, the performance parameters are anything but evident. A technically perfect interpretation is not necessarily the best one. In a study utilising a mixed methods approach the relationship between biomechanical parameters and the perceived beauty was analysed. Part B - Turning things around, in interactive art and from a biomechanical perspective, a dancer can be seen as a generator of kinematic signals. These signals are used for artistic creation in almost any thinkable way. Here a simple case utilising a 3D accelerometer is presented. **Methods** Part A - Four experienced contemporary dancers performed three repetitions of four dance-related motor skills. Motion was captured by a VICON-MX system as well as by conventional video. The resulting 48 animations and videos were viewed by 108 sports students that judged beauty using a semantic differential. The data were then subjected to multiple factor analysis (MFA). Part B - A 3D-accelerometer attached to the dancers body sends its signals via wifi utilising the OSC (Open Sound Control) protocol. These signals are then used to create and modulate sound as well as to generate graphic output using OpenFrameworks and PureData. The result is an interactive loop where the performer directly influences the music he is dancing to. In order to achieve better musicality an electronic musician can coordinate the whole creation. **Results** Part A - A strong association between beauty scores and certain kinematic parameters (especially amplitude related ones) was found. Animations and real videos led to similar results. Part B - On one hand we get the artistic performance as a product to be shown. On the other, we get a whole new way of creating, giving the dancer new roles arising from the interaction with the technology which nourishes from biomechanics. **Discussion** In spite of being subjective, it has been often tried to identify parameters related to the perception of beauty. In this study several kinematic parameters describing four isolated contemporary dance elements proved to be related to subjective beauty scores, suggesting that, to some extent and for a given population, in contemporary dance the perceived beauty can be parametrised. Being so such parameters could be intentionally utilised during the creative process and even teaching or training. In case B, the beauty relies on the transformation of biomechanical parameters (3D accelerations) into part of the creation itself. The dancer is not only "dancing to the music" but she/he is actively intervening in the soundscape he's immersed in. This kind of work demands new skills to the dancer which possibly might become part of the curricula of future dance studies. **References** Brown WM, Cronk L, Grochow K, Jacobson K, Popović Z, Trivers R (2005). *Nature*, 438 1148-1150. **ACUTE EFFECTS OF WHOLE-BODY VIBRATION ON 3KM CYCLING TIME TRIAL PERFORMANCE**

Bhambhani, Y., Fernandes, I.A., Gomes, P.S.C.

*University of Alberta*

**Introduction** Whole-body vibration (WBV) is frequently used by athletes to enhance competitive performance (Alvelar et al., 2012; Ronnestad et al., 2012). Near infrared spectroscopy (NIRS) evidence (Coza et al., 2011; Games and Sefton, 2011) has demonstrated that WBV administration acutely induces muscle hemodynamic changes (increases in (HbO<sub>2</sub>-HHb) difference and total blood volume (Total Hb)) in the lower extremities. This study tested the hypothesis that acute WBV would significantly improve 3KM cycling time trial (TT) performance due to improvements in muscle hemodynamics. **Methods** Thirteen recreationally competitive male cyclists (age: 33±9; height: 175±6cm and mass: 76±11Kg) completed a simulated 3KM TT in two randomly ordered sessions without (CON) and with WBV administration. In the WBV session, athletes assumed a squat position (≈110° of knee flexion) on the WBV platform and completed three 1-min exposures (interspersed by 1-min rest) at a frequency–amplitude combination of 45 Hz and 5 mm. In the CON session, the cyclists stood on the platform in the same posture. Subjects performed the 3KM TT on a mountain bike mounted on a frictionless roller interfaced with TACx software (TACx Fortius, Netherlands). Cardiorespiratory responses were recorded using a metabolic measurement cart (VMax, SensorMedics, CA) and muscle NIRS variables were measured using a dual wave instrument (Artinis Medical Systems, Netherlands) on the right Vastus Lateralis. Finger prick blood lactate [La] was measured prior to and 2 min post race. The mean values for the entire trial were calculated and used for analysis. **Results** When compared to CON, WBV did not significantly alter 3KM TT performance (Time: WBV 19.04 vs. CON 19.2 min, P<0.05), the associated cardiorespiratory (HR: 163 vs. 165 bpm, VO<sub>2</sub>: 2.73 vs. 2.89 L/min, P<0.05), and muscle NIRS responses (HbO<sub>2</sub>-HHb difference: 3539 vs. 2784 μmol, Total Hb: 2002 vs. 1346 μmol, P<0.05). Finger prick blood lactate concentrations (Delta [La]: WBV 5.10 vs. CON 5.15 mmol/L, P<0.05) also did not differ between sessions. **Discussion** All the athletes completed the simulated 3KM TT in a typical racing manner with a final burst towards the last 2 min of the race. Contrary to our hypothesis, WBV did not significantly enhance 3KM TT time or the associated cardiorespiratory and muscle hemodynamic responses. These findings are in contrast to previous observations, which demonstrated significant improvement in high intensity cycling (Alvelar et al., 2012) and muscle power (Ronnestad et al., 2012) induced by WBV at similar doses. This discrepancy could be due to the type of performance investigated: aerobic endurance vs anaerobic or muscle power. **References** Avelar NC, et al. *J Strength Cond Res.*, 2012 (epub). **NEUROMUSCULAR FACTORS AFFECTING PLANTARFLEXOR TORQUE AFTER INTERMITTENT VS. CONSTANT MUSCLE STRETCH**

Trajano, G., Seitz, L., Nosaka, K., Blazevich, A.

*Edith Cowan University*

**Introduction:** Prolonged muscle stretching can have a detrimental effect on maximal force production, and changes in both central drive and muscular properties (i.e. peripheral changes) are the two most likely candidates to explain the force loss. One difficulty in determining the mechanisms underpinning this phenomenon is that different effects may be elicited by different stretch protocols, and in particular the effects of intermittent (i.e. repeated stretch-relax cycles) and constant stretch protocols might be dissimilar. The purpose of this research was to examine the contributions of central and peripheral factors on force-loss after constant and intermittent stretch protocols of equal duration and intensity. **Methods:** Eighteen men randomly performed three conditions: 1) one 5-min stretch (constant stretch; CS); 2) five 1-min stretches (intermittent stretch, IS) and a resting (control) condition, on three separate days at the same time of day. Constant-torque ankle stretches were performed on an isokinetic dynamometer. Measures of isometric peak torque (PT), percent voluntary activation (%VA; interpolated twitch technique), soleus sEMG normalized to the Mmax (sEMG/M; tibial nerve stimulation), first volitional wave (V-wave) and excitation-contraction (E-C) coupling efficiency (i.e. ratio between 20 and 80 Hz tetanic stimulations) were taken before, immediately, and 15 and 30 minutes after each condition. **Results:** Voluntary PT decreased significantly more immediately after IS (-23.8%) than CS (-14.3%) (p=0.033). PT reduction was fully recovered by 15 min after CS, but still remained depressed by -5.7% (p=0.037) and -5.6% (p=0.036) at 15 and 30 min, respectively, after IS. sEMG/M (-29.1%, p=0.004) and %VA (-15.9%, p=0.039) were reduced only immediately after IS. The decrease in PT after CS was correlated with changes in sEMG/M (r=0.63; p=0.006), %VA (r=0.78; p=0.001) and V-wave (r=0.51; p=0.036). Moreover, changes in PT after IS were correlated with changes in sEMG/M (r=0.90; p=0.000), %VA (r=0.93; p=0.000) and V-wave (r=0.52; p=0.028). Tetanic PT was depressed immediately after CS (20 Hz = 10.7%; 80 Hz = 6.6% [p<0.01]) and IS (20 Hz = 13.5%; 80 Hz = 6.9% [p=0.01]), however the 20:80 Hz ratio was not different between conditions. **Conclusion:** These results suggest that: (1) torque production is more compromised after intermittent than continuous stretch, and (2) the torque loss caused by both protocols immediately after stretch seems to largely result from a reduced central drive rather than peripheral changes such as impairments in E-C coupling. Nonetheless, the prolonged torque loss caused by IS could not be explained by central factors and might be at least partly of peripheral origin.

**PRIOR FATIGUING ARM EXERCISE ALTERS PERIPHERAL EXCITABILITY AND VOLUNTARY DRIVE TO THE KNEE EXTENSORS**

Bowtell, J.L.1, Mohr, M.1, Jackman, S.J.1, Fulford, J.1, Ermidis, G.2, Krstrup, P.1, Mileva, K.N.3

1. *Sports and Health Sciences, Exeter University, EX1 2LU*; 2. *Physical Education and Sports Science, Democritus University of Thrace, Greece*; 3. *Applied Science, London South Bank University, SE1 0AA*

**Introduction** After intense arm exercise, pH is lowered and interstitial potassium elevated in knee extensor muscles, resulting in earlier onset of fatigue during subsequent knee extensor exercise (Nordsborg et al., 2003). We investigated whether changes in peripheral and

corticospinal excitatory output and voluntary activation caused by the altered intramuscular ionic balance underpin the premature fatigue development. Methods On 2 occasions separated by 2 weeks, 8 healthy active young men (weight, height, age) performed 4 x 1 min and 1 x 1.5 min intense arm crank exercise with 30 s rest intervals followed by a 4.5 min rest interval and a final 1 min all-out arm exercise. On one occasion quadriceps 31P-MRS scans were performed to quantify pH and high energy phosphate kinetics pre and post exhaustive arm exercise. On another occasion electrical stimulation of the femoral nerve and transcranial magnetic stimulation of the quadriceps cortical motor area were applied during knee extension maximum voluntary contractions (MVC) pre and post arm exercise to quantify voluntary activation (VA) and peripheral (M-wave) and cortical (MEP) evoked responses in m. vastus medialis (VM). Venous blood samples were taken at regular intervals throughout. Data were analysed by paired t-tests. Results Fatiguing arm exercise resulted in significant reductions in blood (pre:  $7.38 \pm 0.01$ , post:  $7.13 \pm 0.02$ ,  $p < 0.001$ ) and quadriceps muscle pH (pre:  $7.04 \pm 0.01$ , post:  $6.95 \pm 0.02$ ,  $p = 0.003$ ), but there was no reduction in knee extension MVC force. During MVC, VM M-wave peak-to-peak amplitude was significantly reduced ( $-17.6 \pm 7.3\%$ ,  $p = 0.034$ ) and there was a significant shortening of the cortical silent period (pre:  $227.0 \pm 26.6$ , post:  $215.4 \pm 27.6$ ; ms;  $p = 0.019$ ), but MEP amplitude was unaffected by prior arm exercise. Voluntary activation of the maximally contracting knee extensors was significantly enhanced by the prior arm exercise (pre:  $82.9 \pm 2.8$ , post:  $87.5 \pm 2.9\%$ ,  $p = 0.045$ ). Discussion Maximal isometric knee extensor force generating capacity was preserved after fatiguing arm exercise despite the reductions in blood and muscle pH and peripheral excitability. This was achieved through increased voluntary drive perhaps via decreased intracortical inhibition as evidenced by decreased duration of the cortical silent period. ### APPROACH OF A NEW NON-LINEAL MODEL OF STRENGTH DECREMENT DUE TO FATIGUE DURING INTERMITTENT HANDGRIP CONTRACTIONS

Marina, M.1, Rios, M.2, Torrado, P.1, Busquets, A.1, Angulo-Barroso, R.1

1: INEFC, GRCE-UB (Barcelona, Spain), 2: Facultad Biología-UB (Barcelona, Spain)

Introduction: Force can decrease exponentially over the maximum rate of decline (Bigland-Ritchie, et al., 1983). Therefore, the relationship between force and time to exhaustion can be described by hyperbolic functions (Burnley, 2009), and support the idea of non-linear force loss with exercise duration (Millet & Lepers, 2004). We check the hypothesis that force loss during an IFP, can be best modeled by a non-linear function. Method: 40 male road racing motorcycle riders ( $27.6 \pm 6.8$  years) participated in the study. A static structure was built to simulate the overall position when the rider is piloting a racing motorcycle (Marina et al., 2012). To measure the force exerted against the brake lever a gauge was connected to the Muscle-Lab system 4000e. The IFP rounds were composed by a succession of submaximal voluntary contractions (%MVC) of different intensities and durations (30%, 100% and 50% MVCs of 5 s, 3 s and 10 s durations respectively). Recoveries of 5 s and 1 min were allowed before the 30%–100% and 50% MVCs respectively. The adjustment of the force fatigue model (FFM) was obtained by the "Method of least squares" and the coefficient of determination  $R^2$  was computed. Residual analysis and normality of errors were examined. Results Force Fatigue Model =  $A - B \cdot \ln(C + D \cdot T) / (C - T)$  Equation 1: A: Force exerted during MVC in basal condition; B: related to the slope of the curve, C: related to the duration of the test, D: related to the moment of the second inflexion of the curve, T: relative duration with respect to the total performance (number of rounds accomplished) At the end of the IFP, NMVC has decreased 40% in comparison to MVCbasal and confirmed the trend observed with MVCraw. Using the best seeds (A, B, C and D) for each individual, and for instance after obtaining the "best interaction" between the FFM and the measured values,  $R^2$  was 0.977 (typical error of the residuals: 0.066; averaged  $\sum$ squares: 0.104). Conclusion The approach of our non-linear MVC model of fatigue proved to be well adjusted in comparison to the values measured for all subjects throughout the IFP. This non-linear model has the advantage of representing not only the hyperbolic functions (Bigland-Ritchie, et al., 1983; Burnley, 2009), but also the three stages fatigue proposed by Allen (2009). ### IMPAIRED NEURO-MECHANICAL CHARACTERISTICS INDUCED BY A REPEATED ANAEROBIC RUNNING SPRINT TEST IN PROFESSIONAL SOCCER PLAYERS

Brocherie, F., Millet, G.P., Girard, O.

Faculty of Biology and Medicine, University of Lausanne

Introduction This study aimed to determine changes in spring-mass model characteristics and quadriceps muscles activity induced by a repeated anaerobic running sprint test in soccer-specific conditions; i.e. on synthetic grass with soccer shoes. Methods Eight members of the Qatar national soccer team, performed 6 x 35 m sprints interspersed with 10 s of active recovery. Stride temporal parameters were obtained from insoles worn in the players' shoes, which allowed spring-mass behaviour to be estimated (three consecutive steps at 30 m distance interval). Surface electromyographic activity was monitored for vastus lateralis (VL), rectus femoris (RF), and biceps femoris (BF) muscles. Results Sprint time, contact time, total stride duration and swing time lengthened from the first to the last repetition (+17.4, +20.0, +17.0 and +16.6%; all  $P < 0.05$ ), while the increase in flight time was not significant (+14.9%;  $P > 0.05$ ) and stride length remained constant ( $P > 0.05$ ). Stride frequency decreased significantly across repetitions (-13.9%;  $P < 0.001$ ). Center of mass vertical displacement increased (+45.7%;  $P < 0.001$ ), together with unchanged (both  $P > 0.05$ ) peak vertical force (+2.8%) and leg compression (+5.3%). Vertical stiffness decreased (-27.2%;  $P < 0.001$ ) across trials, whereas leg stiffness change was not significant (+1.5%;  $P > 0.05$ ). Decreased root mean square EMG activity occurred over sprint repetitions for RF and BF (-18.7 and -18.1%;  $P < 0.01$  and  $P < 0.001$ , respectively), but not VL (-1.2%;  $P > 0.05$ ), muscles. Discussion In professional soccer players, repeated sprinting when performed in an ecological test setting impairs leg-spring behavior towards impaired vertical stiffness and less efficient stride characteristics. Similar changes in sprinting mechanics have been observed when soccer players completed 6 x 20 m with 20 s of passive recovery (Girard et al. 2011). With a larger sprint decrement observed here compared to Girard et al. (2011) (9.5% vs. 2.8% from the first to the last sprint), however, the magnitude of fatigue-induced neuro-mechanical adjustments in general was also larger. Those changes were also accompanied by reductions in RF and BF, but not VL, muscle activation. Training routines that aim at preserving sprinting efficiency when soccer players experience temporary fatigue during a game are encouraged. References Girard O, Racinais S, Kelly L, Millet GP, Brocherie F (2011) Repeated sprinting on natural grass impairs vertical stiffness but does not alter plantar loading in soccer players. *Eur J Appl Physiol* 111: 2547-2555

#### EMERGING CREATIVE BEHAVIOURS UNDER ECOLOGICAL CONSTRAINTS IN CONTACT IMPROVISATION DANCE

Ric, A.1, Torrents, C.1, Hristovski, R.2, Aceski, A.2

*1:INEFC-UdL (Lleida-Spain) 2:Sts. Cyril and Methodius University (Republic of Macedonia)*

Introduction Contact improvisation (CI) dance generates different ways of moving and a varied use of motor creativity depending on the constraints acting on the system (Torrents et al. 2010). Under these constraints, some movement configurations are more likely to occur and some are unlikely, breaking system's replica symmetry (Hristovski et al. 2011). The aim of this study was to analyse the hierarchical structure and softly-assembled dynamics of a couple of improvisers dancing CI under specific task constraints manipulations. Methods Three contact improvisers were video-recorded while dancing 480 seconds duets in three trials with different conditions: a) free dance; b) constraint 1: try to maintain both pelvis as close as possible; c) constraint 2: try to maintain both pelvis as far as possible. Resulting trials from one dancer were sequentially observed using an observational instrument with 49 categories. The data obtained were then analysed using a soft-assembled hierarchy model analysis by means of three statistical analyses: a Hierarchical Principal Components Analysis (HPCA), calculation of Hamming distances (HD) between binary vectors and the calculation of dynamic overlap order parameter  $q$  to determine the structure of the potential landscape of the dancer and its dynamic properties. Results HPCA revealed 8 primary PCs for free dance, 8 for constraint 1 and 11 for constraint 2 accounting for more than 80% of the total variance. These PC typically formed a few higher order PCs pointing to a hierarchically self-organized dynamics. The elevations (motor acrobatic skills that characterize CI dance) appear most frequently in the dance with constraint 1, and less in the dance with constraint 2. The diffusion of these configurations vectors was 0,37 for free dance, 0,36 for constraint 1 and 0,39 for constraint 2. HD revealed higher potential barriers between the different configurations that appeared with constraint 1, because of the abrupt changes of configurations that produce the elevations. The dynamic overlap formed statistically different plateaus for each condition, being 0,45 for free dance, 0,48 for constraint 1 and 0,42 for constraint 2. Discussion Configurations are modified depending on the constraint, but the exploratory rate and plateau values show a higher exploratory behaviour when the system is constrained in a specific way (pelvis far). Constraining the system can enhance creativity, but also force the system to train specific techniques or movement patterns, i.e. elevations in CI dance. #### CONTRIBUTIONS OF THE PHYSICAL EDUCATION TO THE CIRCUS ARTS

Duprat, R., Bortoleto, M.

*Unicamp Brazil*

INTRODUCTION From the second half of 20th century, by the circus schools arise, a new education process and knowledge exchange are added. In the European scenario they act in four education levels: leisure, artistic basis, professional/higher education, carry on education. In Brazil, it's also pointed in four levels: leisure/fitness, carry on education/informal, vocational training school, educational projects. Besides, these arts have also been implemented in the content of the formal education (DUPRAT; DARIDO, 2012) and also as extracurricular activities (TAKAMORI et al., 2010), mainly in the physical education classes (ONTAÑÓN; DUPRAT; BORTOLETO, 2012). In this context, different researches have been carried out by physical education professionals who seek, mainly, the possibility of pedagogical relations inherent in the circus activities. METHODOLOGY It's a theoretical study, carried out through the documental analysis of specialized literature. DISCUSSION The opening of circus schools allowed that new persons could come into the circus professional sphere. It has also allowed that many physical education professors/teachers could act in the circus scope, as an artist, physical trainer, coach, or professor/teacher. In Brazil, as there aren't any higher educational courses in circus art, many artists have been looking through the physical education course as a way to improve their academic formation. There are also records of physical education students who find out in both pedagogical possibility and artistic from experiences gained through their higher education. Thus, the relation between the circus and the physical education is now a reality, provoking an important increase of the academic production (ONTAÑÓN; DUPRAT; BORTOLETO, 2012), mainly on the pedagogical aspects, technical procedures, as well as, experience reports in the scholar scope. We conclude that the physical education and the Science of Sport can help discussing new specific teaching methodologies in relation to the pedagogical approaches and safety (LONG; AMBEGAONKAR; FAHINGER, 2011); helping out in the technical development and in the physical training roles for the amateurs and circus artists. To make this possible it's very important that the physical education courses fully value the circus arts, developing programs which address such knowledge, improving and deeping the researches. #### SHOULD CIRCUS ACTIVITIES COMPOSE THE PHYSICAL EDUCATION UNDERGRADUATE COURSE?

Tucunduva, B.

*UNIVERSIDADE ESTADUAL DE CAMPINAS UNICAMP*

Introduction Nowadays, circus activities are being more widely worked and discussed in the Physical Education context principally due to the increase of its pedagogical experiences (ONTANON, DUPRAT, BORTOLETO, 2012). Although the circus activities compose a new demand on the work market, there still is an insubstantial academic response, where only few undergrad courses have incorporated specific disciplines about this subject. Nevertheless, there are expressive results shown by the universities which have included the circus activities on their curricular grid (BORTOLETO, CELANTE, 2011). Based on these assumptions, this research intends to discuss the accessibility and the specific teaching characteristics of circus activities in the Physical Education undergrad. Methods This study is a theoretical essay, grounded upon the specialized literature. Results Although the circus activities are constituted of practices that are easy to imple-

ment in the Physical Education classes, the undergrad courses must attend to its proper pedagogical processes, such as security procedures and corporal groundwork, aiming on developing professionals who can work adequately with this knowledge (MATEU, 2010; HAUW, 2010). The approach to this matter should include a thorough discussion about the historical, social, ethical, aesthetical and technical aspects of these practices (FOUCHET, 2006), supporting a contextualized comprehension of the circus arts and the necessary adjustments for its inclusion as a Physical Education content. Discussion The incipience of this theme and the constant growing of the demand for its practices have generated a great quantity of short-term courses (intensive), as well as the appearance of proposals with shallow pedagogical grounding, mainly established on the reproductive model (empirical). That shows a reductionist approach to the circus arts as an expressive language, which can be incorporated to the academic development of the Physical Education professionals as a significant resource. ### **MOTOR SKILLS OBSERVATIONS AND MARKS I PHYSICAL EDUCATION; VALIDATION OF MOTORISK UTVECKLING SOM GRUND FÖR INLÄRNING OBSERVATION CHECKLISTS**

Ericsson, I.

*Malmö University*

Introduction Fundamental motor skills may be of importance in motivation for being physically active and take part in social physical play. Children with Developmental Coordination Disorder (DCD) spend less time in formal and informal team play (Smyth & Anderson, 2000). More children and young people would play sport and be physically active if they had better motor skills (Brown, Walkley & Holland, 2004). Aim The aim was to study relationships between motor skills and marks in Physical Education (PE). Another aim was to develop and validate checklists for motor skills observations. Method The study was hypothetic-deductive and had two hypotheses: The Motorisk Utveckling som Grund för Inläring (MUGI) checklists will fulfill criteria of validity and reliability; There are significant correlations between motor skills and marks in PE. All pupils at two schools were studied from school year 1 through 9. In total 263 of 265 pupils participated, 49% boys and 51% girls. To study development of motor skills MUGI checklists were used, measuring two components: balance/bilateral coordination and eye-hand coordination (Ericsson, 2008a; 2008b). Exploratory factor analyses were conducted for validation, Cronbach's alpha for test of reliability. To examine correlations between motor skills and marks in PEH Spearman rank correlations were used. Results Significant correlations were found between motor skills and marks in PE. Pupils with good motor skills had significantly higher marks than students with deficits in motor skills. The MUGI observation checklists were found to fulfill criteria of validity and reliability. Discussion The results indicate that motor skill deficits do not disappear by themselves. Motor skills observations at school start could bring about valuable information for planning motor training and individual programs of motor remediation. The results indicate the possibility to predicate marks in PE from motor skills observations at school start. References Brown, L., Walkley, J., & Holland, B. (2004). ### **CONSTRUCTION, VALIDATION AND STANDARDIZATION OF AN ORIGINAL PHYSICAL EDUCATION TEST BATTERY FOR THE EVALUATION OF FUNDAMENTAL MOTOR SKILLS OF 2ND, 5TH AND 8TH GRADE STUDENTS: PILOT STUDY**

Iancu, H.D.1, Picard, Y.2, Bélanger, M.3,1, Richard, J.F.4

*1: SKR-UM (Moncton, Canada), 2: FE-UM (Moncton, Canada), 3: DFM-US (Sherbrooke, Canada), 4: SP-UM (Moncton, Canada)*

Introduction A key role of quality school physical education is to enable children to learn and master motor skills, which are crucial for the adoption of an active lifestyle. The identification and assessment of fundamental motor skills therefore become essential. A review of the literature shows there is a lack of measurement tools for assessing students' fundamental motor skills (Tremblay and Lloyd, 2010). Accordingly, we have developed an original battery of 24 tests for the evaluation of fundamental motor skills. A pilot study of this battery began in September 2012 in six schools (N = 700 students) of New Brunswick, Canada, in order to verify the feasibility, validity and reliability of these tests. Methods The battery has been designed according to the development steps of psychomotor tests suggested by Morrow, Jackson, Disch & Mood (2010). Specifically, our group of experts: 1) identified the motor skills to be assessed, 2) developed evaluation parameters for each skill by focusing on the performance process (quality) rather than the product (Scallan, 2000), and 3) determined the tests procedures. Then, other experts evaluated the face and content validity of the battery of tests. Each test has been subsequently applied in targeted age groups of students (2nd, 5th and 8th grade) to assess the feasibility of the tests and to refine the evaluation parameters. Preliminary results Following our first visits, we modified the instructions for some tests to improve clarity and we adjusted the estimated time of administration and procedures for some grade levels. The majority of the adjustments have been made and applied on site. At the same time, the physical education teachers used the assessment forms and gave us a first opinion on the test parameters (examples will be presented during the congress). Discussions The first steps of this process suggest that the development of a battery of tests to assess fundamental motor skills of students is promising. The next steps include assessing reliability (inter-judge, intra-judge and test-retest) and validity. A process of establishing standardized norms will also be implemented. This battery of tests could become a standard measure for assessing the objectives of physical education within school curriculums (Durand & Chouinard, 2006). References Durand, M.J., & Chouinard, R. ## ADVANTAGES OF APPLYING ITEM RESPONSE THEORY METHODOLOGIES WHILE ANALYSING STUDENTS' MOTOR TEST DATA

Holzweg, M.

*Stellenbosch University*

Introduction Testing and reporting students' competencies is integral to the field of (school) education. In education there were several large (comparative) studies conducted in the last decade testing certain student competencies (e.g. IAE, 2008; OECD, 2012). Today, there is wide consensus in psychometrics as well as in education that IRT methodologies have several advantages compared with classical test theory methodologies (compare Rost, 1996). Nevertheless there hardly exist any studies in Physical Education and Sport Pedagogy employing those IRT methodologies (compare Strauß et al., in press). Methods The aim of the study is to exemplarily compare two different evaluation processes (uniformly distributed and normally distributed judgment scheme) for analysing data of the German Motor Test (DMT 6-18). The data includes a random sample of 749 five to fifteen-year-old German students from Berlin (366 female, 383 male with an average age of 9.63 years and a standard deviation of 3.27 years) showing their measuring characteristics (sum score, test information and test error). In contrast to the analysis described by Bös et al. (2009) using classic test theory methodologies, the author analyses the data using IRT methodologies based on the Rasch Model (Rasch, 1960) in order to describe advantages and disadvantages of the two different evaluating processes and to present consequences for the test interpretation. Results The results of this study show that the test error and the distribution of the sum score differ considerably, depending on the chosen judgment scheme. This has some crucial consequences for the test interpretation. Conclusions The research findings derived from the motor testing example can be easily generalised and transferred to studies related to assessments of student competencies in wider Physical Education and Sport Pedagogy contexts. ### OP-SH12 Sociology [SO] 2

#### GENDER BIAS IN THE FIELD OF SPORTS MEDICINE – A CASE OF RELEVANCE?

Hartmann-Tews, I., Rulofs, B.

*German Sport University Cologne*

Introduction There is growing consensus in society and health sciences about the necessity to improve excellence in scientific research by incorporating the categories sex and gender into the research design (Holdcroft et al., 2011). i.e. ignorance towards the relevance of sex and gender issues, in sport-related health research. Our research questions are, if there is any gender bias in the field of clinical and academic sports medicine and if so, what kind of social structures foster, stabilize or impede gender bias in research. Methods 1. A content analysis of abstracts of all journal publications in sports medicine published by German researchers during a four-year-period of 2005 to 2008 (N=2922). The content analysis was done by four researchers with an interrater-reliability of CR=0,9. 2. An in-depth content analysis of a sample of publications in sports medicine based on the above results (n=82). The content analysis was done by three researchers with an interrater-reliability of CR=0,9. 3. Interviews with central stakeholders of the scientific community of sports medicine, e.g. members of editorial boards, reviewers, funding institutions (n=17). Results Referring to those abstracts of journal articles that focus a research question relevant for both sexes (n= 2829) we identified that the studies focus more often on male test persons than on females. Thus an androcentric perspective is favored by sports-medical research. Only 7% of all abstracts were identified as "gender-sensitive", i.e. provide information on potential gender issues (either differences or similarities between men and women). The longitudinal analysis does not reveal any significant change with respect to these findings. The expert-interviews document that women are still constructed as the "second" and "more complex gender" by researchers whereas men are idealized as the "perfect test persons" in the field of sports medicine. This construction of an unequal gender order is even more stabilized by the increasing pressure to acquire research grants and to publish ("publish or perish"). Discussion Our studies document that gender bias occurs in clinical as well as in academic sports medicine. To understand the conceptual driving force of this situation we refer to the model of Risberg et al. (2009) who suggest that gender bias in medicine arises from assuming sameness and/or equity between women and men when there are genuine differences to consider and vice versa, assuming differences between women and men when there are none. #### EXAMINING GENDERED IDENTITIES IN YOUNG PEOPLE'S MEDIA CONSUMPTION OF BRITISH WOMEN OLYMPIC ATHLETES.

Curtis, H.

*Canterbury Christchurch University*

Introduction: The Olympic Games is one of the most significant events presented in various media forms (Roche, 2000). Sports media is an important resource for young people as they develop their identities (Bruce and Saunders, 2005; Lines, 2000). Young people's read-

ings of sports stars has been gender differentiated (Lines, 2001). This research considers the intersections of gendered identities for understanding young people's mediated consumption. The feminist concept of intersectionality is utilised to understand how identities interconnect to shape multiple representations of women in sport. Methods: Focus groups were conducted with young people, aged 11-18. Participants were asked to view and evaluate BBC Olympic media coverage of British women Olympic athletes. These provided, "an appropriate research tool for studying the construction of collective identity" (Munday, 2006:89). The researcher investigated participants' meanings and ways of understanding (Lunt and Livingstone, 1993). Qualitative content analysis noted construction of meaning and gendered themes. Results: Multi-layered identities were constructed and negotiated in young people's mediated consumption. Stereotypical assumptions of gendered identities were reinforced, negotiated and resisted. These were contingent on intersections of identity including nation, ethnicity and ability. Discussion: Dominant gendered identities reinforced traditional feminine aesthetics that excluded female athleticism. However, mediated Olympic consumption also offered opportunities to negotiate and resist notions of female appropriateness. The potential for emphasis on performance, athletic and tactical skill were intersected and contingent on affiliation to the nation. Further challenges should be made to dominant, stereotypical conceptions of Olympic women athlete identification. It is vital to address the message-sender-receiver dynamic of media messages for understanding young people's reception and conceptions of Olympic women. References: Bruce, T. and Saunders, R. ### **GENDER ISSUES IN SPORTS ORGANISATIONS – ATTITUDES OF THE OFFICIALS**

Diketmüller, R.

*University of Vienna*

GENDER ISSUES IN SPORTS ORGANISATIONS – ATTITUDES OF THE OFFICIALS Introduction Gender mainstreaming as a strategy was implemented in Austrian's sports organizations in 2001. Nevertheless the situation of women in leading positions has not changed yet. The project 'frau-aktiv-vernetz' (connected women) aims to empower women as officials and to create more women-friendly structures for leadership positions within the sports organizations in one Austrian federal state. Based on the results of a baseline study, where the situation of women in leadership positions in sports clubs on the one hand and the attitudes of the officials towards measures of gender mainstreaming and women's promotion were analyzed, specified interventions were developed in a participatory process. Methods The baseline survey was delivered in an online questionnaire to ~1000 officials of two sports organizations and their sports clubs. The return rate was quite low (n=189) and indicates a low interest in the topic in general (Diketmueller, Hausmair & Urch, 2012). Results The results indicate that women's and gender-issues are not considered of high value. On the one hand gender-issues are regarded to be important, while on the other hand there were nearly no specific reported measures. In addition, female officials rate their situation in sports organizations significantly worse than their male colleagues. While both, men and women, remain skeptical about the implementation of quotas, men refuse this strategy significantly higher. As a key barrier for more female officials in sports organizations the aspect of transparency in the process of personnel recruitment as well as in decision-making processes in general was argued, mostly by women. There were also complaints that offers especially for girls' and women's interests and needs are missing. Discussion In summary, it can be seen that officials are highly skeptical about gender-issues and have low experiences in implementing gender mainstreaming within the sports organizations. In addition only a small number of officials offers expertise in this field. To implement this European strategy of gender mainstreaming in a sustainable way (Dahmen & Hartmann-Tews, 2007), it is necessary to focus on the individuals and their expertise as well as on the level of organization and structures. ### **HIT AND TELL - THE SWEDISH CONTEXT**

Radmann, A.

*Malmö University*

Hooligans telling their own story represent a new voice in the sports narrative: the hooligan memoir. While this is a comparatively new phenomenon in Sweden, this literary genre has a long and productive history in England under the name Hit and tell. The purpose of this article is to expound on the pop-cultural expressions of hooliganism in Sweden, as epitomised by four hooligan memoirs. The article explores football culture, hooliganism, violence, masculinity and media in Sweden, as it is imperative to the understanding of hooliganism that it is analysed in the contexts in which it occurs. Research has demonstrated that hooliganism and violence in football and supporter culture have become increasingly visible in popular culture over the last few years. The article shows how hooligan culture is created in dynamic interaction between media, political reactions and cultural praxis, arguing that the cultural praxis of hooliganism is manifested through actual fights and, to an even greater extent, the various media narratives surrounding the hooligan subculture presented in the four memoirs.

## Plenary sessions

### PS-PL04 Rehabilitation through exercise \*

#### EXERCISE AS PREVENTION AND TREATMENT OF KNEE OSTEOARTHRITIS

Roos, E.

*University of Southern Denmark*

The two most common questions from patients with osteoarthritis are if it is OK that it hurts when exercising, and if exercise will wear the joint down. Recent research suggest that it is OK if it hurts when exercising, and exercise therapy seem not to wear the joint down, if anything small pilot studies suggest the opposite. Our joints need mechanical load to work well, and the cartilage needs mechanical stimuli to produce the building blocks needed. Because of joint pain and varying structural changes of the joint exercise must be adapted to suit this patient group. Systematic reviews of data from randomized controlled trials from many thousands of patients show that both aerobic exercise and strength training are associated with substantial pain relief and improved physical function. Therefore exercise is recommended as first line treatment, together with education and weight loss, for patients with knee osteoarthritis. In many countries initiatives are taken to offer educational classes, exercise and weight loss programs for patients with knee osteoarthritis. Less is however known about the optimal exercise program, but 12 or more supervised sessions are associated with twice the effect compared to less than 12 sessions. The role of exercise in OA prevention in groups at increased risk of knee OA is currently under study. Patients having had treatment because of an injury to the anterior cruciate ligament or to the menisci constitute such easily identified highrisk groups where preventive measures may be possible. Neuromuscular exercise programs have been developed for these groups to improve their symptoms and function and dynamically stabilize the joint. Time will show if these strategies are able to reduce or slow OA development.

#### THE ROLE OF MUSCLE STEM CELLS IN COUNTER-FIGHTING SARCOPENIA BY EXERCISE

Mackey, A.

*University of Copenhagen and Bispebjerg Hospital*

Satellite cells are the resident stem cells of skeletal muscle and have the potential to repair and maintain skeletal muscle throughout adult life. They also maintain their own cell pool through the process of self-renewal, thereby theoretically providing the muscle with a non-exhaustible source of stem cells. However whether ageing muscle is characterised by a reduction in satellite cell number is still questionable, as some reports in the literature provide evidence for a maintained satellite cell pool size up to the eighth decade of life, while others document a reduced pool size. In addition, whether the absolute number of cells is important remains to be investigated. Since it has been shown that healthy elderly individuals can undergo hypertrophy and produce strength gains in response to resistance training, it is possible that the size of the satellite cell pool is not crucial to muscle adaptation. It appears however that satellite cells of elderly individuals, when compared to younger counterparts, are not as easily activated in vitro and in vivo, although there is some disagreement in the literature on this topic. Furthermore, the environment of the satellite cells also undergoes changes with ageing, which likely impacts cell activity. The potential of the satellite cell to influence the onset and progression of sarcopenia is not yet known, although it seems clear that the muscle of healthy elderly individuals does not respond as quickly, and perhaps not to the same extent, as young individuals, both in response to exercise training and muscle injury.

#### DIET INFLUENCE UPON BRAIN CREATINE CONTENT: A CROSS-SECTIONAL STUDY WITH VEGETARIANS AND OMNIVOROUS

Solis, M.Y.1, Painelli, V.S.1, Otaduy, M.C.1, Lancha Jr, A.H.1, Artioli, G.G.1, Gualano, B.1

*1. University of Sao Paulo (Sao Paulo, Brazil)*

Introduction Creatine (Cr) is endogenously produced (approximately 1g/d) as well as ingested (approximately 1 to 5g/d), mostly via meat intake. It has been generally accepted that vegetarians show lower tissue Cr content when compared to omnivores. This assumption particularly holds true in regard to skeletal muscle; however, it is yet unknown whether diet can affect brain Cr content. The aim of this study was to explore the influence of diet on brain Cr content by comparing vegetarians (who consume virtually no Cr in diet) vs. omnivorous. Methods This is a cross-sectional study in which healthy vegetarians (n = 8; 3 women and 5 men, age = 29.63 ± 5.10 years; BMI = 23.98 ± 2.77 Kg/m<sup>2</sup>; schooling = 16.33 ± 2.42 years) were compared with age-, BMI- and gender-matched omnivorous individuals (n = 8; 3 women and 5 men, age = 30.83 ± 9.37 years; BMI = 24.33 ± 2.91 Kg/m<sup>2</sup>; schooling = 19.80 ± 3.74 years). Brain Cr content was assessed at the occipital lobe by in vivo proton magnetic resonance spectroscopy (1H-MRS) using a whole body 3.0T MRI scanner (Achieva Intera, Philips, Best, The Netherlands). Dietary Cr intake was assessed by 3-day food recalls. Differences between groups were evaluated by unpaired T-tests and significance level was previously set at p < 0.05. Results As expected, vegetarians had lower dietary Cr intake than omnivores (0.042 ± 0.01 vs. 1.869 ± 0.745 g/d, respectively, p = 0.05). However, vegetarians and omnivorous displayed comparable brain Cr content (4.38 ± 0.60 and 4.15 ± 0.74 a.u.; p = 0.50). Discussion The main finding of this study is that dietary Cr intake has no influence upon brain Cr content in apparently healthy subjects. Previous studies have shown that oral Cr intake can benefit cognitive function in vegetarians rather than in omnivorous individuals, suggesting that the former may show a deficit in brain Cr content, like

occur in skeletal muscle. However, this study refutes this notion and reinforces previous speculation that brain Cr content mostly rely on endogenous synthesis, whilst dietary intake has a minor, if any, role in brain Cr pool in healthy individuals under no stressing condition (e.g.: sleep deprivation, exhausting exercise, mental disorders). In conclusion, dietary Cr content did not impact brain Cr content in adult healthy individuals.

### **INFLUENCE OF CALCIUM INTAKE ON BONE MASS IN ADOLESCENT SWIMMERS. PRELIMINARY RESULTS.**

Julian Almarcegui, C., Gomez-Cabello, A., Gonzalez-Aguero, A., Gomez-Bruton, A., Matute-Llorente, A., Casajus, J.A., Vicente-Rodriguez, A.

UNIVERSIDAD DE ZARAGOZA

Introduction Inadequate calcium (Ca) intake in adolescence might diminish peak bone mass with adverse implications later in life (Abrahams SA, 2011). Spanish Ca requirements could not be adequate to achieve good bone health (Mesías M et al., 2011). Swimmers might have low bone mass due to the non-osteogenic activity. Therefore, the aim of our study was to describe the Ca intake of adolescent swimmers and study its possible influence on bone mass. Methods 22 adolescent swimmers (11 females;  $14.68 \pm 1.73$  y) from Zaragoza (Spain) were evaluated by the Helena-DIAT (Dietary Assessment Tool) to register their daily Ca intake. Participants were classified as being under or over daily Ca intake recommendations. Dual energy X-ray absorptiometry (DXA) was used to evaluate bone mineral content (BMC) and density (BMD) at subtotal (whole body-head), trochanter, interthrocanter, femoral neck, Wards triangle, total hip and lumbar spine sites. Relationship between Ca intake and bone-related variables was examined by Pearson's bivariate correlation analyses. Differences between under Ca and over Ca groups for bone-related variables were tested by ANCOVA analyses controlling for age, height and subtotal lean mass. Results 55% of swimmers were over and 45% under Ca recommendations. No significant correlations were found between Ca intake and bone-related variables. After adjustments for age, height and subtotal lean mass, no significant differences were found in none of the bone-related variables between under and over Ca recommendations groups. Conclusion About half of the studied adolescent swimmers did not reach the dietary Ca intake recommendations. No association between Ca intake and bone mass related variables was observed. Not-meeting Ca intake recommendations seem not to be associated with lower BMC or BMD in this specific population. Further studies, with higher sample size, are needed to corroborate these preliminary findings. References Abrahams SA. (2011). *Curr Opin Clin Nutr Metab Care*, 14, 605-9. ### **CAN GLUTAMINE SUPPLEMENTATION ATTENUATE THE IMMUNOSUPPRESSION INDUCED BY RAPID WEIGHT LOSE ?**

Jesus de Cillo, M.E.1, Tritto, A.C.C.1, Figueiredo, N.C.C.1, Mendes, S.H.C.C.1, Amano, M.2, Oliveira, V.A.2, Lancha Jr, A.H.1, Gualano, B.1, Roschel, H.1, Camara, N.O.S.2, Artioli, G.G.1

University of Sao Paulo

Introduction In order to qualify for competing in a lighter weight class, many combat athletes reduce weight rapidly using a combination of methods (i.e., energy restriction and increased exercise) that may lead to an immunosuppression (Artioli et al., 2010; Yaegaki et al., 2007; Kowatari et al., 2001). Knowingly, both exercise and energy restriction reduces plasma glutamine, which is essential for the metabolism of immune cells. This suggests that reduced plasma glutamine may play a role in weight loss-induced immunosuppression. Therefore, we sought to investigate whether glutamine supplementation is able to attenuate this consequence. Methods For this double-blind, placebo-controlled, randomized, parallel group study, we recruited 39 athletes. Those who needed to reduce weight to compete were randomly allocated in 3 groups: glutamine supplementation (20 g.day<sup>-1</sup>, n=12), isonitrogenated placebo (albumin 26 g.day<sup>-1</sup>, n=11) and isocaloric placebo (dextrose 20 g.day<sup>-1</sup>, n=8). A 4th group of athletes who did not lose weight was also assessed (n=8). Athletes were assessed for monocyte and neutrophil phagocytic activity 21 days before (normal weight), 1 day before (weight loss) and 5 days after a real competition (recovered weight). Supplementation period was of 10 days, commencing on the 5th day before the competition. Results Rapid weight loss significantly reduced the phagocytic activity in monocytes, but not in neutrophils. However, no supplement has shown any significant effect on phagocytic activity, indicating that glutamine did not attenuate the immunosuppression. Discussion In this study, we confirmed that rapid weight loss negatively impacts selected parameters of the innate immune function, as it was previously shown (Yaegaki et al., 2007; Kowatari et al., 2001). Importantly, all 3 experimental groups responded similarly to weight loss, demonstrating that glutamine supplementation is not able to counteract the negative effects of weight loss on these parameters. Possibly, depletion of plasma glutamine is not the link between rapid weight loss and immunosuppression. References Artioli, G.G., et al., Prevalence, magnitude, and methods of rapid weight loss among judo competitors. *Med Sci Sports Exerc*. ### **DIETARY NUCLEOTIDE SUPPLEMENTATION PREVENTS THE OXIDATIVE STRESS OF LYMPHOCYTES AFTER STRENUOUS EXERCISE IN A COLD ENVIRONMENT**

Riera, J., Pons, V., Ferrer, M., Mestre, A., Martinez-Puig, D., Tur, J., Pons, A.

1. *Universitat de les Illes Balears*, 2. *Centre d'Alt Rendiment GIRSANE*, 3. *BIOIBERICA S.A*

PURPOSE: The aim of the present study was to test the impact of a specific nucleotide formulation (Immunactive®, Bioiberica, Spain) on the oxidative stress of lymphocytes of athletes after a heavy exercise bout in cold conditions. METHODS: Twenty male taekwondo athletes with a mean (±SD) age, height, weight, percent body fat, of  $21.4 \pm 6.3$  years,  $178.1 \pm 8.5$  cm,  $73.86 \pm 12.6$  kg,  $12.53 \pm 3.2$  % were included in a double-blind placebo-controlled trial. Two weeks before the test, all the subjects performed a cycling maximal incremental test to determine his maximal oxygen uptake (VO<sub>2</sub>max). The subjects were randomly divided into two groups of 10 subjects and were supplemented with placebo (P) or Immunactive (I) at 600mg/day during a period of 30 days. On day 0 and on day 30 each subject undertook an exhaustion exercise test using a cycloergometer. Immediately before, 30 minutes and 150 minutes after the test, blood samples were obtained for determination of blood cell concentrations and for the activity of the antioxidant enzymes glutathione reductase (GRd), glutathione peroxidase (GPx), catalase and superoxide dismutase (SOD) in lymphocytes. Malonaldehyde levels were also determined as a marker of lipid peroxidation. 24h after the exercise test blood samples were obtained for lymphocyte total proliferation. RESULTS: The exercise test induced an increase in leukocyte and neutrophil counts and a decrease in lymphocytes in both groups. Supplementation with dietary nucleotides during a period of 30 days resulted in a 60% reduction on the activity GRd as compared to placebo (124 vs 203 nkat/109 cells;

$p < 0.05$ ). After the exercise test a reduction on the activity of GPx and GRd was detected for the nucleotide group as compared to placebo. Differences were significant at 30 min after the exercise for GPx ( $p < 0.05$ ) and at 150 min for GRd ( $p < 0.05$ ). The MDA levels were numerically reduced in lymphocytes both before ( $0.419 \pm 0.063$  vs  $0.742 \pm 0.130$ ) and after the exercise test ( $0.464 \pm 0.034$  vs  $0.825 \pm 0.300$ ) for the nucleotide group as compared to placebo suggesting a trend towards the reduction of the oxidative damage. After the supplementation the rate of lymphocyte proliferation decreased at 24h after the exercise test in the placebo group but not in the Immunactive group ( $-15.34 \pm 5.25$  vs  $13.15 \pm 4.97$ ,  $p < 0.01$ ). CONCLUSIONS: These findings suggest that supplementation with a nucleotide-based product during 4 weeks could exert an antioxidant effect on lymphocytes as shown by a reduction on the glutathione dependant antioxidant enzymes and by a trend towards a reduction on the oxidative damage. The antioxidant response has been simultaneous to maintenance of the lymphocyte proliferation rate after exercise, suggesting a protective effect of dietary nucleotides.

### INFLUENCE OF TRAINING STATUS ON PERFORMANCE IN RESPONSE TO B-ALANINE.

Saunders, B.1,2, Painelli, V.S.1, Sale, C.2, Harris, R.C.3, Solis, M.Y.1, Roschel, H.1, Artioli, G.G.1, Lancha Junior, A.H.1

1: USP (São Paulo, Brazil), 2: NTU (Nottingham, UK), 3: Junipa Ltd (Newmarket, UK)

Introduction: The body of evidence surrounding the ergogenic effects of  $\beta$ -alanine (BA) supplementation is increasing, although the majority of studies showing an effect have used recreationally active participants. The effects of BA on trained athletes remain unclear and some authors speculate that athletes might be less responsive to its supplementation (Bellinger et al., 2012). It is possible that the true effect of BA on trained athletes might be mediated by differences in muscle buffering capacity between trained and untrained individuals (Sahlin and Henriksson, 1984). Therefore, the aim of this study was to investigate whether training status influences the ergogenic effect of BA supplementation on repeated Wingate performance. Methods: Forty males were allocated into a trained group (T; age:  $32 \pm 9$  years; body mass:  $70.4 \pm 7.8$  kg; height:  $1.80 \pm 0.05$  m) and an untrained group (NT; age:  $25 \pm 4$  years; body mass:  $75.1 \pm 9.5$  kg; height:  $1.77 \pm 0.07$  m) and both were further randomly allocated to a BA or matching placebo (PL) group. This provided four experimental conditions: NTPL, NTBA, TPL, TBA. Participants ingested BA (6.4 g/day) or PL for 4 weeks, with participants completing four 30-seconds lower-body Wingate bouts, separated by 3 minutes, before and after supplementation. All data are presented as mean  $\pm$  1SD and statistical significance was accepted at  $P < 0.05$ . Results: Total work done was significantly increased following supplementation in both NTBA ( $+1349 \pm 1411$  kJ;  $P = 0.03$ ) and TBA ( $+1978 \pm 1508$  kJ;  $P = 0.002$ ), and significantly reduced in NTPL ( $-1385 \pm 2815$  kJ;  $P = 0.03$ ) with no difference for TPL ( $-219 \pm 1507$  kJ;  $P = 0.73$ ). Compared to pre-supplementation, post-supplementation mean power output (MPO) was higher in bout 4 for NTBA ( $P = 0.0004$ ), while MPO was higher in bouts 1, 2 and 4 ( $P \leq 0.05$ ) for TBA. No differences were observed in MPO for NTPL and TPL. Discussion: Four weeks of BA supplementation was effective at improving repeated high-intensity cycling performance in untrained and trained individuals. Despite suggestions that trained individuals would not benefit from BA supplementation due to higher initial muscle buffering capacity, BA improved performance to a similar extent in both the untrained ( $2.52 \pm 2.64\%$ ) and trained ( $3.64 \pm 2.87\%$ ) participants. These data highlight the efficacy of BA as an ergogenic aid for high-intensity exercise regardless of the training status of the individual. References: Bellinger PM, Howe ST, Shing CM, Fell JW. (2012). Med Sci Sports Exerc, 44(8), 1545-1551. Sahlin K, Henriksson J. (1984). Acta Physiol Scand, 122(3), 331-339.

### INDICES OF BONE MINERAL STATUS IN OVERWEIGHT AND OBESE ADULTS ARE IMPROVED FOLLOWING VITAMIN D SUPPLEMENTATION DURING RESISTANCE TRAINING

Carrillo, A.E.1, Flynn, M.G.2, Markofski, M.M.3, Pinkston, C.3, Jiang, J.3, Donkin, S.S.3, Teegarden, D.3

1: Chatham University (Pittsburgh, PA, USA), 2: College of Charleston (Charleston, SC, USA), 3: Purdue University (West Lafayette, IN, USA)

Introduction Evidence is accumulating to support that vitamin D recommendations should be increased to achieve optimal bone health. Bone health has also been found to be maintained or improved following resistance exercise training. The purpose of the current study was to investigate the effects of vitamin D supplementation during resistance training on bone mineral status (i.e. bone mineral density and bone mineral content) in overweight and obese adults. Methods In a 12-week, double-blind, placebo-controlled trial, twenty-three overweight and obese (age:  $26.1 \pm 4.7$  years; BMI:  $31.3 \pm 3.2$  kg/m<sup>2</sup>) adults were randomized into a vitamin D supplementation (VitD 4000 IU/day; female 5, male 5) or placebo (PL, female 7; male 6) group. Both the VitD and PL groups performed 12 weeks of resistance exercise training. Parathyroid hormone and bone mineral status were assessed prior to and following the 12-week intervention. Bone mineral status was determined using dual energy X-ray absorptiometry. Results No differences in absolute levels of bone mineral density (BMD) or bone mineral content (BMC) were detected at any of the measured sites between groups at baseline or at 12 weeks ( $P > 0.05$ ). During the intervention, however, android and leg BMC as well as spine BMD were significantly increased in the VitD group only ( $P < 0.05$ ). Furthermore, the change in spine BMD was significantly different between the VitD ( $0.047 \pm 0.033$  g/cm<sup>2</sup>) and PL ( $-0.001 \pm 0.045$  g/cm<sup>2</sup>) groups ( $P = 0.011$ ). For VitD and PL groups combined, PTH was negatively correlated with pelvis ( $r = -0.625$ ;  $P = 0.002$ ), trunk ( $r = -0.505$ ;  $P = 0.02$ ), and spine BMD ( $r = -0.540$ ;  $P = 0.012$ ) at baseline. After the 12 week intervention, PTH was negatively correlated with trunk ( $r = -0.475$ ;  $P = 0.026$ ) and spine BMD ( $r = -0.534$ ;  $P = 0.01$ ) as well as android BMC ( $r = -0.514$ ;  $P = 0.014$ ). Discussion Vitamin D and resistance exercise training have been shown to independently produce small gains in BMD particularly at the hip and spine. In the current study, vitamin D supplementation during resistance training enhanced exercise-induced changes in android and leg BMC as well as spine BMD in healthy overweight and obese participants.

### MUSCLE PROTEIN SYNTHESIS AND MOLECULAR EVENTS UNDERPINNING CHANGES IN TISSUE METABOLISM WITH WHEY AND SOY INGESTION IN ENERGY RESTRICTION IN OVERWEIGHT/OBESE ADULTS

Marcotte, G.1, Hector, A.1, Churchward-Venne, T.1, Breen, L.1, Murphy, C.1, Von Allmen, M.1, Baker, S.1, Phillips, S.1

McMaster University

1: Exercise Metabolism Research Group \*Both authors contributed equally Introduction Diet-induced weight loss results in the loss of fat and lean body mass (1); however, increased protein intake during a hypoenergetic diet can improve fat mass loss and lean mass retention (2). This may be attributed to increased muscle protein synthesis (MPS) rates, which are more effectively stimulated by dairy-based proteins such as whey compared to soy (3). The aim of this study was to evaluate the mechanisms by which whey and soy proteins promote fat mass loss and lean mass retention during a hypoenergetic diet. Methods In a double blind investigation, adult men and women ( $n=40$ , BMI 28-40) underwent a 14 day hypoenergetic diet supplemented with whey (WHY) or soy (SOY) protein, or a carbohydrate (CHO) control. Pre and post diet intervention testing included a primed constant infusion of L-[ring-13C6] phenylalanine with skeletal muscle biopsies to measure MPS in the postabsorptive state and following WHY, SOY, or CHO ingestion. Changes in total fat and fat free

mass were measured by DEXA and immunoassay was used to measure cortisol, TNF- $\alpha$ , IL-6, CRP, IGF-1, glucose and insulin. Results The self-reported energy deficit for WHY, SOY and CHO averaged ( $\pm$  SEM)  $-680 \pm 37$ ,  $-750 \pm 38$  and  $-832 \pm 39$  (kcal/d) respectively, with a significant ( $P < 0.05$ ) difference between WHY and CHO. WHY and SOY consumed significantly ( $P < 0.01$ ) more protein ( $1.26 \pm 0.03$ ) (g/kg\*d) than CHO ( $0.75 \pm 0.02$ ). Daily carbohydrate ( $215 \pm 10$  g/d) and fat ( $47 \pm 2$  g/d) intake, total weight loss ( $-2.29 \pm 0.18$  kg), fat mass loss ( $-1.19 \pm 0.16$  kg) and lean mass loss ( $-0.81 \pm 0.24$  kg) did not significantly differ between groups. No group or time effects were observed for pre- to post-intervention concentrations of TNF- $\alpha$ , IL-6, CRP, and IGF-1. Plasma cortisol was unchanged in WHY but increased significantly ( $p < 0.05$ ) in SOY and CHO. Discussion Regardless of dietary intervention all individuals lost fat and lean mass. The lack of a treatment effect on body composition may be due to the acute nature of the study. Given that cortisol is a signal for muscle proteolysis, the lower levels in WHY may provide one potential mechanism for a lean mass sparing effect. We hypothesize that a group effect will be further reflected in the more sensitive measurements of MPS, protein signaling and gene expression. 1) Weinheimer EM, Sands LP, and Campbell WW (2010). *Nutr Rev* 68.7: 375-388 2) Krieger JW, Sitren HS, Daniels MJ, Langkamp-Henken B (2006). *Am J Clin Nutr* 3:260-274 3) Tang JE, Moore DR, Kujbida GW, Tarnopolsky MA, & Phillips SM (2009). *J App Physiol* 107(3): 987-992

## THE EFFECTS OF TWO DIFFERENT DOSES OF CALCIUM LACTATE ON HIGH-INTENSITY INTERMITTENT PERFORMANCE

Artioli, G.G., Painelli, V.S., Silva, R.P., Oliveira Jr, O.M., Oliveira, L.F., Benatti, F.B., Rabelo, T., Guilherme, J.P.L.F., Lancha Jr, A.H.

*School of Physical Education and Sport. University of Sao Paulo*

Introduction Studies suggest that lactate supplementation may enhance high-intensity exercise performance by increasing extracellular buffering capacity (Van Montfoort et al., 2004; Morris et al., 2011). However, evidence is limited and optimal dosage is not known. Thus, we aimed to examine the ergogenic effects of two different doses of calcium lactate. Methods 12 male individuals underwent performance evaluation trials in 4 different occasions: familiarization, 90 min after ingesting 150 mg.kg<sup>-1</sup> calcium lactate (LOW), 90 min after ingesting 300 mg.kg<sup>-1</sup> calcium lactate (HIGH), and 90 min after ingesting 150 mg.kg<sup>-1</sup> calcium carbonate (placebo - PL). High-intensity intermittent performance was assessed by 3 bouts of the 30-s Wingate Test for upper body (0.4 kp.kg<sup>-1</sup>; 3 min recovery between bouts). The study was conducted in a double-blind, cross-over, counterbalanced design. Venous blood samples were collected before and 90 min after capsule ingestion, and immediately after exercise for bicarbonate and pH determination. Results Pre- and post-exercise blood bicarbonate was not affected by calcium lactate, regardless the dose ingested. Similarly, calcium lactate did not elicit any significant change in blood pH as well as in performance (total work done (J): LOW:  $26252 \pm 2666$ ; HIGH:  $25600 \pm 2271$ ; PL:  $25496 \pm 2679$ ;  $F = 0.30$ ,  $p = 0.74$ ). Discussion A few studies have suggested that lactate ingestion is beneficial for high-intensity exercise performance, since the excess of blood lactate could be oxidized or converted into glucose. In both cases, the overall net balance of reactions would result in the removal of free H<sup>+</sup> ions, which could ultimately elevate blood pH and bicarbonate levels. Van Montfoort et al. (2004) showed a ~1% increase in performance after ingesting 0.36 mosmol.kg<sup>-1</sup> sodium lactate. A remarkably larger performance improvement (+17% in TWD) was observed by Morris et al. (2011) after the ingestion of 120 mg.kg<sup>-1</sup> of lactate. In our study, neither a similar dose (150 mg.kg<sup>-1</sup>) nor the double dose (300 mg.kg<sup>-1</sup>) of calcium lactate was capable of increasing blood bicarbonate and blood pH. Exercise capacity was also unaffected, despite the use of a very acidotic exercise protocol, which was previously shown to be sensitive to detect performance improvements caused by alkalinising agents (Artioli et al., 2007). ## SUBOPTIMAL VITAMIN D INTAKE IN FEMALE ELITE SPANISH GYMNASTS

Grams, L., García, A.I, Ibáñez, A.I, González, A.I, Garrido, G.I

*Faculty of Physical Activity and Sport Sciences-INEF (Technical University of Madrid, Spain)*

Introduction: Gymnasts usually train indoor reducing time to sun exposure. In Madrid (latitude 40°) at least in fall and winter period, vitamin D synthesis associated to sun exposure could be compromised. Furthermore, low caloric intake in gymnastics could lead to low micronutrient consumption. Recently established dietary allowance (RDA) for vitamin D (FNB, 2011) are still controversy discussed for being insufficient (Heaney & Holick, 2011). Therefore the aim was to compare different nutritional patterns in gymnasts and examine the relationship between energy and micronutrient intake derived from food group in order to propose nutritional advice to reach recent RDA recommendations. Methods: Energy intake was analysed in 40 Spanish elite gymnasts -23 rhythmic (R) and 17 artistic (A) - age  $15.5 \pm 1.9$ ,  $15.5 \pm 2.2$  yrs and weight  $48.0 \pm 6.7$ ,  $44.6 \pm 4.7$  Kg respectively. Diet composition was estimated by food weighing (Mettler-Toledo  $\pm$ lg) for a 5-day period. An open database of Spanish food items (Dial Alce®) was used to determine nutrient intakes. Meanwhile gymnasts completed a 24h activity questionnaire to estimate energy expenditure. Results: Energy intake ( $1862 \pm 398$  vs.  $1560 \pm 270$  Kcal/d) was higher ( $p < 0.01$ ) in R. Additionally energy distribution was lower in CH (48% vs 54%,  $p < 0.05$ ) and higher in lipids 35% vs 30% ( $p < 0.05$ ). Vitamin D intake was insufficient ( $6.9 \pm 2.9$  vs.  $5.6 \pm 1.7$   $\mu$ g/d) and no gymnast reached RDA recommendations for vitamin D (15  $\mu$ g/d). Diet vitamin D density was similar in both groups and correlated to energy derived from fish ( $r = 0.495$ ) and cereals ( $r = 0.377$ ). Calcium intake was marginal in both groups ( $991 \pm 300$  vs.  $1047 \pm 226$  mg/d) and only 3 gymnasts reached calcium RDA (1300mg/d). Nevertheless, diet calcium density (mg Ca/1000Kcal) was lower ( $p < 0.01$ ) in R. Calcium intake was correlated to energy derived from dairy ( $r = 0.578$ ) and cereals ( $r = 0.516$ ). Magnesium and vitamin E intake were suboptimal in both groups and only 6 gymnasts reached RDAs. Energy derived from fruit intake was greater ( $p < 0.05$ ) in A. In contrast, group A consumed less energy intake, which comes from meat ( $p < 0.01$ ), fish ( $p < 0.01$ ) and fat ( $p < 0.05$ ) and could explain lower cholesterol intake in this group ( $p < 0.01$ ). Discussion/Conclusion: Nutritional intervention in order to increase the intake of skimmed dairy, white fish, and varied fortified vitamin D and/or calcium products could improve diet composition in these gymnasts. Likewise vitamin D and calcium supplementation could be recommended for these young elite gymnasts. FNB. (2011). Dietary Reference Intakes for calcium and vitamin D. **IMPACT OF INTERMITTENT HYPOXIC EXPOSURE SESSION ON RECOVERY FROM CYCLING IN HEAVY INTENSITY DOMAIN**

Beckert, J.1,3, Minhalma, R.2, Alves, F.2, Neuparth, N.1

1: CEDOC, FCM, UNL (Lisboa, Portugal), 2: CIPER, FMH, UTL (Lisboa, Portugal) 3: INSTITUTO DO DESPORTO DE PORTUGAL

**INTRODUCTION** The intermittent hypoxia exposure (IHE) is a mode of administration of hypoxia already used in ergogenic programs applied to high performance athletes. Generally, coaches consider the 60-minute sessions carried out 5 times per week for 3 weeks as compatible with the normal training. However, it is not known the impact of an IHE session in a subsequent training session. Our aim is to identify the effect of a session of IHE in exchanges of ventilatory gases, testing the hypothesis that IHE decreases overall aerobic efficiency during exercise in the heavy intensity domain and augments the "O<sub>2</sub> debt". The question is relevant in human physiology of hypoxia and has potential to transfer to coaches's practice. **METHODS** We conducted a research study in which we assessed eight triathlon athletes in exercise, before and after the completion of a IHE session correspondent to 4500 m ("Hypoxia"). Each IHE session consist of 5 min of hypoxic administration by facial mask and 5 min of breathing normoxic air. The study was controlled by unilateral occlusion of the exposure condition. So the volunteers athletes performed another evaluation session of exercise before and after normoxic exposition in which the set up for IHE was applied but with an O<sub>2</sub> % of 20.9 ("Normoxia"). Exercise intensity in cycloergometer was normalized to 40% of delta VO<sub>2</sub>, correspondent to heavy domain intensity determined after a maximal incremental test. The intensity was kept constant during each bout and was the same for all the exercise bouts. VO<sub>2</sub>, VCO<sub>2</sub> and ventilation (VE) in exercise and in the first 5 recovery min were recorded breath by breath. Significance was set at p≤0.05. **RESULTS** In this study we find a 4% decrease in mean CO<sub>2</sub> production during exercise but no significant difference in O<sub>2</sub> production or VE in exercise. Otherwise, we find a 8% VO<sub>2</sub> increase during recovery of exercise bouts after hypoxic exposition. **DISCUSSION** The increase in VO<sub>2</sub> during recovery due to the previous hypoxic exposition represents an increase in the "VO<sub>2</sub>-debt". The aerobic efficiency during exercise was not affected. Although the low impact of a single IHE session in subsequent exercise in normoxia, coaches must be aware of the impact in recovery. **REFERENCES** Bailey, S. J., A. Vanhatalo, et al. (2009). *J Appl Physiol* 107(6): 1743-1756. Burnley, M., J. H. Doust, et al. (2006). *J Appl Physiol* 101(5): 1320-1327.

**EFFECT OF PEDAL CADENCE ON THE HETEROGENEITY OF MUSCLE DEOXYGENATION DURING MODERATE EXERCISE**

Zorgati, H., Cillomp, K., Amiot, V., Prieur, F.

*University of Paris Sud*

This study examines the effect of pedal cadence on the heterogeneity of muscle deoxygenation during exercise of moderate intensity. Twelve healthy subjects performed six minutes of cycling at 40 and 100 rpm at 80% of the workload corresponding to the gas exchange threshold. Gas exchanges were measured breath-by-breath during each exercise. Muscle deoxygenation (HHb i.e. O<sub>2</sub> extraction) and blood volume (tHb) were monitored continuously by near-infrared spectroscopy at eight sites on the vastuslateralis. The heterogeneity of HHb and tHb was assessed using the relative dispersion of the signal measured at the eight sites (i.e. 100 x standard deviation/mean). HHb and tHb were not altered by the pedal cadence, while pulmonary V'O<sub>2</sub> was higher at 100 than at 40 rpm (p < 0.001). The relative dispersion of HHb was significantly higher at 100 rpm compared to 40 rpm (p < 0.001) whereas no significant difference was shown for the relative dispersion of tHb. These results indicate that the pedal cadence has no effect on O<sub>2</sub> extraction but that an elevated cadence would increase muscle V'O<sub>2</sub>, suggesting an increase in muscle blood flow. Elevated cadence also induced greater heterogeneity of the muscle's V'O<sub>2</sub>/Q'O<sub>2</sub> delivery ratio, suggesting impairment in the adequacy between O<sub>2</sub> demand and O<sub>2</sub> delivery in some regions of active muscle.

**ARTERIAL DESATURATION IN BLACK AND WHITE RUNNERS IN NORMOXIC AND HYPOXIC CONDITIONS**

Santos-Concejero, J.1, Myburgh, K.H.2, Kohn, T.A.1,2

1. UCT/MRC Research Unit for Exercise Science and Sports Medicine, University of Cape Town (South Africa); 2. Department of Physiological Sciences, University of Stellenbosch (South Africa)

**Introduction** It has been hypothesized that early life factors in African runners can influence their cardiopulmonary function, reducing the degree to which arterial saturation (SpO<sub>2</sub>) drops during high-intensity exercise. Consequently, this may contribute to the development of a later life phenotype optimized for physical performance (1). Since this hypothesis has never been investigated, the main purpose of this study was to examine SpO<sub>2</sub> in Black and White runners under normoxic and hypoxic conditions at different exercise intensities. **Methods** Eight well-trained Black South African (23.7 ± 3.2 years and 33.4 ± 0.4 min 10-km race time) and six White (21.5 ± 1.7 years and 33.5 ± 0.8 min) runners participated in this study. VO<sub>2</sub>max and peak treadmill speed (PTS) were measured using a progressive test. Submaximal physiological responses (including SpO<sub>2</sub> via pulse oxymetry) were measured at 64, 72, 80, and 88% of PTS in normoxic and hypoxic (FI<sub>O2</sub>≈14%) conditions. Skeletal muscle enzyme activities (citrate synthase, phosphofructokinase, 3-hydroxyacetyl CoA dehydrogenase and lactate dehydrogenase) and muscle fibre composition were also determined. **Results** Black runners were shorter (171.4 ± 2.4 vs. 181.2 ± 2.4 cm, p<0.05) and had lower maximal minute ventilation (VE) than the White runners (137.4 ± 7.9 vs. 162.3 ± 5.4 L/min, p<0.05), but they did not present any other difference in maximal parameters, including VO<sub>2</sub>max. Black runners displayed higher SpO<sub>2</sub> than the White runners when running at 80% of their PTS in hypoxic conditions (81.3 ± 11.2 vs. 70.1 ± 7.1%, p<0.05), but not in normoxia. No differences in the enzyme activity and muscle fibre composition were found. **Discussion** The present study provides evidence that Black runners are less susceptible to hypoxia than White runners, especially with regard to exercise-induced hypoxaemia. It has previously been reported that a low arterial saturation may imply a reduced muscle O<sub>2</sub> supply (2). Additionally, it is known that performance is seriously impaired when the SpO<sub>2</sub> drops below 87% (3). Therefore, results of this study may imply that outstanding running performance in Black runners is attributable, at least when running under hypoxic conditions, to less severe exercise-induced hypoxaemia. **References** 1. ### EFFECTS OF CONVENTIONAL ALTITUDE TRAINING ON TOTAL HAEMOGLOBIN MASS IN FEMALE KAYAKERS

Malczewska-Lenczowska, J.1, Sitkowski, D.1, Pokrywka, A.1, Kryk, T.2, Szygula, Z.3, Grochowska, J.1

*Institute of Sport, Warsaw; 2Polish Canoe Federation, Warsaw; 3University School of Physical Education, Cracow*

Do not insert authors here Introduction Total haemoglobin mass (tHb-mass) is one of the key factors contributing to aerobic performance [2]. Conventional altitude training can bring about an increase in tHb-mass although the reported results are often controversial [1,4]. Furthermore, little research has focused on the persistence of tHb-mass after descending from altitude, especially after a prolonged stay there [3]. The aim of this study was to examine the impact of 3-week classical altitude training on tHb-mass and to evaluate its stability after 24 days of residing at the sea level. Material and Methods Five elite female kayakers (age: 20.5±7.8 years, height: 1.67±0.04 cm, body mass: 65.7±7.57 kg) stayed at 2000 m and trained at about 2400 m above the sea level for 21 days. The tHb-mass (optimised CO-rebreathing method), haemoglobin concentration (Hb) and hematocrit (Ht) were measured in venous blood (Advia 120) and plasma volumes were computed. All measurements were taken at baseline and at two points after training camp, i.e. one and 24 days later. Differences in mean changes between consecutive measures were analysed using Wilcoxon's signed-rank test ( $p < 0.05$ ). Results After training camp, the tHb-mass increased, on average, by 2.2% but individual responses of that index varied from -1.6% to +8.9%. Haemoglobin concentration and hematocrit increased significantly ( $p < 0.05$ ) by 8.3% (0.7 – 14.1%) and 4.7% (1.8 – 8.6%), respectively; 24 days after the training camp, tHb-mass decreased significantly ( $p < 0.05$ ) by 1.6% (-0.6 to -4.0%). Significant decreases in Hb concentration and Ht value were also observed. Mean value of Hb decreased by 12.6% (-8.2 to -16.3%) and mean Ht value by 9.0% (-7.5 to -11.3%). Conclusions The tHbmass responds to training under hypoxia conditions to a variable degree but decreases significantly upon the return to the sea level. Marked changes in plasma volume support the theory that Hb concentration and Ht value are not reliable in assessing changes in the total amount of haemoglobin in blood under hypoxia conditions or immediately after the return to normal conditions. ### INTERMITTENT HYPOXIC TRAINING IMPROVES SEA LEVEL PERFORMANCE IN TEAM SPORT ATHLETES

Aughey, R.J.1,2, Inness, M.W.H.1,2, Billaut, F.3

*Victoria University / Western Bulldogs FC, Institut national du sport du Québec*

Introduction Altitude training has been used extensively by endurance athletes, however less is known on the efficacy of this method for enhancing team-sport (TS) athlete performance. Intermittent hypoxic training (IHT), improves glucose and glycogen handling, and pH regulation.1-3 Such adaptations may positively influence TS performance. This study therefore investigated whether IHT is superior to normoxic training to improve TS athlete performance at sea level. Methods: Twenty-one Australian footballers volunteered for the study, were matched for Yo-Yo intermittent recovery test level 2 performance (Yo-YoIR2), and assigned to either the IHT (n=10) or control (n=11). The IHT group performed 11 40-min IHT sessions over 4 weeks at 2500 m simulated altitude consisting of 3 to 4, 5-min cycling intervals separated by 2.5 min. The control group performed 2 bike sessions per week in normoxia, while the IHT group was removed from portions of normal squad training to ensure training load was matched based on session RPE. The Yo-YoIR2 was performed on both groups at baseline, after 3, 6, and 11 IHT sessions, and 30 and 44 days post intervention. Haemoglobin mass (Hbmass) was measured in the IHT group at baseline, after 3, 6, 9 and 11 IHT sessions. No Hbmass measures were obtained from the control group. Differences were assessed using effect size and magnitude based inferences. Results Training was not clearly different between groups (ES -0.35±0.69). Baseline Yo-YoIR2 was not different, yet IHT improved, 15% (ES 0.44±0.63) more than control after just one week, 28% (ES 0.77±0.57) after two weeks and this was maintained until 30 days post training. This enhancement was likely independent of Hbmass change as this did not change from pre-training until week 2. Discussion Three IHT sessions increased Yo-YoIR2 performance in TS athletes over control with matched training load. Further improvement in Yo-YoIR2 was evident after 2 weeks of IHT, and this was maintained until 30 days post training. Short-term IHT is therefore an effective strategy to enhance team sport athlete performance. References 1. Dufour SP, Ponsot E, Zoll J, et al. *J Appl Physiol* 2006; 100(4):1238-1248. 2. ### EFFECTS OF EXERCISE TYPE PERFORMED UNDER HYPOBARIC HYPOXIC CONDITIONS ON BLOOD PRESSURE AND VASCULAR ADAPTATIONS

Ogita, F.1, Kurobe, K.2, Huang, Z.3, Nagira, A.1, Nishiwaki, M.4, Yotani, K.1, Tanaka, T.1, Tamaki, H.5

*National Institute of Fitness and Sports*

Introduction Recently, we have observed that aquatic exercise in hypobaric hypoxia could induce beneficial vasculature adaptations, such as a decrease in blood pressure and arterial stiffness, and an increase in flow mediated vasodilation (FMD) response, within a relatively short training period (Ogita 2011). However, it has not been clarified whether such vascular adaptations can be also obtained by another type of exercise. Therefore, the present study aimed to examine the effects of exercise type performed under hypobaric hypoxic conditions on vascular adaptations. Methods Thirty-eight healthy male adults (24±3 yrs) were matched for baseline measurements into groups of 4 and then randomized to 1) aquatic exercise in normobaric normoxia (N-AE, n=10), 2) in hypobaric hypoxia (H-AE, n=10), 3) cycling exercise in normobaric normoxia (N-CE, n=8), or 4) in hypobaric hypoxia (H-CE, n=10). The exercise training was done at the intensity of 50%VO<sub>2</sub>max for 30 minutes/training session for consecutive 5 days. H-AE and H-CE were done in the hypobaric hypoxic conditions corresponding to 2500m above sea level, and they were exposed to the conditions for 2 hours/session. Before and after the training, systolic (SBP), diastolic (DBP) and mean blood pressure (MBP) were determined at rest and during cycling exercise at 50%VO<sub>2</sub>max. FMD was evaluated by determining the change in popliteal artery diameter during reactive hyperemia, which was measured by ultrasound imaging system. Also, arterial stiffness was assessed by brachial-ankle pulse wave velocity (baPWV). Results After the training, no significant changes were observed in all measured values for N-AE, N-CE, and H-CE. Blood pressure at rest did not change significantly in H-AE, either, however, SBP and MBP during moderate exercise decreased significantly after the training ( $P < 0.05$ ). The popliteal artery diameter during reactive hyperemia significantly increased ( $P < 0.01$ ), and consequently, %FMD significantly increased ( $P < 0.01$ ). Furthermore,

baPWV significantly decreased ( $P < 0.01$ ). Discussion Our findings suggest that exercise in hypobaric hypoxia induces a decrease in blood pressure and arterial stiffness, and also an improvement of endothelial function within a relatively short period more effectively than exercise in normoxia, and that the induced vascular adaptations might vary with the exercise type. Reference Ogita, F., et al. (2011) Effects of intermittent hypobaric hypoxic exercise of 5 days on blood pressure and vascular adaptations. Book of Abstracts, 16th Annual Congress of ECSS: 546.

### **SYNERGISTIC EFFECTS OF ENDURANCE TRAINING AND INTERMITTENT HYPOBARIC HYPOXIA IN THE DECREASE OF BODY WEIGHT, FOOD INTAKE AND OXYGEN CONSUMPTION IN RATS**

Torrella, J.R., Ascensão, A., Rizo, D., Pagès, T., Viscor, G., Magalhães, J.

*Facultat de Biologia - Universitat de Barcelona*

We aimed to analyze the effects of combined protocol of endurance training (ET) and chronic-intermittent hypobaric-hypoxia (IHH) on body and heart weight, food and water intake, and oxygen consumption in rats. Twenty-eight young-adult male rats were divided into four groups ( $n=7$ ): normoxic sedentary (NS), normoxic exercised (NE), hypoxic sedentary (HS) and hypoxic exercised (HE). Trained animals ran 1 h/day in a treadmill during 5 weeks at a speed of 25 m/min (0% gradient) and hypoxic animals were exposed for 5 weeks, 5 h/day, 5 days/week to a simulated atmospheric pressure of 493 hPa (6,000 m). Body weight and food and water intake were controlled individually every three days. The oxygen consumption was measured before and after the protocol in a sealed chamber connected to a multichannel pump air supply unit and to an oxygen gas analyzer. Both hypoxic groups showed significant decreases in body weight from the twelfth day of exposure, reaching final 10% (HS) to 17% (HE) differences when compared to the control group (NS). ET normoxic rats (NE) also showed a significant weight reduction after the ninetieth day of training with a decrease of 7% at the end of the protocol. Since heart weight was not altered between groups, the ratio heart-to-body weight was significantly greater in both hypoxic groups. The decrease in hypoxic animals' body weight was related with significant hypophagia elicited by IHH exposure, (from 8% to 10%). In contrast, ET had no effect on food ingestion. Total water intake was not affected by hypoxia but was significantly increased in exercised animals. Data regarding oxygen consumption (expressed as mean mL O<sub>2</sub>/kg/min  $\pm$  SEM) exhibit two interesting findings. First, there is a significant decrease in both hypoxic groups after the protocol (HS,  $21.7 \pm 0.70$  vs.  $19.1 \pm 0.78$  and HE,  $22.8 \pm 0.80$  vs.  $17.1 \pm 0.90$ ). Second, a significant difference was found between NE ( $21.3 \pm 0.77$ ) and HE ( $17.1 \pm 0.90$ ). These results demonstrate a synergistic effect of ET and IHH in the decrease of body weight that could open new insights regarding weight control strategies. Moreover, our study provides evidence that rats underwent a hypometabolic state after being exposed to an IHH program.

### **EFFECTS OF HYPOXIA AND ACCLIMATION ON THE ENZYMATIC ACTIVITY OF MATRIX METALLOPROTEINASES 2 AND 9 IN RAT LUNG**

Rizo, D., Coimbra, D., Ríos-Kristjánsson, J.G., Núñez, C., Pagés, T., Torrella, J.R., Viscor, G.

*Facultat de Biologia-Universitat de Barcelona*

Introduction: Matrix Metalloproteinases (MMPs) are zinc-dependent endopeptidases (always synthesized as proenzymes) able to degrade the endothelial basal lamina, thus increasing vascular permeability. Because of vascular permeability alteration seems to be involved in the origin of High Altitude Pulmonary Edema (HAPE), to study the effects of hypoxia on MMPs activity could improve our knowledge about the molecular and physiological mechanism of HAPE. The aim of this study was to determine the response of MMP-2 and MMP-9 to an acute normobaric hypoxia bout and the possible benefit of an intermittent hypobaric hypoxia exposure (IHHE) program as pre-acclimation protocol. Methods: Thirty Sprague-Dawley male rats ( $250 \pm 13$  g) were randomly divided into five groups. Three groups (H0, H24 and H48) were exposed to 6 hours of 7% oxygen concentration (deep normobaric hypoxia) and then euthanized after 0, 24 or 48 h. Another group (Acl) was acclimated with an IHHE protocol consisting of 8 sessions (one per day) of 4 hours at an equivalent altitude of 4000m and then exposed to an acute hypoxia bout. The last group (Ctr) was used as control. Rats were anesthetized with an i.p. injection containing ketamine (60 mg/Kg) and xylazine (7.5 mg/Kg). Lungs were excised, frozen in liquid N<sub>2</sub> and stored at  $-80^{\circ}\text{C}$ . The pro- and active forms of MMP-2 and MMP-9 were analyzed by gelatine zymography. Results: In H0 group pro- and active MMP-2 and proMMP-9 activities were increased by 2, 1.8 and 3.6 fold, respectively ( $P < 0.05$  vs Ctr). ProMMP-2 maintained the same levels after 24 and 48 h, while its active form continued increasing until reaching a 2.7-fold increase in H48 group ( $P < 0.05$  vs H0), and proMMP-9 decreased its levels in H48 group ( $P < 0.05$  vs H0). In the Acl group the proMMP-2 and the proMMP-9 increase was significantly smaller than in the non-acclimated group ( $P < 0.05$  and  $P < 0.001$  vs H0, respectively), while the active MMP-2 form remained at the basal level. Conclusions: These data demonstrate that MMP-2 is more sensitive to normobaric hypoxia than MMP-9. Although both proforms are quickly increased by hypoxia, the active form was only significantly increased in MMP-2. Regarding the acclimation, these results show that IHHE can be a useful tool to avoid the increase in matrix metalloproteinases levels and, consequently, to reduce the risk of HAPE.

### **INFLUENCE OF CARBON MONOXIDE BOLUS AND HYDRATION ON THE ROBUSTNESS OF TOTAL HAEMOGLOBIN MASS MEASUREMENT**

Turner, G.1,2, Pringle, J.2, Ingham, S.2, Richardson, A.1, Maxwell, N.1

*1: University of Brighton (Eastbourne, UK), 2: English Institute of Sport (Loughborough, UK)*

Introduction The optimised carbon monoxide (CO) rebreathing method (oCOR-method) (Prommer and Schmidt, 2007) is used routinely to measure total haemoglobin mass (tHbmass). Altitude exposure can typically elicit 5-8% increases tHbmass, which may lead to improvements in endurance performance. However, the tHbmass measure is subject to error of  $\sim 2\%$ , mostly from the precision of carboxyhaemoglobin (HbCO) measurement. We sought to establish the robustness of the tHbmass measure in relation to differences in the bolus of CO administered during the oCOR-method and under different states of hydration. Methods Twelve physically active, healthy subjects (10 males and 2 females; age  $27 \pm 6$  yr, height  $177 \pm 11$  cm, weight  $73.9 \pm 12.1$  kg) completed the oCOR-method in a randomised order. Study 1 ( $n = 7$ ) investigated the influence of hydration status (hypohydrated; HYPO, hyperhydrated; HYPER and euhydrated; EU), whilst administering a CO bolus of 1.0 ml/kg. Study 2 ( $n = 12$ ) investigated size of CO bolus (LOW: 0.6 ml/kg; MED1: 1.0 ml/kg and HIGH: 1.4 ml/kg). To determine the repeatability of MED1, a second trial was conducted (MED2). Hbmass was calculated from three replicates of carboxyhaemoglobin concentration (%HbCO) at each time point of the oCOR-method. Results The %TEM ( $\pm$  confidence intervals) for tHbmass measure with a MED bolus was  $0.8\% (\pm 2.3\%)$ . ANOVA revealed no significant differences ( $p > 0.05$ ) between tHbmass measured in HYPO ( $757 \pm 135$  g), EU ( $769 \pm 138$  g) and HYPER ( $768 \pm 149$  g) states. tHbmass was found to be significantly less in the HIGH CO bolus ( $776 \pm 148$  g) when compared to the LOW CO ( $791 \pm 149$  g) or MED CO ( $787 \pm 149$  g) trials. Discussion Altering hydration status when

completing the oCOR-method did not affect the measurement of tHbmass. However, the derived tHbmass value was slightly different when using the HIGH CO bolus, being 1.4% less compared to MED1 and 3.2% less compared to LOW. In the absence of a gold standard comparison, but given that the TEM of the oCOR-method in the current study was 0.8%, the bolus administered during the test is meaningful. An adequate CO dose is particularly important if estimating %HbCO levels with commercial CO-oximeters that display readings only to a single decimal place (usually  $\pm 0.1\%$ ). Therefore, with progressively lower doses of CO, a 0.1% difference in the %HbCO is associated with a substantial increase in the measurement error of tHbmass (Burge and Skinner, 1995). In the elite athlete setting where identifying marginal increases in tHbmass is important, consistency in the CO bolus administered is critical. References Prommer N, Schmidt W. ### EFFECT OF HIGH-INTENSITY INTERMITTENT TRAINING IN HYPOXIA ON REPEATED PEDALING PERFORMANCE IN FEMALE ATHLETES

Kasai, N., Ishimoto, S., Sakamoto, E., Maruta, M., Mizuno, S., Goto, K.

*Ritsumeikan University*

**Introduction** Until now, advantage of hypoxic training on endurance capacity has been widely acceded among long distance athletes. Recently, a growing evidence suggests the favorable effect of high-intensity training at a simulated altitude on improvement of anaerobic capacity. However, little information is available regarding impact of high-intensity training in hypoxia among female athletes. Therefore, the purpose of this study was to determine the effect of intermittent hypoxic training in female ball game players. **Methods** Thirty-two college female athletes were randomly assigned to either normoxic training group (NOR, n=16) or hypoxic training group (HYPO, n=16). The HYPO group conducted 2 sessions of 10x7s maximal pedaling (30s rest between sets) under normobaric hypoxic condition (FIO<sub>2</sub>:14.5%), whereas the NOR group performed equivalent training under normoxic condition (FIO<sub>2</sub>:20.9%). Each training session was repeated twice per week for 4 week. Before and after the training period, power output during intermittent maximal pedaling (10x7s maximal pedaling) and VO<sub>2</sub>max were determined. **Results** The HYPO group showed a significant increase in maximal power output during intermittent maximal pedaling test after the training period (P<0.05), whereas no change was observed in the NOR group. Both groups showed significant increases in average power output after the training period (P<0.05). However, the percentage change between before and after the training period was significantly greater in the HYPO group (9.7 $\pm$ 0.9%) than in the NOR group (6.0 $\pm$ 0.8%, P<0.05). There was no significant change in VO<sub>2</sub>max after the training period in either group. **Discussion** To our knowledge, this is the first study that focused on effect of high-intensity training in hypoxia among female ballgame players. In the present study, the HYPO group showed further increases in maximal power output and average power output during intermittent maximal pedaling compared with the NOR group. The mechanism for augmented anaerobic capacity remains unclear, but increases in muscle glycogen content and lactate metabolism capacity might be involved. **Conclusion** Hypoxic training causes further increases in maximal and average power output during intermittent maximal pedaling test compared with the equivalent training under normoxic condition in female athletes. However, it did not affect the improvement of VO<sub>2</sub>max. References Dufour et al. J Appl Physiol 100: 1238-1248, 2006. Hamlin et al. Scand J Med Sci Sports: 20: 651-661, 2010.

### IS HYPOXIA-DECREASED FAT OXIDATION ATTRIBUTED TO THE INTRAMYOCYELLULAR LIPID OXIDATION?

Takuya, O., Arimitsu, T., Takahashi, H.

*Japan Institute of Sports Sciences*

**Introduction:** Intramyocellular lipids (IMCL) are mostly adjacent to mitochondria, and utilized as an important energy source, especially during prolonged exercise. Similar to free fatty acids (FFA), the IMCL utilization is largely related to whole-body fat oxidation (FO), but it was recently reported that the change of FO was not always parallel to that of the IMCL utilization (van Loon et al., 2005, Stellingwerff et al., 2010). FO during exercise is attenuated in hypoxia. Although previous studies have reported a decrease of FFA uptake in hypoxia (Roberts et al., 1996), the possibility that the IMCL utilization was also inhibited could not be excluded. The aim of this study was to test whether the IMCL oxidation was inhibited under hypoxic conditions, in comparison with both the same absolute and relative intensities. **Methods:** After peak O<sub>2</sub> uptake under normoxic (FIO<sub>2</sub> = 0.209, VO<sub>2</sub>peak\_N) and hypoxic conditions (FIO<sub>2</sub> = 0.148, VO<sub>2</sub>peak\_H) of six male runners (age, 25  $\pm$  3 yr) were assessed, they ran for 90 min under hypoxic conditions (167  $\pm$  16 m/min, 65%VO<sub>2</sub>peak\_H; HH) or under normoxic conditions matched to the same absolute (167  $\pm$  16 m/min, 65%VO<sub>2</sub>peak\_H; NH) or relative velocity (192  $\pm$  16 m/min, 65%VO<sub>2</sub>peak\_N; NN). FO was calculated by respiratory gas exchange. Before and after 90-min running exercise, venous blood samples were taken, and IMCL at the soleus muscle was non-invasively evaluated by proton magnetic resonance spectroscopy. **Results:** Hypoxia tended to decrease FO at the 90th min (NN: 619  $\pm$  183 mg/min, NH: 531  $\pm$  90 mg/min, HH: 693  $\pm$  115 mg/min). Hence, plasma growth hormone, stimulating triglyceride breakdown, in HH tended to be higher than NN, and was significantly higher than NH, but plasma FFA was similar among the three conditions. On the other hand, the IMCL content was significantly decreased in all conditions after exercise, and the IMCL degradation was significantly lower in HH than NN and NH (NN: 3.64  $\pm$  1.56 mmol/kgww, NH: 3.74  $\pm$  1.66 mmol/kgww, HH: 2.27  $\pm$  1.09 mmol/kgww). **Discussion:** Our findings indicate that the IMCL degradation may be impaired under hypoxic conditions, despite a directly used energy source in mitochondria, in comparison with not only the absolute, but also the relative intensities. Furthermore, these results suggest that a decrease of FO in hypoxia is partly ascribed to the inhibition of the IMCL oxidation. ### ERYTHROPOIETIN RESPONSES TO MODERATE NORMOBARIC HYPOXIA AND HYPEROXIA IN HEALTHY HUMANS

Uchimaru, J., Takemura, H., Yamano, H., Takahashi, H., Suzuki, S.

*Sendai University*

**Introduction** It is well-known that decreased renal tissue O<sub>2</sub> partial pressure (PO<sub>2</sub>), i.e. absolute renal tissue hypoxia, triggers de novo of erythropoietin (EPO) synthesis in humans. Even short periods (90–120 min) of hypoxic exposure have been well documented to induce to EPO production. Interestingly, the “normobaric O<sub>2</sub> paradox” (NOP theory) (Balestra et al. 2004, 2006) proposes that relative changes in PO<sub>2</sub> from hyperoxia to normoxia may also induce de novo EPO synthesis; however, this point is open to debate. We examined the effect of absolute and relative changes in PO<sub>2</sub> on serum EPO concentration following short-term moderate normobaric hypoxia and hyperoxia exposures. **Methods** Eight healthy male volunteers, aged 21-22 yr, participated in this study. Blood samples were drawn to establish

subjects' baseline EPO concentrations one week before experimental trials. Subjects were exposed to 3 h of normobaric hypoxia (14.5% O<sub>2</sub>) and/or normobaric hyperoxia (27.4% O<sub>2</sub>) inside a tent. The order of exposure was randomized and trials were spaced by exactly one week to control for circadian effects. Serum erythropoietin (EPO) concentration was measured before, immediately and 3 hours after each trial. Venous PO<sub>2</sub> was measured during normoxia, hypoxia and hyperoxia exposure to assess relative change in PO<sub>2</sub>. Results  $\Delta$ PO<sub>2</sub> from hyperoxia to normoxia (17.4 $\pm$ 8.2 mmHg) was similar to that from normoxia to hypoxia (15.5 $\pm$ 5.6 mmHg). A 23% increase in serum EPO was observed 3 h after normobaric hypoxia (20.8 $\pm$ 2.4 vs 25.4 $\pm$ 1.9 mU/mL,  $p < 0.05$ ). In contrast, a slight, non-significant decrease in serum EPO was observed 3 h after normobaric hyperoxia (19.8 $\pm$ 2.7 vs 18.8 $\pm$ 1.7 mU/mL). Conclusion Short-term absolute normobaric hypoxia increased serum EPO concentration, but the relative hypoxia induced by the change from normobaric hyperoxia to normoxia did not affect EPO concentration, despite a similar change relative PO<sub>2</sub>. Further studies with greater levels of hyperoxia are needed to confirm whether relative changes in PO<sub>2</sub> (hyperoxia to normoxia) can increase serum EPO concentrations before normobaric O<sub>2</sub> breathing could be suggested as a new training or clinical strategy.

### NOT ALL HIGH INTENSITY INTERVAL TRAINING PROTOCOLS IMPROVE VO<sub>2</sub>MAX

Hindsø, M., Dohlmann, T., Larsen, S., Dela, F., Helge, J.W.

*University of Copenhagen*

Introduction VO<sub>2</sub>max improvements after low-volume HIT varies from 1.5% (non-significant) to 21% in the literature. However, direct comparisons are somewhat difficult since both the work to rest ratio, interval duration, total work volume and workload intensity differs markedly between the studies. The aim in this project was to study VO<sub>2</sub>max and time to exhaustion after 6 weeks of HIT and to register the relative intensity of the training (%HRmax and %VO<sub>2</sub>max). Methods Subjects (n = 9) were healthy sedentary overweight men and women between 18-50 years of age. VO<sub>2</sub>max was measured on two separate occasions prior to training and 3 days after the last training day using an incremental test with 25W increments every 3 min until voluntary exhaustion and a brief confirmation ramp test. All subjects completed 18 training sessions over 6 weeks. A session consisted of 2 min warm up followed by 7x1 min of high intensity cycling (95-105% VO<sub>2</sub>max) separated by 1-min recovery periods. During session 6, 12 and 17 VO<sub>2</sub> and HR were recorded. VO<sub>2</sub> was measured using breath by breath method (COSMED, Quark CPET). Heart rate was monitored using telemetry (Polar T31). Exercise was performed on a cycle ergometer (Lode Corival). Results are means  $\pm$  SD. Baseline VO<sub>2</sub>max and time to exhaustion values are taken from the pretest that yielded the VO<sub>2</sub>max. Results VO<sub>2</sub>max was not significantly improved (~3%; pre 2474  $\pm$  408 ml/min vs post 2555  $\pm$  501 ml/min,  $p = 0.225$ ). Time to exhaustion improved by ~17% (pre 701  $\pm$  234 s vs post 818  $\pm$  245 s,  $p = 0.002$ ). Peak and average values for HR and VO<sub>2</sub> during session 6, 12 and 17 were not different. At session 17 (exclusive warm up) HRpeak was 94.0  $\pm$  4.0 %, HRaverage was 82.5  $\pm$  6.5 %, VO<sub>2</sub>peak was 99.5  $\pm$  10.4 % and VO<sub>2</sub>average was 78.1  $\pm$  9.8 % of baseline HRmax and VO<sub>2</sub>max, respectively. Discussion The intensity of the training was achieved as planned (VO<sub>2</sub>peak  $\approx$  100% baseline VO<sub>2</sub>max) and yet there was no improvement in VO<sub>2</sub>max. We observed a large individual variation in relative HR and VO<sub>2</sub> responses during training, thus highlighting the importance of the initial determination of training workloads for HIT protocols. The ~17% improvement in time to exhaustion with only a small non-significant change in VO<sub>2</sub>max, could be due to a learning effect. However, at the two pretests there was no difference in time to exhaustion (pre1 710  $\pm$  189 s vs pre2 695  $\pm$  158 s) and therefore a more likely explanation is that 6 weeks of HIT improved the capacity to tolerate and perform high intensity exercise. Further experiments, where the interval workload intensity or the work to rest ratio is increased, are needed to demonstrate a VO<sub>2</sub>max improvement in sedentary subjects following a 15-min 3 times a week HIT protocol. The project is funded by the EU FP7

##### THE PHYSIOLOGICAL AND PERCEPTUAL EFFECTS OF PLANT EXTRACTS DURING SUSTAINED EXERCISE

Sallam, M.A., Baxendale, R.H.

*Glasgow University*

The chewing of khat leaves (*Catha Edulis* Forsk) is widely practised in southern Saudi Arabia, such as Jazan region for their central stimulant properties. These effects are due to cathinone which is present in khat leaves. The aim of this study was to investigate the effect of consuming 45g of khat during sustained exercise. The study protocol was approved by the Ethical Committee of Medical Research Center in Jazan University. 21 healthy male volunteers were recruited to a double-blind random order study. Each volunteer visited the lab three times. During the first visit: volunteers were familiarized with the tests after they performed 10 km on a cycle ergometer. On the second visit, one hour before experiment subjects asked to orally ingest either 33ml of fruit juice or juice with 45g of ground khat leaves filtered to remove particles. At the last visit they ingested the other drink. On the Second and Third visits participants performed 10 Km cycling on an ergometer. Heart rate, tympanic temperature and perceived exertion were measured every 5 minutes of cycling and at fatigue. In addition to, record the time to complete 10 km cycling. All volunteers completed the experiment without any ill effect. Analysis showed that the baseline study variables were not significant different on both test days. Heart rate and tympanic temperature were significantly higher and time to complete 10 km cycling was significantly quicker after khat consumption when compared with the placebo after injection (heart rate  $p < 0.001$ , tympanic temperature  $p < 0.005$ , and time trail  $p < 0.005$ ) perceived exertion did not differ significantly. These results confirm that 45 g of khat leaves contributed to higher exercise which caused to reduce time trail, increase heat rate and tympanic temperature in healthy young men level in Jizan district.

## THE EFFECT OF A WEIGHT-BEARING PHYSICAL ACTIVITY INTERVENTION ON BONE HEALTH IN PRE-PUBERTAL SOUTH AFRICAN BLACK CHILDREN

Meiring, R.M., Norris, S.A., Avidon, I., McVeigh, J.A.

*Exercise Physiology Laboratory, School of Physiology, Faculty of Health Sciences, University of the Witwatersrand*

Bone fractures in the South African Blacks (a population historically thought to be better protected from low bone mass) could soon pose a significant problem on an overburdened health care system as the population continues to age and partake in less physical activity. The effects of physical activity on bone health in Black children have been largely overlooked and while numerous studies have examined the role of physical activity interventions in White and Asian children to the best of our knowledge, none have set out to determine whether a weight-bearing physical activity intervention improves measures of bone mass and structure in a pre-pubertal Black cohort. Two groups of children between the ages of 9-11 participated: EX (n=12) and CON (n=11). DXA was used for whole-body and site-specific measurements of bone mineral content (BMC). Peripheral quantitative computed tomography at 4, 14, 38 and 65% of the length of tibia was performed for measurements of bone structure. Urinary levels of cross-linked N-telopeptides of Type I collagen (NTX) were analysed as a measure of bone resorption. The intervention consisted of a 20 week weight-bearing exercise program performed twice a week for 45 minutes per session. CON children continued their regular activities. The EX group showed a greater change in total hip and intertrochanteric BMC compared to the CON group ( $p=0.02$ ). Peripheral QCT measures of bone mass (vBMC), area and strength showed greater changes occurring in the EX compared to the CON group at all sites measured along the tibia ( $p<0.05$ ). Change in tibial periosteal circumference ( $p = 0.04$ ) and cortical thickness ( $p = 0.03$ ) was greater in the EX group than in the CON group. The EX group had a lower concentration of NTX after the intervention compared to before the intervention ( $p=0.04$ ). Black pre-early pubertal South African children who undertook a 20 week weight-bearing exercise intervention had greater gains in bone mineral content at the hip as well as in bone geometry and strength measures at trabecular and cortical sites along the length of the tibia compared to children who did not take part in the exercise intervention. Bone resorption was also decreased in the intervention children. Similar to studies in White children, this novel intervention can be used as a model for further research into the best methods as to how to maximise bone strength in childhood in order to offer protection of bone health into adulthood.

## DIETARY PROTEIN INTAKE MODULATES SATELLITE CELL MYOSTATIN EXPRESSION FOLLOWING A BOUT OF RESISTANCE EXERCISE

Snijders, T.I, Verdijk, L.B.1, McKay, B.R.2, Parise, G.2, Greenhaff, P.3, van Loon, L.J.C.1

*1. Maastricht University Medical Centre+, Maastricht, the Netherlands. 2. McMaster University, Hamilton, Canada. 3. University of Nottingham Medical School, Nottingham, United Kingdom*

**Introduction:** Skeletal muscle satellite cells (SCs) play a significant role in the myogenic adaptive response to exercise. It remains to be established whether nutrition plays a role in SC activation and/or signaling in response to exercise. In the present study we assessed whether dietary protein alters the SC response to a single bout of resistance-type exercise. **Methods:** Twenty healthy young ( $21\pm 2$ y) males were randomly assigned to consume a controlled diet that provided either  $1.2 \text{ g protein} \cdot \text{kg BW}^{-1} \cdot \text{d}^{-1}$  (normal protein diet; NPD) or  $0.1 \text{ g protein} \cdot \text{kg BW}^{-1} \cdot \text{d}^{-1}$  (low protein diet; LPD). On the second day of the controlled diet, subjects performed a single bout of resistance-type exercise. Muscle biopsies from the vastus lateralis muscle were collected prior to exercise and after 12, 24, 48, and 72h of post-exercise recovery. Muscle fiber type-specific SC content and activation status were determined using immunohistochemical staining. In addition, myostatin protein expression was determined at the different time points using western blotting. **Results:** The number of SCs per muscle fiber increased significantly by  $26\pm 8$  and  $23\pm 12\%$  (NPD) and  $39\pm 6$  and  $26\pm 8\%$  (LPD) following 72h of post-exercise recovery in type I and type II muscle fibers, respectively ( $P<0.05$ ), with no difference between groups. The number of myostatin+ SCs decreased significantly at 12, 24 and 48h after exercise cessation ( $P<0.05$ ), with no difference between groups. Yet, whereas the number of myostatin+ SCs returned to baseline in the type II muscle fibers on the NPD after 72h of recovery, the number remained low on the LPD. Myostatin protein expression remained unchanged at 12 and 24h after the single bout of resistance exercise, in both groups. However, at the 48 and 72h time point myostatin protein expression was elevated  $\sim 2$  fold on the NPD ( $P<0.05$ ), whereas no change was observed on the LPD. **Conclusion:** Dietary protein intake modulates SC activation and myostatin expression following a single bout of exercise in humans. This is the first study to demonstrate that nutrition may modulate the regulation of SCs.

## TRUE IDENTITY TO MOVE THE FOOT QUICKLY

Kinugasa, R., Ishikawa, M., Yamamura, N., Taniguchi, K., Fujimiya, M., Katayose, M., Edgerton, V.R., Sinha, S.

*Kanagawa University/RIKEN*

**Introduction** During muscle contraction, curvature of the tendon (1) suggests that posterior movement of the Achilles tendon (AT) is constrained, even though there does not appear to be any definitive anatomical structure. Such a constraint would increase the proximo-distal excursion of the calcaneus relative to excursion of the AT above the ankle (2). This curvature, referred to as the AT inflection point, remains largely unexplored. We therefore investigated the predominant mechanisms and mechanical significance of the AT inflection point using imaging modalities and mathematical modeling. Our working hypothesis is that the AT inflection point arises from the differences in mechanical properties between the most distal edges of the soleus muscle (Sol) and the fat tissue just below it. **Methods** For six young volunteers, tissue displacement was determined during active plantarflex contraction using velocity-encoded phase-contrast (VE-PC) MR techniques. Further, small amounts of Sol from its most distal edge, were dissected from eight human cadavers. The position of inflection point was then determined before and after the Sol dissection. We modeled how the inflection point impacted generated force in the AT and calcaneus movement velocity. **Results** VE-PC imaging revealed that during plantarflex contraction, the distal portions of the Sol moved rapidly in the proximal direction, but fat tissue remained almost static. The distance from the calcaneus to the AT inflection point was significantly longer after the Sol dissection than before, suggesting that AT inflection point moved proximally after the Sol dissection. Mathematical simulation reveals that the force generated is lesser with the presence of an inflection point than without it; however the calcaneus movement velocity is faster with inflection point than without. **Discussion** AT inflection point was observed to be outlined by the boundary region of the Sol and fat tissue, and was moved proximally after Sol dissection, suggesting that the appearance of inflection point has a possibility of originating from the difference in the mechanical properties of Sol and fat tissue. In addition, AT inflection point is instrumental in causing greater movement of the calcaneus by small displacement of the muscular tissue (2), but would decrease the generated force at the AT due to a shorter AT moment arm (3). On the other hand, AT inflection point can cause quicker movement of the calcaneus, since a deformation time is shortened due to the shortening of the distance to pull the AT. It is suggested

that terminal part of a joint such as fingertip of the foot or hand is responsible for quicker movement with inflection point but necessitate larger force exertions. References 1. Maganaris et al. Eur J Appl Physiol 2000 2. Hodgson et al. J Morphol 2006 3. Sinha & Kinugasa Achilles Tendon 2012

### **EFFECT OF WHOLE-BODY MICROTITANIUM-TREATED GARMENTS ON METABOLIC COST OF EXERCISE 48-H FOLLOWING STRENUOUS HILL RUNNING**

Rowlands, D., Graham, D., Fink, P., Wadsworth, D., Hughes, J.

*Massey University*

**Introduction** A previous report (Wadsworth et al., Med Sci Sports Exerc 2010, 42(12):2273) provided evidence that wearing sports garments treated with microscopic titanium particles (AQUA TITAN) during a 48-h period of recovery from strenuous running may benefit subsequent running economy. Therefore, the purpose of this study was to determine if the effect size of AQUA TITAN-treated garments was worthwhile for recovery, as measured by the magnitude of restoration of running economy during subsequent exercise. **Methods** A double-blind crossover was used to determine the effect of AQUA TITAN on running metabolic cost in 10 healthy men. Participants performed 40 min of treadmill running comprising 2 times (10 min at 5% and 10 min at -10% grade), followed by random allocation to skin-tight nylon-polyurethane AQUA TITAN treated or non-treated placebo control garments covering the torso, limbs, and feet. Garments were worn continuously throughout the next 48-h, during which time participants rested (day 2) then completed a graded treadmill run to determine metabolic outcome (day 3). Body-weight normalised running metabolic cost was evaluated by indirect calorimetry and the effect size referenced against the smallest meaningful change in economy (0.9%) for improvement in distance running performance. **Results** The fatigue effect while wearing control garments on metabolic cost at 48-h was small (2.2% 95%CL +/-1.2%). In contrast, AQUA TITAN garments most certainly reduced running metabolic cost (-3.1% +/-0.9%) vs control. Additionally, AQUA TITAN increased the respiratory exchange ratio (0.011 +/-0.005) and lowered minute ventilation at intensities below the ventilatory threshold (-4.0% +/-0.9%). **Discussion** AQUA TITAN garments worn during recovery from strenuous exercise improved subsequent running economy to a magnitude likely to restore endurance performance. Future research should verify the magnitude of garment effects on performance outcomes, and on identifying the acute or passive neural, musculotendinous or metabolic mechanisms responsible.

### **EFFECT OF POSTURE AND MODE OF EXERCISE ON PLASMA FIBRINOGEN CONCENTRATION: THE ROLE OF PLASMA VOLUME CHANGES**

Omar, A., El-Sayed, M., Hadida, M.

*University of Tripoli, Faculty of Physical Education and Sport Sciences*

**Introduction:** Cycling and running at the same intensity may produce different physiological responses. However, the combined effects of posture and exercise modality on plasma volume and fibrinogen are not known and discrepancy still exists over the interaction between plasma volume and alterations in fibrinogen levels in exercise. **Aims** To examine the effect body posture and mode of exercise performed at similar fraction of maximal oxygen consumption on fibrinogen in healthy moderately trained subjects. **Investigating** the effect of exercise-associated haemoconcentration on plasma fibrinogen changes following alterations in body posture and after exercise. **Methods:** Fifteen subjects performed two exercise trials at approximately 70% VO<sub>2</sub> max for 30-min with one week intervening. One trial was performed on a treadmill at an intensity corresponding to 70%VO<sub>2</sub> max, while the other was performed on bicycle ergometer at similar intensity. In the cycling trial subjects stood for 30-min, followed by sitting for 30-min then cycled for 30-min at 70%VO<sub>2</sub> max. In the treadmill trial, subjects sat for 30-min followed by standing for 30-min then ran on the treadmill for 30-min at 70% VO<sub>2</sub> max. Blood samples were taken at the end of each 30-min period and analysed for lactate, haematocrit, and haemoglobin and fibrinogen. Plasma volume changes were estimated according to Dill and Costill, 1974. **Results:** There were significant changes in blood lactate, hemoglobin, hematocrit and fibrinogen in response to changes in posture and following exercise. Data also revealed a significant interaction effect of trial and time on blood lactate and plasma fibrinogen. Post hoc analysis showed similar blood lactate pre-exercise between trials, followed by an increase during both cycling and running. During recovery, blood lactate, plasma volume contraction and fibrinogen returned rapidly to baseline, with no significant difference between trials. Changing body posture prior to exercise from standing to sitting and vice versa were associated with opposite variations in haematocrit and haemoglobin and consequently estimated plasma volume and these alterations mirrored the changes in plasma fibrinogen. In addition, exercise at the same relative intensity, irrespective of its modality, transiently increased fibrinogen mainly due to exercise-associated haemoconcentration. **Conclusion:** Concurrent assessment of plasma volume and plasma fibrinogen shed some light on the mechanism responsible for posture and exercises related changes in fibrinogen. Exercise at the same fraction of maximum oxygen consumption, irrespective of its modality, transiently increased plasma fibrinogen and that can mainly be attributed to exercise associated haemoconcentration. Plasma volume changes mirrored the alterations in plasma fibrinogen in response to postural modifications and following exercise. **References:** Dill D.B and Costill D.L, Calculation of percentage changes in volumes of blood, plasma, and red cells in hydration, 272 Journal of Applied Physiology 37 (1974), 247–248.

### **COMPARISON OF METHODS FOR ASSESSMENT OF EXERCISE-INDUCED MECHANICAL HYPOALGESIA**

Grancharska, K., Pencheva, N.

*South-West University*

**Introduction** Methodologies for evaluation of mechanically-induced hypoalgesia related with physical loading are less investigated. The aim of this study was to compare and to assess advantages and disadvantages of the following methods for experimental pain assessment, applied before and after exercise: - tourniquet algometry (TA); - hand-held algometry (HHA); and - computer-controlled cuff pressure algometry (CA). **Methods** Pressure pain threshold (PPT) and pain tolerable threshold (PTT) in healthy, untrained males were determined, before and after incremental test to exhaustion. The TA was applied with blood pressure apparatus to 10 subjects (19.1±1.2 years) and assessed with verbal scale (VS). Algometer Somicid was used for HHA. It was applied to five points upon m. gastrocnemius-soleus (GS) in 11 subjects (22.3±1.1 years) and assessed with VS. The experimental setup for CA, according to Stoilov et al., 2009 was applied to 12 males (23.7±3.4 years), consisted of an electro-pneumatic regulator (0-2 kPa/s range) with a tourniquet cuff, electronic visual analogue scale and quantitative evaluation of pressure-time-pain curves. **Results** The hypoalgesia after exercise, was established with: - TA, although in some subjects the PTT values were underestimated; - HHA in GS the PPT (kPa/cm<sup>2</sup>) for lateral and medial head, before or after exercise were: 464.8±148.3 or 676.0 ± 166.4 and 399.9±133.9 or 521.5± 90.6, respectively. The differences between values (kPa) of PPT and PTT, obtained with CA, and calculated before and after exercise, were 4.8 and 7.4, respectively. The similar tendency was proved

with compression rates of 0.25, 0.50 and 1.00 kPa/s. The pressure – time and pain –time curves were linear with different slope. Discussion Although, the TA is an easy way to evaluate changes in pain perception, it did not allow assessment of manifested hypoalgesia, especially in trained males after exercise to exhaustion (Koltyn, 2000). HHA allows evaluation of PPT in different points of the muscle tested, but it is not suitable for PTT and has high variability (Giburm et al., 2011). The advantages of CA, as a novel experimental technique, is the precise quantitative evaluation of stimulus-response pressure-pain function (Jespersen et al., 2007), but it is not suitable for specific location of the muscle and for field application. ## SERUM CONCENTRATIONS OF ESSENTIAL TRACE ELEMENTS IN SPORTSMEN OF DIFFERENT METABOLIC MODALITIES

Crespo, C., Llerena, F., Robles, M.C., Iglesias, P.J., Maynar, M., Caballero, M.J.

UNIVERSITY OF EXTREMADURA

Introduction Changes in trace element concentrations are of especially vital importance. The homeostatic balance of chemical elements in an organism is the basic requirement of good health (Kabata-Pendias and Mukherjee, 2007). Methods This study was performed on 31 active subjects as control group (24.72±6.06 yrs) and 80 high level sportsmen. The sportsmen were divided into three groups according to sport type: 28 aerobic sportsmen (21.03±3.71 yrs), 24 anaerobic (16.65±1.22 yrs) and 28 aerobic-anaerobic (21.04±3.98 yrs). Analysis of serum samples was carried out in an ICP-MS Nexion model 300D (PerkinElmer, Inc., Shelton, CT). The validity of the methodology was checked by the biological certified reference material. We used the Student t test for comparison of independent groups (differences between control group and sportsmen of different metabolic patterns and these together). Results The results indicated that the concentrations (µg/L) of essential trace elements were different in serum samples of control group and different sports types. Aerobic sportsmen have significantly higher serum concentrations than the control group (p<0.001), of Cr (3.435±4.103 vs 0.155±0.207), Mn (2.545±1.747 vs 1.104±0.413), Mo (0.873±0.835 vs 0.319±0.108), Ni (2.876±2.954 vs 0.471±0.438). Anaerobic sportsmen have significantly higher serum concentrations than the control group (p<0.001), of Cr (0.442±0.242 vs 0.155±0.207), Mo (2.083±0.674 vs 0.319±0.108), Ni (1.110±0.356 vs 0.471±0.438). Sportsmen aerobic have significantly higher serum concentration (p<0.001) of Cr, Mn and Zn than the sportsmen anaerobic and sportsmen aerobic-anaerobic: Cr (3.435±4.103 vs 0.442±0.242 vs 0.708±0.504), Mn (2.545±1.747 vs 0.819±0.246 vs 1.027±0.392) and Ni (2.876±2.954 vs 1.110±0.356 vs 1.008±0.695). All concentrations are in the normal range in terms of reference levels found. Discussion Aerobic exercise has shown the ability to increase the serum concentration of Cr, Mn and Zn. These elements are associated with metabolism of insulin and Glucose Tolerance Factor, the response antioxidant (Bicer et al., 2011) and enzyme activity, respectively. ## TIBIAL AND RADIAL BONE STRUCTURE AND GEOMETRY IN ROAD CYCLISTS, MOUNTAIN BIKERS AND SEDENTARY CONTROLS.

McVeigh, J., Cimato, A., Avidon, I.

Exercise Laboratory, University of Witwatersrand

The high risk nature of cycling predisposes participants to fractures. Traditionally road cycling has been thought to not be osteogenic. Mountain biking may impose a greater osteogenic stimulus than road cycling, however much of the data for cyclists has been obtained from DXA scans, which provide two dimensional information of the bone. Little is known about the structural and geometric properties of the tibia and radius in road cyclists and mountain bikers. Ten sedentary (SED) controls (27.1 ± 5.2yr) and 20 trained male (23.9±3.9yr) road cyclists (RC(n=10)), mountain bikers (MB(n=10)) were compared for radial and tibial bone geometry, area, content (BMC), density (BMD), and estimates of strength using pQCT. pQCT was used to assess volumetric BMC (vBMCtot, mg/mm<sup>3</sup>), area (Ar.tot, mm<sup>2</sup>), cortical bone area (Ar.ct, mm<sup>2</sup>), and vBMC (vBMC.ct, mg/mm<sup>3</sup>), periosteal circumference (mm), bending strength (polar strength strain index (SSIp), mm<sup>3</sup> and bone strength index (BSI)) at the proximal (66%) radius and tibia and distal (4%) radius. Variables were adjusted for body size differences. RC had less vBMCtot, Ar.tot and Ar.ct (-12% to -17%, p<0.05) than MB and smaller periosteal circumferences than MB (-8%, p<0.05) at the proximal radius. RC had smaller vBMCtot, Ar.Tot and BSI than MB (-10% to -21%, p<0.05) at the distal radius. No differences were noted at the tibia between RC, MB or SED. MB had more favourable bone geometry at the radius, when compared to RC. Interestingly, RC who are known to have lower bone mass, particularly at the lumbar spine compared to sedentary controls, displayed a structurally similar tibia to MB and SED.

## EFFECT OF DIFFERENT SET CONFIGURATIONS OF HIGH-INTENSITY SQUAT ON ACUTE HEMODYNAMIC RESPONSE

Mayo, X.I, Iglesias-Soler, E.I, Carballeira, E.I, Sánchez-Otero, T.I, Boullosa, D.A.2

1: UDC (A Coruña, Spain), 2: UCB (Brasília, Brazil)

Introduction Blood pressure (BP) rises with successive repetitions within a set and with each subsequent set (Gomides et al., 2010; McCartney, 1999). Similarly, heart rate (HR) increases with the number of repetitions and sets, thus further increasing the rate-pressure product (i.e. HR x SBP). The rate at which BP rises is related to both intensity and length of the set, which are two load parameters that could be easily manipulated. The introduction of pauses between intra-set repetitions has been suggested as an alternative to traditional set configuration in order to improve mechanical performance (Haff et al., 2003; Iglesias-Soler et al., 2012). This type of set configuration has been termed Cluster Training (CT). During CT, higher mechanical performance is observed, in association with a shorter time of muscle contraction. Therefore, a decrease in time of mechanical compression of the skeletal muscle vasculature is expected. This may allow lower acute increases in BP. Methods Ten male subjects completed a session of three sets to failure (FS) of parallel squat with 4 repetitions maximum (4RM), and a rest of 180 seconds between sets (total resting time of 360 s). At least 72 hours after, subjects performed a cluster session (CS) with the same volume (load x repetitions) and total resting time but distributed between each repetition. SBP and RPP were obtained at the end of each set during FS, and at the end of each repetition in CS. Beat-to-beat HR was recorded before, during, and after sessions. Results Mean SBP and mean RPP were higher in FS (147±24 mmHg; 17886±3394 bpm x mmHg) respect to CS (133±21 mmHg; 15025±3598 bpm x mmHg) (p=0.016 and p=0.01 for SBP and RPP, respectively). Differences between sessions were observed for volumes corresponding to set 2 (p=0.019, Cohen's d= 0.62; p=0.009, Cohen's d= 0.93 for LnSBP and RPP, respectively), and

set 3 ( $p=0.03$ , Cohen's  $d=0.68$ ;  $p=0.028$ ,  $d=0.78$  for LnSBP and RPP, respectively). Discussion The main finding of this study was that set configuration employed in CS induced lower intra-session cardiovascular stress with respect to FS, as reflected by the SBP and RPP responses. Lower cardiovascular response observed during CS could be partially caused by reduced involvement of central command, a lower pressor response from muscle metaboreflex or a reduced time and magnitude of mechanical compression of the skeletal muscle vasculature and, consequently, a lower increment of peripheral resistance. ### INCREASED TIBIAL DENSITY AND CROSS-SECTIONAL AREA ASSESSED BY pQCT FOLLOWING 12 WEEKS OF ACADEMY FOOTBALL TRAINING

Varley, I., Hughes, D.C., Greeves, J.P., Fraser, W.D., Sale, C.

*Nottingham Trent University*

Increased tibial density and cross-sectional area assessed by pQCT following 12 weeks of academy football training 1 BLHS Research Centre, Nottingham Trent University, UK. 2 Norwich Medical School, University of East Anglia, UK. 3 Department of Occupational Medicine, HQ Army Recruiting and Training Division, UK. Introduction: Football-specific training has been shown to increase bone density, geometry and cross sectional area at different tibial sites when measured using peripheral computed tomography (pQCT) (Nilsson et al., 2012). Little is known about the effects of large increases in football specific training volume in adolescent bone. Therefore, the aim of this study was to investigate changes in bone following acute increases in training volume in adolescent academy footballers. Methods: Thirty-five male full time academy footballers from four football clubs (age  $16\pm 0$ ; height  $1.76\pm 0.07$  m; body mass  $69.6\pm 7.6$  kg) volunteered to take part. Whole bone scans of the tibia were performed immediately before (baseline) and following 12 weeks of full time training using pQCT (XCT2000L, Stratec Pforzheim, Germany). Scans were obtained at the 4%, 14%, 38% and 66% sites measured from the distal end plate of the self-determined dominant leg. Trabecular density (mg/cm<sup>3</sup>), cortical density (mg/cm<sup>3</sup>), cortical area (mm<sup>2</sup>), cortical thickness (mm) and strength strain index (mm<sup>3</sup>) were estimated. Differences in bone were analysed using two-sample t test. All data are presented as mean $\pm$ 1SD and statistical significance was set at  $P<0.05$ . Results: Participant training time significantly increased following full-time academy induction ( $6.4\pm 3.9$  to  $12.4\pm 1.1$  hr/wk;  $P>0.05$ ). Significant increases in trabecular density (mg/cm<sup>3</sup>) were observed at the distal tibia (baseline:  $289.7\pm 34.6$  to;  $295.1\pm 33.2$ ;  $P>0.05$ ). Cortical density (mg/cm<sup>3</sup>) increased at the 14% (baseline:  $1056.6\pm 40.0$  to;  $1063.8\pm 35.5$ ), 38% (baseline:  $1109.6\pm 34.25$  to;  $1115.8\pm 30.0$ ) and 66% site (baseline:  $1072.9\pm 29.5$  to;  $1077.8\pm 3$ ) ( $P>0.05$ ). Cortical cross-sectional area (mm<sup>2</sup>) increased along the tibial diaphysis (14%: baseline:  $210.8\pm 23.6$  to;  $212.8\pm 22.5$ ; 38%: baseline:  $357.7\pm 38.9$  to;  $360.9\pm 35.8$ ; 66%: baseline:  $822.9\pm 89.2$  to;  $828.4\pm 88.6$ ) ( $P>0.01$ ). Bone strength strain index (mm<sup>3</sup>) also increased (14%: baseline:  $1094.3\pm 155.8$  to;  $1113.2\pm 154.2$ ; 38%: baseline:  $1294.1\pm 257.3$  to;  $1310.9\pm 257.4$ ). Conclusion: Significant improvements in bone density of the tibial metaphysis and diaphysis, cortical area and tibial strength strain index were observed with acute increases in football-specific training in adolescent boys. The osteogenic benefits of training may be derived from training volume, from the nature of football-specific activities, or a combination of both. These changes may have implications for strategies aimed at bone accrual and football-specific training. References: Nilsson M, et al. (2012). *Osteo Int*, DOI 10.1007/s00198-012-2142-3

### MATCH RUNNING PERFORMANCE OF YOUNG SOCCER PLAYERS IN WARM AND COOL CONDITIONS

Gurr, S.I, Al Haddad, H.2

*1:Aspetar (Doha, Qatar), 2:Aspire Academy (Doha, Qatar)*

Introduction Environmental conditions are likely to affect match running performance in elite adult soccer players. Authors has consistently reported a decrease in total distance covered, with a maintenance of high intensity activity, during the second half of the match (Ozgunen et al., 2010; Mohr et al., 2010). Given the differences in thermoregulatory mechanisms in adolescents (Falk, 2008), it's unclear whether the same strategy would be observed in youth soccer players. Therefore in this study we compared the match running performance and sweat response of adolescent soccer players during matches played in warm and cool conditions. Methods Starting players from two teams (U13 and U14) were monitored during eleven matches lasting 70-75 minutes. Match running performance was measured using GPS (GPSports, 15Hz). total distance covered per minute played and distance at high intensity running ( $>14.4$  km/h) per minute played were collected. Heat Index (HI) was used as a marker of environmental conditions. Matches were grouped based on the environmental conditions; warm (HI -  $34.6\pm 3.6^{\circ}\text{C}$ , 5 matches, 30 players, age:  $13.1\pm 0.8$  y; weight:  $46.3\pm 7.6$  kg) and cool ( $19.6\pm 2.0^{\circ}\text{C}$ ; 6 matches, 47 players, age:  $13.2\pm 0.6$  y, weight:  $43.6\pm 8.0$  kg). Sweat loss was assessed from the change in body mass after correction for fluid intake and urine losses. Cohen's effect size (ES) was used to assess the differences between the two conditions. Results There was no clear difference (ES=0.03, 90% confidence interval  $[-0.24; 0.30]$ ) in the total distance covered in either the first (cool:  $114\pm 14.4$  m/min vs. warm:  $113.6$  m/min) and or the second halves  $[[0.22[-0.05; 0.49]]$  (cool:  $105.2\pm 13.8$  m/min played vs. warm:  $102.1\pm 13.8$  m/min played). There was no clear difference in the at high intensity running distance in either the first (warm:  $21.9\pm 8.0$  m/per min played vs. cool:  $19.2\pm 12.6$  m/per min played)  $[-0.26$  (-0.01; 0.53)] or second (warm:  $18.4\pm 7.8$  m vs. cool:  $16.8\pm 10.3$  m/per min played)  $[-0.18$  (-0.09; 0.45)] halves. There was a moderate difference  $[-0.43$  (0.16; 0.70)] in sweat losses (warm:  $12.3\pm 3.7$  ml/per min played vs. cool:  $10.2\pm 6.3$  ml/per min played) between the conditions. Discussion In contrast with previous studies conducted with elite adult soccer players, there was no difference in total distance covered and high intensity running distance between matches played in warm and cool conditions in youth. While tactical differences and other specific requirements are placed on players in each game, this study suggests that game running patterns in young soccer players is not different between games played in warm and cool environments. **METABOLIC SPECIALIZATION IN YOUNG FOOTBALLERS**

Noite Mendes, J.1,2, Costa, F., Fernandes, R.2, Rodrigues Ferreira, M.A.1,2, Vences Brito, A.M.2

*1: University of Madeira (Funchal, Portugal); 2: Escola Superior de Desporto de Rio Maior, IPS (Rio Maior, Portugal)*

Introduction It is noticeable that high level athletes have a higher level of specialization, whether in a morphologically or neuromuscular manner, cognitively, and energetically (by means of a more effective use of the aerobic and anaerobic systems) (Bar-Or & Rowland, 2004). However, some studies indicate that there is a strong tendency in children to present good performance levels in aerobic tasks and good results in anaerobic ones (Matos & Winsley, 2007; Rowland, 2005), contrarily to what is seen in elite athletes, raising, henceforth, the hypothesis that pre-pubescent children might not be metabolically specialized (Rowland, 2002). Methods Eleven trained (T) footballers (age:  $11.3 \pm 0.5$  yr.) and another eleven without any formal sports training (NT) (age:  $10.9 \pm 0.3$  yr.). Both groups were matched for Tanner Maturity Test stage I. Using modified Balke protocol with direct gas analysis (KOSMED K4B2, Rome) and a treadmill, the absolute and relative peak  $\dot{V}O_2$  ( $\dot{V}O_{2Abs}$  e  $\dot{V}O_{2Rel}$ ) were evaluated, as well as the ventilation (VE) and the heart rate (HRB). Using the Wingate Anaerobic Test for anaerobic parameters (Monark 894E), the relative and absolute peak power ( $PPAbs$  e  $PPRel$ ) were calculated, as well as the absolute average and relative average power ( $APPAbs$  e  $APPRel$ ), the drop power (DP) and the heart rate (HRW). Results Results were analyzed using PASW (18.0) for both groups and significant differences in the HRB were observed between the groups (T:  $193.7 \pm 7.11$  b •  $\text{min}^{-1}$ ; NT:  $104.5 \pm 5.97$  b •  $\text{min}^{-1}$ ),  $PPAbs$  (T:  $333.2 \pm 39.0$  W; NT:  $288.6 \pm 59.4$  W), and  $APAbs$  (T:  $210.5 \pm 22.1$  W; NT:  $183.5 \pm 31.8$  W) variables. Results showed a strong correlation between  $\dot{V}O_{2Abs}$  and  $PPAbs$  (T:  $p = .8$ ; NT:  $p = .7$ ) and  $APAbs$  (T:  $p = .8$ ; NT:  $p = .6$ ) and between  $\dot{V}O_{2Rel}$  and  $PPRel$  (T:  $p = .8$ ; NT:  $p = .7$ ) and  $APRel$  (T:  $p = .9$ ; NT:  $p = .7$ ) for both groups. Discussion It is expected that, contrarily to adults, children that run faster are also able to run for a longer period of time at an elevated speed. As such, the collected data suggests that individuals who obtained higher and better performances in one test, also achieved better results in the other test, either absolutely or relatively. The results of the present study may suggest that no metabolic specialization occurs in trained nor untrained prepubescent boys. References Bar-Or, O., & Rowland, T. **SERUM CONCENTRATIONS OF TOXIC ELEMENTS IN SPORTSMEN OF DIFFERENT METABOLIC MODALITIES**

Crespo, C., Llerena, F., Robles, M.C., Iglesias, P.J., Maynar, M., Caballero, M.J.

*UNIVERSITY OF EXTREMADURA*

Introduction. Environmental and occupational exposure to toxic elements is of growing concern as large quantities of toxic and carcinogenic elements, due to human activities, are released to the environment polluting air, soil or water in certain areas being a health risk for the population living in that same area (Kabata-Pendias and Mukherjee, 2007). Methods. This study was performed on 31 active subjects as control group ( $24.72 \pm 6.06$  yrs) and 80 high level sportsmen. The sportsmen were divided into three groups according to sport type: 28 aerobic sportsmen ( $21.03 \pm 3.71$  yrs), 24 anaerobic ( $16.65 \pm 1.22$  yrs) and 28 aerobic-anaerobic ( $21.04 \pm 3.98$  yrs). Analysis of serum samples was carried out in an ICP-MS Nexion model 300D (PerkinElmer, Inc., Shelton, CT) (Sarmiento-González et al., 2005). The validity of the methodology was checked by the biological certified reference material. We used the Student t test for comparison of independent groups (differences between control group and sportsmen of different metabolic patterns and these together). Results. The results indicated that the concentrations ( $\mu\text{g/L}$ ) of toxic elements were different in serum samples of control group and different sports types. Aerobic sportsmen have significantly higher serum concentrations than the control group ( $p < 0.001$ ), of Be ( $0.075 \pm 0.034$  vs  $0.036 \pm 0.011$ ), Cd ( $0.079 \pm 0.039$  vs  $0.037 \pm 0.010$ ), Pb ( $1.763 \pm 2.033$  vs  $0.119 \pm 0.238$ ). Anaerobic sportsmen have significantly higher serum concentrations than the control group ( $p < 0.001$ ), of Be ( $0.070 \pm 0.028$  vs  $0.036 \pm 0.011$ ), Pb ( $2.634 \pm 1.591$  vs  $0.119 \pm 0.238$ ); ( $p < 0.05$ ) in Cd ( $0.079 \pm 0.088$  vs  $0.037 \pm 0.010$ ). Aerobic-anaerobic sportsmen have significantly higher serum concentrations than the control group ( $p < 0.001$ ), of Be ( $0.073 \pm 0.021$  vs  $0.036 \pm 0.011$ ) and Pb ( $2.388 \pm 1.257$  vs  $0.119 \pm 0.238$ ). Sportsmen aerobic-anaerobic have significantly lower serum concentration ( $p < 0.001$ ) of Cd than the sportsmen aerobic and sportsmen anaerobic ( $0.039 \pm 0.037$  vs  $0.079 \pm 0.039$  vs  $0.079 \pm 0.039$ ). All concentrations are in the normal range in terms of reference levels found. Discussion. All sportsmen show serum concentration toxic trace elements greater than the control group of active men. These results suggest an increase in the uptake of toxic elements through exposure routes since athletes consume more water and move great volumes of air during training (Speich et al., 2001). **PHYSIOLOGICAL PROFILES IN DIFFERENT LEVELS OF WINDSURFERS**

Lo, K.K.1, Raymond So, C.H.1, Wong, S.H.2, Appel, R.1

*Hong Kong Sports Institute (Hong Kong), Chinese University of Hong Kong (Hong Kong)*

Introduction Since the sanction of sail pumping in all Olympic windsurfing competitions in 1993, windsurfing has become a physically demanding sport. However, no researchers raised a more fundamental question as to what physical and physiological attributes of elite windsurfers set them apart from sub-elite players. Our study below mainly focused on the physiological attributes of the windsurfers at different levels with a view to bridging the information gap between the athletes and the academics, and facilitate talent identification as well as targeted training. Methodology A total of 82 male windsurfers has participated in the study and was divided into four groups namely the Elite Senior (ES), Elite Junior (EJ), Sub-Elite Junior (SEJ), Novice Junior (NJ) according to their competitive levels. All subjects were required to participate in the assessment of anthropometry and physical fitness on two separate sessions with one week apart. In the first

session, anthropometric evaluations on height, body mass, arm span and leg length were conducted. This is followed by sit & reach, vertical jump, handgrip strength and 1-minute sit-ups assessments. The second test session consisted of torso pull, 1-minute push-ups, hanging and 20-m multi-stage shuttle run tests. Results Significant higher values were found from flexibility, handgrip strength, torso pull, sit-ups, modified pull-ups and hanging tests of SEJ players than NJ players, whilst handgrip strength, push-ups and 20m shuttle run tests were higher for SJ players than SEJ players, with no difference were observed in other physiological variables. Hanging test was higher in ES player than all other levels players. Discussion Consistent with Castagna's study, the estimated VO<sub>2</sub>max values from the 20-m multi-stage shuttle-run test on ES and EJ players were significantly higher than SEJ and NJ players that sailing can be considered physical task associated with a high-level aerobic demand. Specific endurance ability is beneficial for improving competition performance as windsurfers possess in greater forearm endurance ability, which is the only indicator among the test items that shows significantly higher values in ES players of reflecting the importance of endurance ability in elite level. To conclude, the present study shows that there is a progressive improvement in the physiological capacities of windsurfers as the playing level increases. It extends the scope of study on the elite windsurfers by providing normative data and performance standard for elite, sub-elite and novice junior players. ## MOTHER'S SACRIFICES AND CONCERNS ASSOCIATED WITH HIGH LEVEL SPORT

Palomo, M., Ruiz, L.M., García, V.

*Universidad de Castilla La Mancha*

**Introduction** The demands of competitive sport, but also of training, are unique circumstances that divert the normal course of family life. Numerous family resources are absorbed as a result of the sport, assuming a strong impact on the family (Bloom, 1985; Coakley, 2006; Cote, 1999; Gould, Lauer, Rolo, Jannes and Pennisi, 2008; Holt and Dunn, 2004). Aim Therefore, the objective of this research was to determine what it means, in particular for the mother, helping her child in the sport and in the reach of that high level. Method To that end, 20 high-level athletes and 17 of their mothers were interviewed. We used a qualitative methodology, inductive, based on technical and typical procedures of Grounded Theory (Corbin and Satruss, 2008). Results The results show two categories. On one side, one called pain, fear and concern of the Mother, and on the other side, Sacrifices, withdrawals and efforts of the mother. The first category refers to feelings of grief or uneasiness because of the child's sport. This category consists of four dimensions: 1. concern for their child in himself, for his happiness, 2. concern for injuries or health as a result of the high demands of top-level sport, 3. concern for the future and how the child, after a lifetime devoted to the sport, may be affected; 4. concern about studies and how the huge time spent on sport can reduce the time devoted to the studies. The second category, related to the sacrifices, withdrawals and efforts, refers to various negative situations related to the child's sport. This category consists, in turn, of eight dimensions: 1. Leisure, the mother reduces and in many cases withdraws her leisure activities. 2. Economy, for the families and for mothers in particular, sport is a significant economic cost that may result in important efforts or simple withdrawals. 3. Time, the mother gives up his own time for the child's sport. 4. Son, the mother refuses her own son for the sport; 5. Labor, the mother even refuses his own professional growth for the son's sport, 6. Energy, the mother makes a physical effort to help her child on the road to the high level; 7. Psychological welfare, for the mother, the child's sport is a source of uneasiness, fears, which affect her daily welfare; 8. Schedules, family life is completely changed and altered by the sport. **Conclusion** In general it can be concluded that the mother helps her son in his pursuit of excellence and that such support is a big negative emotional investment, yield in different ways

## COMPARISON OF AEROBIC AND ANAEROBIC CAPACITY IN PROFESSIONAL AND AMATEUR VOLLEYBALL PLAYERS

Jastrzębski, Z.1, Jaskulska, E.1, Radzimiński, Ł.1, Bichowska, M.1, Jastrzębska, M.1, Kortas, J.1, Konieczna, A.1

*Gdansk University of Physical Education and Sport*

**Introduction** Volleyball is a game performed worldwide by professionals and amateurs on different surfaces (hall, beach). Time of match varies from several dozen minutes to over 1 h. Thus, aerobic capacity in the players is as important as anaerobic power. Other authors confirm this statement, though most of them concern vertical jump power (explosive power) one of crucial abilities of volleyball players, determining their game effectiveness (Kollias et al., 2004). Methods Amateur volleyball players, AVP, (n=26, age 20.9•0.1.25 yr, body height 188.3•5.14 cm, mass 80.2•5.14 kg) and professionals, PVP, (n=14, 26.5•4.49 yr; 199.5•5.06 cm; 93.5•7.49 kg respectively) participated in the study. Maximal oxygen uptake (VO<sub>2</sub>max) and anaerobic threshold (AT) were measured by continuous graded test until exhaustion using gas analyzer and cycloergometer (Oxycon Pro, Erich JAEGER GmbH, Hoechberg, Germany) (Beaver et al., 1986). Total anaerobic work and peak power were measured by 30-s Wingate test on cycloergometer (Monark Ergonomic 894 E, Monark, Sweden) (Bar-Or, 1981). Results Statistical significant differences between AVP and PVP were stated twice for VO<sub>2</sub>max /AT% (79.32•5.66% and 74.3•7.13%) and for HRmax (188•9.22 bpm and 182.9•5.44 bpm). VO<sub>2</sub>max per mass unit were similar in both groups (45.8•5.50 ml/kg/min and 43.2•5.0 ml/kg/min respectively). No significant differences were stated for anaerobic capacity indices: Pmax 10.6•0.50 W/kg and 10.7•0.67 W/kg, and total work 251.0•13.4 J/kg and 252.7•15.1 J/kg respectively. Discussion No statistical significant differences of crucial aerobic and anaerobic capacity indices were stated between amateur and professional volleyball players. Therefore, we can conclude that technical and tactic skills of the players play crucial role in game effectiveness. Similarly, Willmore and Costill (1994) or Jastrzębski (2004) state that physical capacity is an important but not most important factor of high performance in team games players including volleyball. ## PHYSIOLOGICAL AND BIOMECHANICAL DIFFERENCES BETWEEN SMALL-SIDED SOCCER GAMES ON 21X21M PITCHES <3X3> VERSUS 30X30M PITCHES <6X6 PLAYERS>

Vallejo, L.1, Barbero, J.C.2, Cos, F.3, Seirullo, F.3

1: *Institut Nacional d'Educació Física INEF Barcelona.* 2: *University of Granada, Melilla* 3: *Futbol Club Barcelona.*

**Physiological and biomechanical differences between small-sided soccer games on 21x21m pitches (3x3) versus 30x30m pitches (6x6 players).** Introduction Small-sided ballgames adapt to the specificity of the game of soccer and will improve endurance (1). Lengthening

and shortening the playing area, changing rules, one-touch and two-touch play, controlled passing and trainer motivation have a bearing on the number of ball touches and the intensity of the exercise (2). The objective of this study was to analyze the effects playing on a small-sided 21 x 21 m pitch with 3x3 players versus playing on a 30x30m pitch with 6x6 players has on the variables of the distance run, changes in running speed, accelerations in  $m \cdot s^{-2}$  and impacts, and also on maximal and mean heart rate (HR). Methods Twelve professional Spanish Soccer League players took part in this study. The physiological profiles and biomechanical loads were recorded by means of an SPI Elite GPS and Team AMS software, the resulting tri-axis acceleration also having been recorded at a data storage rate of 100 times/second. The HR was also recorded during the small-sided games (SSG), in addition to the technical playing actions having been filmed with a Sony camera and analyzed using the SportsCode software. Results Significant differences were found to exist between the small-sided 21x21m soccer field (3x3) and the 30x30m (6x6) series for the following variables: distance (m) and average distance (ad)  $p=0.008$ , respectively. For the high-intensity distance Area (m)  $p=0.001$ , Sprint distance Area  $p=0.050$ , Sprints  $p=0.048$ . For accelerations  $p=0.006$ , top acceleration  $p=0.016$  and for Impacts  $p=0.035$ . As also for the Average HR  $p=0.000$ , the maximal HR  $p=0.025$ , the HR for zone Mins\_167  $p=0.004$ , the sum of HR  $p=0.05$  and the New HR Ex\_  $p=0.003$ . Discussion These results lead us to the conclusion that by increasing the number of players from 3x3 to 6x6 players per game played on small-sided fields, the biomechanical and physiological strains are greater on small-sided fields, in consonance with the studies published by Dellal, Drust and Lago-Penas (3). ### EFFECTS OF CONCENTRIC AND ECCENTRIC EXERCISE IN HEMOSTASIS

Reischak-Oliveira, A., Teixeira, B.C., Lopes, A.L., Macedo, R., Jeremia, J., Aguiar, L.F.L., Correa, C.L., Bandinelli, E., Ribeiro, J.L.

*Universidade Federal do Rio Grande do Sul - UFRGS*

Introduction Different types of contraction during resistance exercise, could cause distinct changes in hemostasis and inflammation. Exercise stimulates clotting by increasing factor VIII (FVIII) and von Willebrand factor (vWF). The fibrinolytic activity is primarily regulated by tissue plasminogen activator (t-PA) and plasminogen activator inhibitor type 1 (PAI-1) and increased fibrinolytic activity as a consequence of exercise is attributed to the increased release of t-PA from the vascular endothelium and decreased PAI-1 activity. Eccentric exercise is metabolically less demanding but causes more damage to muscle fiber and a greater response of c-reactive protein (CRP). The increased CRP deregulates the balance between coagulation and fibrinolysis due to increased PAI-1 which increases the risk for thrombosis (Singh et al, 2005). Methods This study included eleven sedentary young subjects with a mean age of  $25.4 \pm 2.8$  years, height  $176.2 \pm 4.4$  cm, body mass  $77.1 \pm 8.7$  kg, fat mass of  $32.3 \pm 5.2$  kg and  $VO_{2max}$  of  $41.4 \pm 6.5$  ml / kg / min. Subjects attended three visits to the laboratory: The first visit consisted of pre and post protocol blood sampling, a maximal voluntary contraction (MVC) on an isokinetic damage protocol. In the second and third visit, subjects performed only the MVC and blood sampling. After seven days of rest, subjects repeated all the previous tests changing the type of contraction. The protocols were randomly assigned to prevent an order effect. Results The eccentric protocol resulted in higher strength deficits 24h ( $62.4 \pm 30.6$  5.3  $\pm$  29.9 Nm) and 48h ( $64.3 \pm 33.6$ , 2.5  $\pm$  31.1 Nm) post exercise. There was also an increased CRP ( $0.140 \pm 0.04$ ,  $0.06 \pm 0.04$  mg / L) and increased PAI-1 (13, 5  $\pm$  7.5, 7.3  $\pm$  6.7 ug / L) 48h post exercise when compared to the concentric protocol. In addition, a positive correlation was found between CRP and PAI-1 48h after eccentric protocol  $r = 0.69$ ,  $p < 0.05$ . Discussion There is evidence that an increase in CRP can disrupt the balance between coagulation and fibrinolysis (Ribeiro et al, 2007). In the present study found a higher concentration of PAI-1 in eccentric exactly at the point where the CRP level was increased compared to concentric, agreeing with the findings in the literature showing that CRP stimulates the release of PAI-1 (Fay, 2010). Moreover, a positive correlation was found between PAI-1 and CRP ( $r = 0.69$ ) showing that the higher the concentration of CRP also higher PAI-1. The literature show that CRP is a predictor for cardiovascular disease, because it interferes directly on the balance between coagulation and fibrinolysis (Devaraj et al, 2003). ### CORRELATIONS BETWEEN EXPLOSIVE POWER AND RUNNING SPEED OF WOMAN HANDBALL PLAYERS OF POLISH NATIONAL TEAM

Bichowska, M.

*Gdansk University of Physical Education and Sport*

Introduction Handball is a team game involving various activities performed in changeable conditions. Field size and game specificity result in the fact that running speed and explosive power play crucial role in this game (Jastrzebski and Ciepliński, 2001; Cardiale, 2002). The aim of the study was to determine correlations between running speed and explosive power in female handball professionals. Methods Polish female handball representatives volunteered for the study ( $n=19$ ,  $26.58 \pm 3.72$  yr, body height  $176.95 \pm 6.66$ cm, mass  $70.42 \pm 8.13$ kg). The participants were subjected to 15-min warm-up including explosive exercises followed by 10-min of recovery. Then explosive power was measured by force plate, Kistler brand. The subjects performed a single vertical jump with arms swing (Hfmax) and a series of maximal vertical jumps with arms swing within 10s period (Hfmean). Moreover, mean value of power of the jumps Pmean [W/kg] and mean time of contact with the plate Tcont [ms] were calculated. After 10 min of recovery, running speed of 5, 20 and 30m was measured by Swiss photocells Tag Heuer HL 2-31 model. There were 3-5 min of rest between the trials depending on the covered distance. Results The results showed significant ( $p < 0.05$ ) correlations (r) between indices. Positive relations were observed between Hfmax and Pmax (0.76), Hfmean (0.87), Pmean (0.83) and negative between Hfmax and 5m run (-0.67), 20m (-0.58), 30m (-0.55). Significant associations were stated between Pmax and Hfmean (0.77) or Pmean (0.87) and negative between Pmax and 5m run (-0.59), 20m (-0.54), 30m (-0.53). Moreover, strong correlations were revealed between Hfmean and Pmean (0.77), and negative for 5m (-0.54) and 20m run (-0.47). Negative relations were also observed between Pmean and run on 5m (-0.50), 20m (-0.53), 30m (-0.46), as well as Tcont and k (-0.59). Discussion The results revealed strong correlations between explosive power and running speed in handball players. The higher explosive power achieved, the shorter running time of 5, 20 or 30m run. Moreover, longer contact with the plate (tcont) involves less take off power generation. Similar studies (Jastrzebski and Ciepliński, 2001; Cardiale 2002) reported crucial role of jumping explosive power generated during ball shots as well as running speed on 30m (e.g., during counter-attack) for game effectiveness. References Cardiale M. (2002). Handball performance: physiological considerations and practical approach for training metabolic aspects. The

### DOES LOWERING EVENING RECTAL TEMPERATURE TO MORNING LEVELS OFFSET THE DIURNAL VARIATION IN MUSCLE FORCE PRODUCTION?

Edwards, B.J., Robinson, W.R., Pullinger, S.A., Jonathan, W., Kerry, J.W., Reilly, T.P., Robertson, C.M., Burniston, J.G., Waterhouse, J.M.

*Liverpool John Moores University*

Muscle force production and power output in active males, regardless of the site of measurement (hand, leg or back), are higher in the evening than the morning. This diurnal variation is attributed to motivational, peripheral and central factors and higher core and, possibly muscle temperatures in the evening. This study investigated whether decreasing evening rectal temperature to morning resting values, by immersion in a water tank, leads to muscle force production and power output becoming equal to morning values in motivated subjects. Ten healthy active males (mean±SD: age, 22.5±1.3 yrs; body mass, 80.1±7.8 kg; height, 1.72±0.05 m) completed the study, which was approved by the Ethics Committee of the University. The subjects were familiarized with the techniques and protocol and then completed three sessions (separated by at least 48 h): control morning (07:30 h) and evening (17:30 h) sessions (with an active 5-min warm-up on a cycle ergometer at 150 W) and then a further session at 17:30 h but preceded by an immersion in a cold water (~16.5°C) to lower rectal temperature (T<sub>rec</sub>) to morning values. During each trial, 3 measures of handgrip strength, isokinetic leg strength measurements (of knee flexion and extension at 1.05 rad.s<sup>-1</sup> and 4.19 rad.s<sup>-1</sup> through a 90° ROM) and 3 measures of maximal voluntary contraction (MVC) on an isometric ergometer (utilizing the twitch-interpolation technique) were performed. T<sub>rec</sub>, rating of perceived exertion (RPE) and thermal comfort (TC) were measured. Measurements were made after the subjects had reclined for 30-min at the start of the protocol and prior to the measures for handgrip, isokinetic and isometric ergometry. Muscle temperature (T<sub>m</sub>) was taken after the warm-up or water immersion and immediately before the isokinetic and MVC measurements. Data were analysed using ANOVA with repeated measures. T<sub>rec</sub> values were higher at rest in the evening (0.37°C; p<0.05) than the morning, and values were no different to that of the morning immediately after the passive pre-cooling, but progressively decreases over time thereafter; the subjects' ratings of thermal comfort reflecting this. T<sub>m</sub> also displayed significant diurnal variation, with higher values in the evening (0.39°C, p<0.05). Right grip strength, isometric peak power, isokinetic knee flexion and extension for peak torque and peak power at 1.05 rad.s<sup>-1</sup>, and knee extension for peak torque at 4.19 rad.s<sup>-1</sup>; all showed higher values in the evening (a range of 3-14%). All other measures of strength or power showed a statistical trend to be higher in the evening than in the morning (0.10>p>0.05). Pre-cooling in the evening reduced force or power variables, and subjects reported maximal values for effort for each strength measure. In summary, effects of time of day were seen in some measures of muscle performance, in agreement with past research. However, in this population of motivated subjects, there was evidence that decreasing evening T<sub>rec</sub> to morning values by cold water immersion decreased muscle strength to values similar to that found in the morning.

### THE EFFECT OF HIGH AMBIENT TEMPERATURE ON THE RESPONSES TO A CONTROLLED FOOTBALL SIMULATION

Hughes, M.G., Meyers, R., Nokes, L., Oliver, J., Stenbridge, M., Stone, K.

*Cardiff Metropolitan University*

**Introduction** The performance characteristics of match-play in football, such as the number of sprints and distance covered are thought to be reduced when ambient temperature is high (Ozgunen et al. 2010). However, assessment of the extent of additional fatigue due to temperature is difficult owing to the voluntary nature of football activity. The present study demonstrates the responses to a controlled football match-play simulation (Stone et al. 2011) performed in contrasting mean ambient temperatures of 19 and 27 degrees ('normal' and 'hot', respectively). **Methods** Semi-professional, male University football players (n=13) were tested. The procedure was divided into identical six 16-min blocks of activity, comprising sprinting and controlled-speed walking, jogging and running with a 15-min break to replicate half-time. The total distance covered in each trial was 11.2km. Single-sprint performance over 15m was assessed through each 16-min block. Midway through each 16-min block, one bout of repeated sprint (RS) exercise (6 x 15m starting every 18 seconds) was also used. All sprints were made from a standing start. Heart rate (HR) and blood lactate were monitored through the whole procedure. Data were analysed using 2 way (time \* temperature) repeated measures ANOVA and Bonferroni post hoc. Significance was accepted at P<0.05. Data are reported as mean ± SD. **Results** Players consumed more fluid in 'hot' ('hot'; 2.3 ± 0.6 vs. 'normal'; 1.6 ± 0.6 l; P<0.05) with no significant difference in the change of body mass. Within the football simulation, mean RS speed was reduced in 'hot' by around 3% in the fourth ('hot'; 5.49 ± 0.24 vs. 'normal' 5.65 ± 0.17 m/s; P<0.05) and sixth block ('hot'; 5.47 ± 0.28 vs. 'normal' 5.64 ± 0.18 m/s; P<0.05). Similarly, mean single-sprint performance was lower by 2-3% in blocks 4, 5 and 6. Mean HR across the six blocks was significantly higher throughout 'hot' ('hot'; 170 ± 9 vs. 'normal'; 165 ± 10 bpm; P<0.05), however, blood lactate concentration was not different between the conditions ('hot' 5.3 ± 1.8 vs. 'normal'; 4.8 ± 2.1 mM; P>0.05). **Discussion** The 'hot' trial led to more fatigue and greater HR than the 'normal' condition. Sprint performance over 15-m was slower by around 3% in 'hot' vs. 'normal' conditions and, in keeping with the match-play data from Ozgunen et al. (2010), the decline in performance was only significant in the second half of the simulation. By controlling distance covered and using standard exercise intensities for all but the sprints, these data show the extent to which ambient temperature is likely to influence responses to football match play. Stone, K. et al. (2011). *Int. J. Sports Physiol. & Perform.* 6: 427 - 431. Ozgunen, K.T. et al. (2010). *Scand. J. Med. Sci. Sports* 20. (Suppl 3): 140-147.

### EFFECTS OF SOCCER ON THE PLATELETS MEMBRANE FATTY ACIDS

Maynar, M., Iglesias, P.J., Grijota, F.J., Montero, J., Muñoz, D.

*University of Extremadura*

**Introduction** Furthermore, a relationship exist between free fatty acids and health. They are presently considered as an attractive target to regulate the human diseases as obesity, diabetes, cancer, and cardiovascular complications (Wakil, 2009). So, high concentrations of saturated fatty acids may have potentially harmful health effects, while unsaturated fatty acids may play a protective role (Woodside and Kromhout, 2005). Therefore, the aims of this study were to compare basal levels of fatty acids platelet in trained and untrained subjects; and to compare n6/n3, desaturation and lipidic peroxidation index in trained and untrained subjects and performance status relationship. **Method** The sample of this study was made for 44 subjects, were divided into 2 groups: Trained subjects (T), consisted in 22 players from youth level, following a regular training schedule 10 hours/week. Untrained subjects (UT) consisted in 22 subjects who did not follow

a systematic training plan with an activity not exceeding 3 hours/week. Each subject was performed anthropometric evaluation, following the indications of the Spanish Group Cineanthropometry (Esparza, 1993), and an assessment of platelet fatty acids, these being determined by the technique of Lepage and Roy (1986). Results Significant differences were found in the acid C24:0, C16:1, C20:3n6, C18:3n3 and the peroxidation index C20:4n6/C16:0, obtaining higher values in untrained subjects, therefore of the acid C18:2n6, n6/n3 index and delta5-n6 index were higher in trained subjects. Moreover, correlations were observed in these parameters with the degree of training. Discussion Currently, in the literature we have not found similar researches to ours in this biological matrix in humans, on the other hand, there are other studies that have determined lipid profiles in plasma and erythrocytes in different sports (Arsic et al., 2012; Tepsic et al., 2011). References Arsic, A., Vucic, V., Tepsic, J., Mazic, S., Djelic, M., & Glibeti, M. (2012). ## COMPARISON BETWEEN EXPLOSIVE POWER OF HALL AND BEACH VOLLEYBALL PLAYERS

Jaskulska, E.1, Jastrzębski, Z.1, Radzimiński, Ł.1, Kortas, J.1, Jastrzębska, M.1, Bichowska, M.1, Konieczna, A.1

*Gdańsk University of Physical Education and Sport*

Introduction Previous studies regarding hall and beach volleyball focus on vertical jumping ability of the players (Newton et al., 1999; Kollias, 2004), which is related to attack and block effectiveness. The type of surface, on which the players perform, determines the type of training developing their power of legs. Methods The study participants were recruited from hall volleyball players Gr1 (n=13, 20.5±0.56 yr, 190.9±5.51cm, 79.2±4.67kg) and beach volleyball players Gr2 (n=21, 23.4±3.64 yr, 193.1±5.2cm, 85.5±4.23kg respectively). Explosive power was measured by force platform, Kistler brand. First, the participants were submitted to 15-min warm-up including explosive exercises followed by 10-min recovery. Then they performed a single vertical jump with arms swing (Hfmax) and a series of maximal vertical jumps with arms swing within 10 s period (Hfmean). Moreover, mean value of power of the jumps (Pmean [W/kg]) and mean time of contact with the platform (Tcont [ms]) were calculated. Results The study revealed significant differences between hall (Gr1) and beach (Gr2) volleyball players regarding Hfmax and Hfmean. The results in Gr1 were as follow: Hfmax 56.9±4.02cm, Hfmean 53.3±3.85cm, Pmean 40.3±4.25 W/kg, Tcont 371.9±57.6 ms, and in Gr2: 50.6±5.46cm; 41.7±4.65cm, 43.5±2.14 W/kg, 223.6±32.5 ms respectively. Discussion Results of the study (Hfmax and Hfmean) revealed greater explosive power in beach volleyball players than in hall volleyball players. Their longer time of contact with the platform (Tcont) corresponds with the sport specificity that involves training of explosive power (jumps) on the sand. Our results are in line with the research of other authors (Homborg and Papageorgiou, 1994; Riggs and Sheppard, 2009), which stated that beach volleyball players perform jumps with greater explosive power, and the jumps make up 27% of all jumps executed during the match. #### INJURIES ARISING FROM KART COMPETITIVE RACING IN CHILDREN: AN EPIDEMIOLOGICAL STUDY

Delmuns Carvajal, S.1, Javierre, C.2, Roig, M.3, Mans, C.4, Giné-Garriga, M.1

1:FCS Blanquerna, URL (Barcelona, Spain), 2:Facultat de Medicina, UB (Barcelona, Spain), 3:Departments of Neuroscience and Pharmacology, University of Copenague, 4:Fundació Privada Llegat Roca i Pi

Introduction. Kart competitive racing (KR) is a sport modality where children compete from very early ages. Traditionally, KR has been the stepping stone for the formation of current F1 Spanish pilots. There are no epidemiological data regarding the incidence and characteristics of injuries derived from KR practice.(1) Objective. To explore the incidence and characteristics of injuries derived from KR practice among children aged 7 to 15 years in the Catalan Championship during 2005 to 2009. Design. Longitudinal epidemiological study with retrospective data. Methods. Data from medical records of races taking place between seasons 2005 to 2009 were extracted. Data retrieved included number of pilots, participations, kilometres covered as well as number and characteristics (severity and location) of injuries. Injuries were categorized according to the Orchard Sports Injury Classification System guide (OSICS). A descriptive stratified analysis taking into account seasons, races and age categories was performed. Results. Data from 334 pilots that participated 2485 times and covered a cumulative total of 445591 kilometres were retrieved. Only 38 children presented an injury during the five years of study. Overall the risk of suffering an injury per participation was low, with risk ratios (RR) ranging from 0.001 to 0.02 depending on the season. Hand and wrist (42.1%) followed by thorax and elbow (13.1%) were the most commonly injured areas. Most injuries were mild, only involving bruises and superficial lacerations and allowing for the prompt incorporation of pilots to competitions. Four serious injuries (fractures) were reported. Significant differences (p=0.026) in the number of injuries per year were found, being 2007 (RR=3.06; IC 95%=1.45, 6.43) the year with the highest incident rate. There were differences in the number of injuries depending on where the race took place (p=0.015) with some races showing higher injury incidence. Differences in injury occurrence among age categories were not statistically different although pilots in older categories showed a greater injury incidence. Conclusion. KR is a sport with a low incidence of injuries. However, our data suggest that injuries occur in specific parts of the body and in some specific races. It is important to improve safety

measures for these bodily areas and analyse why specific races show a higher incidence risk. References. (1) Eker HH, Van Lieshout EM, Den Hartog D, Schipper IB. (2010). *Open Orthop J*, 17(4), 107-110.

### ASSESSMENT OF THE EFFECT OF QUADRICEPS STRETCHING

Grazziani, F., Coudreuse, J.M., Nicol, C., Mesure, S.

*ISM UMR 7287 (Marseille, France)*

Introduction In Patellofemoral pain syndrome (PFPS) many authors found a weakness in eccentric muscle strength, within the quadriceps muscle and in terminal knee extension. It could represent a runway for treatment of PFPS. The evidence that muscular eccentric work is more effective in treating PFPS than others muscular work or others treatment protocol was limited. So what can be expected with stretching Quadriceps on the PFPS? Our objective is to compare the knee pain and the quadriceps strength before and after Quadriceps Stretching. Methods For each patients the two knees were selected to make comparison between healthy and not healthy knee. EVA method was used to assess the pain at each speed of the isokinetic test (60°sec /180° sec/30°sec) and that before and after Quadriceps stretching .In the same time each patients do the isokinetic test always in the same chronology: Training the test with the healthy knee at the three mode : 60°sec concentric /180°sec concentric /30°sec eccentric. Then, assessment of the injured knee at the three same speeds followed by Quadriceps stretching (3x 20 sec) and a last isokinetic evaluation made three minutes after stretching. Results With 27 patients evaluated we found a pain decrease after stretching: 55%. (P<0,02) .We found also an increase of the quadriceps strength after stretching at each speed : + 15,8% ( p<0,02) . (r significatif correlation R=0,44445) Discussion On looking at the results there are important modifications of the knee pain and the quadriceps muscular strength before and after stretching. We should certainly include the quadriceps stretching as efficiency therapeutic and it must be added in the treatment protocol of PFPS. ### TRUNK MUSCLE ACTIVITY AND SPINAL MOVEMENT WHILE STANDING UP IN INDIVIDUALS WITH A HISTORY OF LOW BACK PAIN

Masaki, M., Tateuchi, H., Otsuka, N., Takeno, Y., Sakuma, K., Koyama, Y., Ichihashi, N.

*Human Health Sciences, Graduate School of Medicine, Kyoto University*

Introduction Previous research has demonstrated that activity of the lumbar multifidus (MF) muscle is decreased during rapid arm movements in individuals with low back pain history (LBPH). Decreased activity of this muscle leads to altered spinal movement, which may contribute to the recurrence of LBP. Furthermore, standing up is associated with the occurrence of LBP (Xu, 1997). The aim of this study was to analyze activity of the trunk muscles and spinal movement during standing up in individuals with LBPH. Methods Eight healthy males (control (CTR) group; age, 22.4 ± 1.2 years) and 8 males with LBPH (LBPH group; age, 21.5 ± 1.5 years) participated in the study. The LBPH group included subjects who had experienced LBP over at least 3 months, with a severity rating of >30 mm on a visual analog scale, and had no pain at the time of intervention. The study's exclusion criteria were as follows: slipped intervertebral disc, spondylolisthesis, spondylolysis, and/or any neurological symptoms concomitant with LBP. Subjects were asked to rise from a seated position in 2 s and spinal movement was recorded using a 6-degree-of-freedom electromagnetic tracking system. Activity of the thoracic and lumbar erector spinae, MF, rectus abdominis, obliquus externus abdominis, and gluteus maximus muscles was recorded using a surface electromyography system. Angular changes in the sagittal axis of the upper and lower thoracic and lumbar spine, and the spine, i.e. the sum of these three segments, were computed for the entire standing up movement (from sitting to maximum extension of the spine), flexion phase (from sitting to maximum flexion of the spine), and extension phase (from maximum flexion to maximum extension of the spine). Peak muscle activity in the flexion and extension phases was computed. The Mann-Whitney U-test was employed to assess differences in variables between the CTR and LBPH groups. Results MF muscle activity in the extension phase was significantly lower in the LBPH group [34.1 ± 7.3% of maximum voluntary contraction (MVC)] than in the CTR group (43.2 ± 8.3% MVC). Angular change in extension of the spine during the entire standing up movement was significantly greater in the LBPH group (35.2 ± 10.4°) than in the CTR group (22.3 ± 10.3°). Furthermore, angular change in flexion of the lower thoracic spine in the flexion phase was significantly lower in the LBPH group (0.1 ± 3.0°) than in the CTR group (3.9 ± 2.5°). Discussion Peak activity in the MF muscle was decreased and spinal movement increased while standing up in individuals with LBPH. This excessive spinal movement may contribute to the recurrence of LBP. Reference Xu Y, et al. (1997). *Occup Environ Med*, 54(10), 741-745.

### THE EFFECT OF MYOFASCIAL RELEASE INTERVENTION ON THE SHOULDER INTERNAL/EXTERNAL ROTATION RANGE OF MOTION AND MUSCLE STRENGTH FOR COLLEGIATE SOFTBALL PLAYERS

Chang, H.Y.1,2, Chen, C.N.1, Cheng, S.C.3

*College of Medical Science & Technology, Chung Shan Medical University*

Softball or baseball players had often observed the posterior shoulder tightness at throwing arm. However, lack of evidence related myofascial release technique applied over posterior shoulder tissue. Therefore, the aim of this study was to investigate the effects of myofascial release intervention on the shoulder internal external rotation range of motion and muscles strength for collegiate softball players while applied over dominate throwing shoulder of athletes. Fourteen collegiate softball players participated in this study. Myofascial release technique (MFR) applied over Latissimus dorsi, Deltoid, and Pectoralis majors of dominate throwing shoulder. The range of motion and muscles strength of dominant shoulder internal/external rotation (IR/ER), and horizontal adduction (HA) were measured by goniometer and handheld muscle tester before and after MFR intervention and with non-dominant shoulder of players as control group. After MFR intervention, the ROM of internal rotation, external rotation, and horizontal adduction were improved 34.3±8.5%, 12.5±8.8%, and 37.6±24.1% in the dominant arm, respectively. However, the muscles strength of dominant shoulder had no significantly changed between before and after intervention. The results showed that the MFR were able to improve the shoulder IR/ER and HA range of motion without loss muscle strength while the MFR applied for softball players. However, previous studies did not investigate the influence on strength of muscles that the soft tissue technique applied on. Our study had investigated both ROM and muscle strength while technique applied. Base on aforementioned evidences, this study concluded that acute application of MFR successfully improved IR/ER and HA of ROM of shoulder and without loss of strength collegiate softball players. Future study may examine the difference of MFR and stretch on posterior shoulder tightness in athletes.

## REFERENCE DATA FOR THE ASSESSMENT OF LUMBAR EXTENSION BY MEANS OF VIDEO RASTERSTEREOGRAPHY

Schroeder, J., Reer, R.

*Hamburg University*

Introduction: Three-dimensional x-ray investigations revealed relevance of spinal mobility for low back pain (LBP) (4). By means of dynamic MRI, Kulig et al. (2) could demonstrate that decreased as well as increased lumbar mobility might indicate LBP, and diagnosis results might lead to specific consequences, especially in conservative therapy settings. Therefore, it appeared to be reasonable to look for a diagnosis system that is non-invasive on the one hand, and less expensive than MRI on the other hand. Recent research could establish a functional test protocol using dynamic video rasterstereography for the assessment of lumbar extension mobility (5). The present study was aiming at presenting lumbar extension reference data of pain free persons for a latter clinical use with LBP patients. Methods: 50 pain free volunteers (28 females: age  $27\pm 7$  y, BMI  $22\pm 2$  kg/m<sup>2</sup> and 22 males: age  $31\pm 8$  y BMI  $24\pm 2$  kg/m<sup>2</sup>) went through a standardized test protocol: static spine shape analysis (Formetric®: resolution 10 Pts./cm<sup>2</sup>, reconstruction error <0.2 mm) (1), followed by a functional dynamic test of lumbar hyperextension in terms of an increasing lumbar lordosis angle ( $rtt=0.93$ ) (5). Results: Lumbar hyperextension ranged between 7° and 53° within the total sample, while females ( $25\pm 11^\circ$ ) and males ( $18\pm 8^\circ$ ) differed significantly ( $p=.014$ ). Females showed an angle of 12° at the 5% quantile, and 42° at the 95% quantile level, whereas males had 8° and 34° at these levels, respectively. Conclusions: Our results were according to the literature (3) and might serve as a reference pool to judge future data assessed for LBP patients. So far, out-liers of a two standard deviation interval were assumed as LBP indicators (2). Here, it is proposed to use the 5% and 95% quantile as boarder lines for restricted or extended lumbar extension mobility. References: 1. Drerup B, Hierholzer E. 1994. ## KINESIO TAPE – IMMEDIATE EFFECTS ON SPINAL ALIGNMENT: AN RCT PILOT APPROACH

Schroeder, J., Braumann, K.M.

*Hamburg University*

Introduction: Recent reviews of RCTs did not reveal evidence of efficacy of Kinesio Tape and its assumed positive effects on blood flow, lymphatic drainage, pain decrease, or increases in proprioception, muscle activation, force, and performance (1, 3). Solely, benefits for the range of motion could be proved as evident (4). This current approach was seeking for immediate effects of elastic Kinesio taping on the spinal alignment in pain free persons in the sense of a memory tape. Methods: 12 pain free volunteers (6 female, Age:  $28.7\pm 7.8$ , BMI:  $21.1\pm 2.1$  and 6 male, Age:  $32.8\pm 11.9$ , BMI:  $23.9\pm 1.8$ ) were randomly blinded assigned to a verum or a placebo group: verum taping with approx. 135% tape tension, and placebo taping with no tension. Spinal alignment of all participants was examined at a baseline level without tape and afterwards under tape conditions (double tested and averaged) within 30 minutes at the same day. Spinal alignment (trunk inclination, pelvis inclination, thoracic and lumbar angle) was assessed using video rasterstereography (Formetric®), which was proved to be a valid and high resolution instrument (10 Pts./cm<sup>2</sup>, error < 0.2 mm) for non-invasive back shape reconstruction (2). Data were analyzed using non-parametric procedures (SPSS 12.0). Results: There were no significant differences between both groups at the baseline level ( $P>.05$ ). Taping did not lead to significant changes of spinal alignment, neither in the verum nor the placebo group ( $P>.05$ ). Although adaptations were more extended in the verum group, samples did not differ significantly in their differences from baseline to tape condition ( $P>.05$ ), except for the lumbar angle, when only the value, not the direction of adaptation, was taken into account ( $P=.029$ ). Conclusions: No evidence could be shown for the assumption that Kinesio taping should be leading to a spinal erection. But with respect to single case analyses, there seemed to be two different patterns of Kinesio tape induced spinal erection, depending on a de- or increasing trunk inclination. Further reseach is necessary. References: 1. Bassett KT, Lingman SA, Ellis RF. 2010. ## VALIDITY AND RELIABILITY OF AN INSTRUMENT MANUFACTURED FROM A HAND-HELD DYNAMOMETER FOR MEASURING THE STRENGTH OF TRUNK MUSCLES

Jubany, J., Busquets, A., Marina, M., Cos, F., Angulo-Barroso, R.

*INEFC*

Introduction The measurement of maximum isometric strength is necessary in many areas of health and sport. Trunk muscles have some particular characteristics that make them hard to evaluate with simple, inexpensive instruments a like hand-held dynamometer. The aim of this study was to evaluate the validity and reliability of an instrument manufactured with a hand-held dynamometer and a metallic structure (HHD+S) for measuring the maximum isometric voluntary strength of the trunk muscles. Methods The maximum isometric voluntary strength of the trunk muscles (extension, flexion and lateral flexion) was measured in 20 healthy individuals (mean age 27.6 years, SD 10.1) using the manufactured instrument HHD+S and the gold standard Back-Check (BC). Participants performed three trials in each instrument in a random order. Three different methods to compute a single value of maximum muscle force were used: (1) average of the three attempts, (2) average of the best two, or (3) average of the two closest. Relative reliability (coefficient of variation, CV, and intra-class correlation, ICC), absolute reliability (standard error of measurement, SEM), minimum detectable change (MDC), and validity (Pearson correlation) were computed. Results The results showed that the two instruments had high and similar intra-subject reliability. Both instruments had CV <8% (95%CI=4.1-9.7%); ICC >0.96 (95%CI=0.91-0.99%); SEM <0.80; MDC between 0.85 to 2.22 Kg or 1.64 to 3.70%. The validity of the HHD+S was demonstrated by the high Pearson correlation between the two instruments ( $r = 0.78$ ) despite the averaging method used: the three attempts, the best two, or the two closest. Discussion Given the close correlation between the two devices

and the good reliability between trials, we believe that the use of an HHD jointly with the manufactured metallic structure (HHD+S) gives an evaluation of the maximum isometric voluntary strength of the trunk muscles that is very similar in quality, accuracy and reliability to the BC. The metallic structure made the hand-held dynamometer suitable to assess back muscles' strength. Good validity using just two measurement trials may imply a major advantage in populations with poor physical condition, history of lesion (i.e. people with back pain) or unaccustomed to big efforts. Although the HHD+S has no support software for data analysis and interpretation, which the BC instrument does, it provides other advantages like low cost, easy assembly and light weight.

### EFFECT OF ROTATOR CUFF TRAINING OF SUPRASPINATUS ON MUSCLE THICKNESS

Takahashi, M.1, Watanabe, H.2, Kaji, K.1, Tsumura, K.2, Hashimoto, M.2, Nakanishi, K.1, Kenmoku, T.3, Takahira, N.1,2

1: Graduate School of Medical Sciences, Kitasato University 2: School of Allied Health Sciences, Kitasato University 3: School of Medicine, Kitasato University

**Introduction** Rotator cuff training of the supraspinatus muscle is important to prevent shoulder injuries (Tsutsui et al., 1992). However, the effect of rotator cuff training on supraspinatus is still unknown, because there is no appropriate method for evaluating this muscle in clinical practice. Hodges et al. (2003) reported that muscle thickness (MT) in the case of other muscles, such as transversus abdominis, is related to muscle activity. Therefore, MT may be a useful indicator of the effects of training on muscles. The purpose of this study was to examine the effect of rotator cuff training of supraspinatus on MT. **Methods** Sixteen healthy male subjects (age: 21.7±1.9 years; height: 169.8±4.2 cm; weight: 62.2±4.2 kg) participated in the study. At a frequency of 5 days a week for 6 weeks, the subjects performed training by abducting the arm from 0 to 30 degrees in the scapular plane with humeral external rotation, using a yellow Thera-Band (#DAB-1, D&M, Japan). Supraspinatus MT was measured by ultrasonography (SSD-4000, Aloka, Japan). MT was determined as the distance between the superficial fascia and the deep fascia of supraspinatus at positions 10% and 50% of the distance from the medial edge of the scapular spine (scapular spine length was 100%). At the time of measurement, the seated subjects performed abduction at 30 degrees in the scapular plane with humeral external rotation. MT was measured during three tasks: 1) with the arm supported by a sling (0 kg); 2) with the wrist loaded by using a yellow (2 kg) Thera-Band; and 3) in maximum voluntary contraction (MVC). MTs before and after the end of training were compared by using the Wilcoxon signed rank test. **Results** At a position 10% of the distance from the medial edge of the scapular spine, MT under 0 kg (before: 0.31±0.20 cm; after: 0.46±0.19 cm,  $P < 0.01$ ) and 2 kg (before: 0.64±0.22 cm; after: 0.84±0.23 cm,  $P < 0.01$ ) loads was increased after the end of training. At a position of 50% from the medial edge, MT at 0 kg (before: 1.79±0.26 cm; after: 2.10±0.17 cm,  $P < 0.01$ ) was increased after the end of training. **Discussion and Conclusion** MT was increased after training for 6 weeks. The results of a preliminary experiment (data not shown) revealed that the MT of supraspinatus was related to muscle activity, as measured by electromyography. Our results suggested that rotator cuff training of supraspinatus increased the MT and activity of this muscle. **References** Hodges PW, et al. (2003). *Muscle Nerve*, 27(6), 682-692. ### INTER-HEMISPHERIC TREATMENT OF VISUAL CUES: EFFECTS ON POSTURAL CONTROL FOR HEMIPARETIC PATIENTS

Duclos, N.C.1, Barthélemy, J.1, Maynard, L.2, Abbas, D.2, Mesure, S.1

1: ISM UMR 7287 (Marseille, France), 2: CRF Valmante, UGECAM-PACAC (Marseille, France)

**Introduction** Postural strategies are depending on a fine sensorimotor control. When the inter-hemispheric relation is disturbed, this control is not so efficient anymore. In this framework, we have considered the hemiparesis model through an auto-stabilization paradigm, with the aim to improve knowledge about a probably right hemispheric specificity for postural control (Bonan et al., 2004). As visual information is known to play a major role in postural control, our main purpose was to examine the potential influence of visual cues treatment on posture depending of the injured cerebral hemisphere. **Methods** 12 healthy subjects and hemiparetic patients with either a right (RH lesion, 12 subjects) or a left (LH lesion, 10 subjects) cerebral hemisphere lesion were asked to maintain their position as stable as possible while sitting on an instable seesaw in either sagittal or frontal plan. Four visual conditions were tested: vision (Vis), free right visual field (RVF), free left visual field (LVF) and darkness (NVis). Standard posturographic parameters and mean position ranges (Y & X range) were computed. Statistical analysis was performed using ANOVA with repeated measures. **Results** Surface and length covered by the center of pressure (CoP) were always higher for hemiparetic patients than healthy subjects. In the frontal instable condition, CoP surfaces were for the sole RH lesion group significantly lower in the Vis than in the NVis condition. In the sagittally unstable condition, CoP surfaces were for all groups 3 to 5 times lower than in the frontal unstable condition. LVF and RVF testing conditions had an effect on hemiparetic patients, with similar CoP surfaces between the Vis condition and the condition with visual field opposite to the hemiparetic side. LVF and RVF testing influenced on the X range for "RCH lesion" group and on the Y range for "LCH lesion" group. **Discussion** Auto-stabilizations in the frontal plan confirm a visual reliance for RH lesion patients. LH lesion patients seem to adopt a non-visual strategy. It leads us to consider a sensory hemispheric more than a postural hemispheric specificity, with some plan-dependent strategies (Van Nes et al., 2008). Auto-stabilizations in the sagittal plan show a specific hemispheric selectivity of visual cues for the two hemiparetic groups, known as spatial neglect strategy. This selectivity seems to organize more accurately the postural control. A hemispheric control of postural directions appears with a medio-lateral sensitivity for RCH lesion patients and antero-posterior for LCH lesion patients. These hemispheric specificities bring major elements for adaptability and efficiency of rehabilitation programs for hemiparetic patients. **References** Bonan, I., Colle, F.M., Guichard, J.P., Vicaut, E., Eisenfisz, M., Tran Ba Huy, P., Yelnik, A.P. (2004) *Arch Phys Med Rehabil*, 85(2):268-273. Van Nes, J., Nienhuis, B., Latour, H., Geurts, A.C. (2008) *Gait Posture*, 28(3):507-12.

### THE ROLE OF HIP ABDUCTOR AND EXTERNAL ROTATOR MUSCLE STRENGTH IN THE DEVELOPMENT OF EXERTIONAL MEDIAL TIBIAL PAIN: A PROSPECTIVE STUDY.

Verrelst, R.

Ghent University

**ABSTRACT Objective:** To prospectively identify proximal risk factors contributing to the development of exertional medial tibial pain (EMTP). **Methods:** Data were prospectively collected on healthy female students in physical education, who were freshmen in 2010-2011 and 2011-2012. Ninety-five female students aged 18.15±0.84, were tested at the beginning of their first academic year. Testing included isokinetic hip strength measurements of abductors, adductors, internal rotators and external rotators. The follow-up of the subjects was assessed using a weekly online questionnaire and a three-monthly retrospective control questionnaire. EMTP was diagnosed by an experienced M.D. (Doctor of Medicine). Cox regression analysis was used to identify the potential risk factors for the development of

EMTP. Results: Twenty-one subjects were diagnosed with EMTP during follow-up. The results of this study identified that decreased hip abductor concentric strength is a predictive parameter for the development of EMTP in females. More specific, total work ( $P=0.010$ ) and average power ( $P=0.045$ ) for concentric abduction strength were found to be significant predictors for this lower leg overuse injury. Conclusions: Hip abductor weakness is a significant predictor for EMTP in females. Preventive screening methods for EMTP should therefore include this proximal contributing factor.

### THE EFFECT OF DEEP TRANSVERSE FRICTION MASSAGE ON THE ACHILLES TENDON BLOOD FLOW IN HEALTHY VOLUNTEERS

Mahieu, N.

*Ghent University*

Introduction: There is a hypothesis in literature that the mechanical action of deep transverse friction massage (DTF) produces vasodilation and increases blood flow. But as yet, no experimental study has confirmed this effect in healthy subjects. The purpose of the present study was to investigate whether one session of DTF can influence the Achilles tendon blood flow. Methods: A randomized pre- posttest trial was set up. Sixty-two healthy participants volunteered. Each person underwent the following four steps of the procedure: 1. Measuring the tendon blood flow (PRE), 2. fifteen minutes of DTF on the Achilles tendon, 3. Measuring of the tendon blood flow (POST), 4. follow-up measurement after 20 minutes of rest (POST20). One leg of each person was randomly assigned to deep transverse friction session, the other leg was used as a control leg. Friction was applied continuously for a total of 15 minutes. The microcirculation was determined at 2 and 8 tissue depths at the distal and the proximal midportion of the Achilles tendon. For each level, the capillary blood flow, the tissue oxygen saturation, and the postcapillary venous filling pressure was registered. Results: The blood flow and the tendon oxygen saturation increase after DTF, while the postcapillary venous filling pressure decreases. After 20 minutes of rest, all parameters normalized towards their baseline - values. Discussion: These findings confirm that the Achilles tendon blood flow increases after one session of DTF in healthy volunteers. To what extent the described microcirculatory effects of sole deep transverse massage are evident in patients with Achilles tendinopathy should be investigated in future research.

### SUPRASPINATUS TENDON AND SUBACROMIAL SPACE PARAMETERS MEASURED ON ULTRASONOGRAPHIC IMAGING IN SUBACROMIAL IMPINGEMENT SYNDROME

Yesilyaprak, S., Michener, L., Seitz, A., Timmons, M., Walsworth, M.

*Dokuz Eylul University (Virginia Commonwealth University)*

Introduction The purpose of this study was to characterize the supraspinatus tendon thickness, subacromial space, and the relationship between tendon thickness and subacromial space in patients with subacromial impingement syndrome to understand the mechanisms of subacromial impingement syndrome. Methods Single-blind cross-sectional design was used. Subjects diagnosed with subacromial impingement syndrome ( $n=20$ ), and asymptomatic controls ( $n=20$ ) matched for age, gender, and hand dominance were recruited. Ultrasound images were collected using a 4-12MHz linear transducer in B-mode of the supraspinatus tendon in the transverse (short-axis) and the anterior aspect of the subacromial space outlet. Using image calipers, measurements of tendon thickness were made at 3 points along the tendon and averaged for a single thickness measure. The subacromial space outlet was measured via the acromiohumeral distance (AHD) defined by the inferior acromion and superior humeral head. The occupation ratio was calculated as the tendon thickness as a percentage of AHD. Results The subacromial impingement syndrome group had a significantly thicker tendon [mean difference= $0.6\text{mm}$ ;  $t=1.924$ ,  $p=0.048$ ], and a greater tendon occupation ratio [mean difference= $7.5\%$ ;  $t=2.57$ ,  $p=0.014$ ] as compared to the matched controls. There were no AHD group differences. Discussion An intrinsic mechanism is supported with a thicker supraspinatus tendon (Joensen et al., 2009; Leong et al., 2012) and a potential extrinsic mechanism with the tendon occupying a greater percentage of the AHD. Tendon extrinsic compression may occur if the unoccupied AHD is reduced during arm elevation when the tendon is directly under the acromion (Giphart et al., 2012); future studies that image the tendon during arm elevation are needed to confirm direct tendon compression. #### ENERGY COST DURING REPEATED SPRINT ABILITY IN PROFESSIONAL FUTSAL PLAYERS

Olla, S.1, Crisafulli, A.1, Cominu, M.2, Ghiani, G.1, Marcelli, M.1, Pinna, M.1, Milia, R.1, Tocco, F.1, Concu, A.1, Angius, L.1

1: Sport Physiology Lab, Department of Medical Science, University of Cagliari (Italy); 2: Regional School of Sport of Sardinia, Italian Olympic Committee, Italy.

Introduction Futsal like other team sports is classified among activities where both aerobic and anaerobic energy sources are recruited. An important skill of team sport has been termed repeated-sprint ability (RSA). Despite large amount of studies investigated the RSA response, a lack of knowledge is present when players underwent a RSA test using the ball. The aim of the study was to investigate how the use of the ball affects RSA test performance. Methods Six male professional futsal players were recruited, goalkeepers were not included. They underwent two RSA field tests randomly assigned on different days. The test consisted on 8 shuttle maximal sprints with passive recovery of 10s. The first part of the track consisted of seven changes of direction (20.1 m) while in the second part the subject ran straight towards the starting line (15.5 m). RSA test was repeated with (RSABall) and without ball (RSAnoball). Ventilatory response during both tests was continuously monitored breath-by-breath by means of portable gas analyser. Results Values were averaged for the entire test duration. No statistical differences in  $\text{VO}_2$ ,  $\text{V}_e$ ,  $\text{VCO}_2$ , RER and HR between two tests were observed. Averaged time of RSABall was higher compared to RSAnoball ( $14.49 \pm 0.29$  s vs.  $10.53 \pm 0.22$  s). Speed was significantly reduced when players ran with the ball ( $8.87 \pm$

0.18 km vs. 12.19 ± 0.25 km). Energy cost of running in RSAnoball was lower respect to RSAball (0.56 ± 0.17 cal vs. 1.00 ± 0.04 cal). portable gas analyser. Discussion Our data show a significance increase of energy expenditure when players used the ball, probably caused by a different pattern of muscle activation or change in running technique that lead to a less efficient technique. A second reason could be addressed to the impossibility of the gas analyser to detect the high anaerobic component during RSAnoball. References Buglione A, di Prampero PE. ### **BRAIN ACTIVATION AND INHIBITION DURING CYCLING INCREMENTAL EXERCISE: A FMRI STUDY**

Yoshida, H.M.1, Fontes, E.B.2, Castanho, G.K.F.1, Machado de Campos, B.2, Li, L.M.2, Fernandes, P.T.1,2

<sup>1</sup>Physical Education Faculty - FEF/UNICAMP; <sup>2</sup>Department of Neurology - FCM / UNICAMP

Introduction Perceived exertion indicates the conscious tolerance to a physical exercise (1), however, little is known about the activation and inhibition patterns of cerebral areas involved in this regulation. Objective Verify the brain areas involved during cycling in different intensities of perceived exertion. Methods Eight healthy adult males (79.7 ± 10.5 kg; 177 ± 9.1 cm; 27.4 ± 4.8 yrs) participated in this study. The participants were positioned carefully to a adapted cycling ergometer attached to a Magnetic Resonance Scanner (MRI) and performed an incremental test consisted in blocks of 30 seconds cycling and 30 seconds rest. At the end of each cycling block the perceived exertion was reported with hands based on 6-20 Borg Scale displayed on the MRI internal screen. The initial load was 50 W which was increased in 25 W at the end of every four blocks of exercise. Workload was increased until the volunteers reached the perception '17 - Very hard' on the Borg scale Results During the perceived exertion related to 'light intensity' (6 to 9 on Borg scale), the brain activation indicated the medial frontal gyrus, inferior frontal gyrus, pre-central gyrus, superior temporal gyrus and ipsilateral cerebellum. For the inhibition were identified fusiform gyrus, frontal superior gyrus, medial frontal gyrus, parahippocampal gyrus and precuneus. For the efforts perceived as 'high intensity' (Borg scale 13-15), activation also indicated the pre-central gyrus, the medial frontal gyrus and paracentral lobule. For the inhibition were identified the upper and lower temporal gyrus, frontal superior and medial gyrus as well as the fusiform gyrus and precuneus. Conclusion The present study elucidated brain areas involved in regulating the exercise at low and high intensity indicating activation of regions associated to motor control and inhibition of several areas as known to exert cognitive functions. ### **EFFECT OF CONTINUOUS TRAINING ON DISTRIBUTION OF BONE AND MUSCLE IN COLLEGIATE WATER POLO PLAYERS**

Iizuka, S.1, Torii, S.2

1: GRADUATED SCHOOL OF SPORT SCIENCES, WASEDA UNIVERSITY (Saitama, Japan), 2: FACULTY OF SPORTS SCIENCES, WASEDA UNIVERSITY (Saitama, Japan)

Introduction There are many previous studies demonstrating the effect of different types of sport activity on the distribution of bone and muscle in athletes. The knowledge about the body composition of the elite athletes helps to build and maintain the body of young athletes. However, there is no report about the water polo players in Japan. So in this meeting last year, we reported the distribution of muscle and bone of water polo players comparing with those in handball player and competitive swimmer. As further study of last year report, we had 2-years follow-up study of Japanese water polo players. Methods 10 collegiate male water polo players participated in this study and their body composition was assessed using dual X-ray absorptiometry (DXA), when they are sophomore and senior degree. We examined the changes of their bone mineral content (BMC), bone mineral density (BMD) and lean mass (LM), and also, the relative value of the upper limb to the lower limb (Up/Low). Results BMC and LM significantly increased in bilateral upper limb. In the trunk, only lean mass significantly increased. BMD significantly increased only in the dominant arm. However, BMC and LM in lower limbs did not change. Also, Up/Low of BMC and LM significantly increased. Discussion It is considered that the increase of BMC and LM in dominant and non-dominant arm was resulted from their swimming movement, throwing movement, as well as strength training on land. From these results, the training of the upper limbs would be important for improvement in the skill of water polo players. However, further researches are needed about the effect of lower limbs training on water polo skills. Conclusion Continuous water polo training develops LM and BMC of the upper limbs.

### **THE EFFECTS OF TENDONS TEMPERATURE ON THE RATE OF TORQUE DEVELOPMENT**

Kang, H.W., Huang, C.H.

National Taiwan sport university

Jumper's knee is one of the common injuries especially for athletes anticipated in sports such as basketball, volleyball or handball. The tendon's capacity to transmit the forces generated by the muscles plays an important role in sports performance. Furthermore, the examination of the tendon stiffness could provide us some information on the tendon's capacity. Temperature is one of many factors could affect the tendon stiffness. Studies in the past have demonstrated that tendon can be more compliant as the temperature increased. However, the degree of compliance associated with the sports performance has not been closely observed. The purpose of the study was to exam the effects of tendons temperature on the rate of torque development. Subjects : Eight competitive male athletes with patella tendinitis participated in the study. Research Design : Cross-over design. Methods: Each subject received the short-wave diathermy and/or ice for twenty minutes in different days. The isokinetic machine – BIODEX III was utilized to collect the rate of torque development before and after the applications of heat/cold interventions, respectively. Statistical analysis : Descriptive statistics and Pair T-test were used for data analysis. The level of significance is set at .05. Result: Under cooling condition, the average RTD within 200ms was greater than under heat condition(p< 0.05). However, the maximum RTD of 10ms within 200ms was not significantly different in cooling, heat or regular condition.

### **COMBINATION OF ULTRASOUND AND EXERCISE ON NEUROPATHIC PAIN IN RATS**

Huang, P., Chen, Y., Hung, C.

National Cheng Kung University

Introduction Neuropathic pain is a common neurological disorder which affects 7% of general population (Bouhassira et al., 2008). Clinical interventions for neuropathic pain included medication and transcutaneous electrical nerve stimulation (Somers and Clemente, 2009).

However, the effect of ultrasound treatment on neuropathic pain remains unclear. Also, previous report suggested that treadmill exercise alleviated neuropathic symptoms (Chen, 2012). Therefore, we investigated the effect of ultrasound treatment and the outcome of combining treadmill exercise and ultrasound treatment in chronic constriction injury (CCI) induced neuropathic rats in this study. Methods We provided a constricted injury by loose ligation on rat's sciatic nerve (Bennett and Xie, 1988). Forty Sprague-Dawley rats were randomly assigned to five groups: Naïve, sham operation, CCI with ultrasound treatment (CCI+USD), CCI with treadmill exercise treatment (CCI+TME), and CCI with combine treatment (CCI+TME+USD). Ultrasound treatment of 1 w/cm<sup>2</sup> with 100% duty cycle started immediately after surgery and gently applied on the skin surface above sciatic nerve for 5 minutes per day, 5 days a week for 4 weeks (Somers and Clemente, 2009; Yang et al., 2008). Exercise treatment started at post-operative day 7 with intensity of 14-16 m/min with 8% incline grade, 5 days a week for 3 weeks (Stagg et al., 2011). Thermal hyperalgesia and mechanical allodynia were used to determine the level of neuropathic pain by using Plantar Test and Von Frey Hair Aesthesiometer, respectively. Results In thermal hyperalgesia, we found that i) the withdrawal latency of CCI rats was shorter than sham ones; ii) all three treatments groups significantly increased the latency of withdrawal responses; iii) the withdrawal latency of CCI+TME+USD group was significantly higher than CCI+USD group or CCI+TME group; iv) No significant difference between CCI+USD and CCI+TME group; v) after 4-weeks intervention, withdrawal latencies were indistinguishable between sham and CCI+TME+USD group. Discussion In conclusion, ultrasound treatment reduced neuropathic pain and combination of ultrasound and treadmill exercise could even provide a better outcome. ### QUADRICEPS ISOMETRIC STRENGTH AS PREDICTOR OF DECREASED Z-SCORE BMD IN ADOLESCENTS WITH DOWN SYNDROME

Gonzalez-Aguero, A.1,2, Gomez-Cabello, A.1, Matute-Llorente, A.1, Gomez-Bruton, A.1, Guppy, F.M.2, Vicente-Rodriguez, G.1, Casajus, J.A.1

*1GENUD Research Group, Department of Physiatry and Nursing, University of Zaragoza, Spain; 2Department of Sport and Exercise Science, Aberystwyth University, UK*

**Introduction** Adolescents with Down syndrome (DS) have shown low levels of bone mineral density (BMD). In addition, maximal isometric strength (MIS) seems a good predictor of BMD in some populations. As BMD is related with age, Z-score might be a more suitable method to evaluate risk of low BMD in growing populations. **Aim** To observe possible relations between MIS and Z-score from BMD in adolescents with DS, and to investigate whether MIS tests might predict risk of low BMD in this population. **Methods** Whole body, hip and lumbar spine BMD of 31 adolescents (15.8±2.9 yr) with DS was evaluated with dual energy X-ray absorptiometry (DXA), and Z-scores were calculated based on age- and sex-matched reference values. Participants were classified as at risk of having low BMD (Z-score ≤ -2SD) or not (Z-score > -2SD). MIS was evaluated for leg extensors (quadriceps) and forearm and hand (handgrip) muscular groups. Age-controlled partial correlations between Z-scores and MIS were conducted. Three different stepwise linear regressions including age, height, weight, and MIS for quadriceps and handgrip as independent variables were performed with the three different Z-scores as dependent variables. This provided 3 prediction equations for estimate Z-score. Estimated Z-scores were calculated and participants were reclassified as at risk of having low BMD or not with these estimations. The risk of having low BMD was compared between the actual DXA values and those calculated with the prediction equations. **Results** Correlations were found for both handgrip and quadriceps MIS and BMD Z-score at lumbar spine (r=0.4 and 0.5 respectively, both p<0.05), and also between quadriceps MIS and BMD Z-score at hip and whole body (both r=0.5 and p<0.05). Linear regressions showed quadriceps MIS as the stronger predictor for BMD Z-score overall. The prediction equations had an accuracy of prediction for the risk of having low BMD of 68, 61 and 84% for whole body, hip and lumbar spine respectively. **Discussion** Quadriceps MIS is an important predictor of Z-score BMD in adolescents with DS and it might, by itself, or in combination with age, height or weight provide an accurate estimation of the risk of having low BMD. This is an important issue that quadriceps MIS could act as a first screening which would inform regarding the importance of performing a DXA scans in certain adolescents with DS. **References** Gonzalez-Aguero A, Vicente-Rodriguez G, Moreno LA, Casajus JA.(2011). *Osteopor Int*, 22(7), 2151-7. ### DOES MUSIC INTERVENTION FACILITATE CARDIOPULMONARY FUNCTION DURING HEAVY CYCLING EXERCISE AND RECOVERY PHASE

Hu, C.Y., Ko, H.T., Lin, H.T.

*Kaohsiung Medical University*

**Introduction** The music stimulation has been extensively applied in the process of exercise or during sports competition (Karageorghis et al., 2011). Listening music during exercise could increase the degree of the awakening and enhance the performance of the exercise. However, the mechanism of music intervention affected physiological change is still not clear. Therefore, the aim of this study is to explore the impact of the music intervention in the cardiopulmonary system function during cycling. **Methods** Three female university students without cardiopulmonary system syndrome were participated in this study. The exercise intensity was based on each subject's power output at maximum VO<sub>2</sub>, and it was determined by the Astrand's program (Astrand 1965). During testing, the pulmonary gas exchange system (K4b2, cosmed, Italy) and heart rate detector were worn on the subject to record the cardiopulmonary parameters during cycling. The subjects were asked to keep at rest for five minutes to record the data as the baseline, and then doing cycling at resistance of 40% of maximum power for warm-up for 10 minutes and 60% of maximum power for exercise for 20 minutes. The pedaling rate was set at 50 rpm. The data recording was still continued for 15 minutes after exercise for detect the effect of music in recovery. Cycling with music and without music were tested. The music is at tempo 134 bits/min. **Results** Under music intervention, in the warm-up (low intensity exercise) phase, oxygen uptake was increased, and during exercise and recovery phase, heart rate was increased, all of them reached the statistically significant differences. The respiration frequency and oxygen uptake had increasing trend but did not reach statistically significant difference. In the recovery phase, after ten minutes rest, the rise in oxygen uptake reached statistical significant difference under music intervention. **Discussion** The results of this study found that music intervention can enhance subject to have better oxygen uptake and efficiency use of oxygen that could access to the status of the exercise faster in the warm-up stage. In the main exercise, music intervention could increase heart rate and can make the body to adapt the faster oxygen consumption during the exercise. The music intervention during the recovery, the heart rate of subjects decreased faster but still keeps higher oxygen uptake, that could use oxygen more

efficiently and recovery faster. These mechanisms can cause the metabolic rate rose. This physiological change under music intervention could help body to adopt exercise quickly and help body to remove metabolic waste quickly during exercise and recovery fast. ### ADAPTATION OF THE AUTONOMIC NERVOUS SYSTEM FROM RECOVERY TO COMPETITION PERIOD IN ELITE TRACK AND FIELD ATHLETES.

Schäfer, D., Frey, M.T., Radtke, T., Saner, H., Wilhelm, M.

*University Clinic for Cardiology, University Hospital and University of Bern*

**Introduction** Successful endurance training must balance overload and recovery to prevent overreaching (OR). Analysis of markers of the autonomic nervous system measured by heart rate variability (HRV) has the potential to guide training by monitoring the increase in vagal tone, generally associated with repetitive training loads (Kiviniemi et al., 2007). However, a conversion from vagal to sympathetic predominance has been observed in successfully performing elite rowers (power endurance athletes) immediately before competition (Iellamo et al., 2002). To confirm this result in endurance athletes, we investigated HRV in elite track and field athletes during recovery period (RP) and competition period (CP). **Methods** Seventeen male athletes competing at national level were examined ( $20 \pm 3$  years, body mass index  $21.2 \pm 1.3$  kg/m<sup>2</sup>, running speed  $17.5 \pm 1.9$  km/h at the anaerobic threshold and  $20.2 \pm 1.6$  km/h at maximum). The power spectrum of HRV was measured in supine position and after an orthostatic load during RP and CP. Four minutes segments were analyzed with an autoregressive spectrum. Three spectral components were distinguished: Total power (TP) in ms<sup>2</sup>, and low frequency (LF) and high frequency (HF) power in normalized units (n.u.). The sympatho-vagal balance was calculated as LF/HF power ratio after the orthostatic load test. HRV parameters of RP were compared with CP by Mann-Whitney U tests. Results Fourteen athletes had sufficient data quality in both tests and were included in the final analysis. No athlete exhibited symptoms of OR during the CP. Comparing orthostatic load test in the RP and CP, athletes showed an increase of the LF/HF power ratio (median (IQR) 5.6 (6.8) vs. 10.2 (8.5);  $p=0.009$ ), and of LF power (84.8 (13.8) vs. 91.0 (7.9);  $p=0.016$ ), and a decrease of HF power (15.3 (13.8) vs. 8.9 (7.9);  $p=0.016$ ). No changes were observed for TP. **Discussion** The results of our study show a shift of sympatho-vagal balance towards higher sympathetic tone before competitions in male elite track and field athletes. In the absence of symptoms of OR, this pattern of adrenergic activation may reflect readiness for competition. Kiviniemi, A.M., Hautala, A.J., Kinnunen, H., Tulppo, M.P. (2007). *Eur J Appl Physiol*, 101:743-751. Iellamo, F., Legramante, J. M., Pigozzi, F., Spataro, A., Norbiato, G., Lucini, D., Pagani, M. (2002). *Circulation*, 105:2719-2724.

### THE DIFFERENCES OF MUSCLES CO-CONTRACTION AROUND THE SHOULDER AT VARIOUS POSITION AND VELOCITIES

Ko, H.S., Hu, C.Y., Lin, H.T.

*Department of Sports Medicine*

**Introduction** Muscle co-contraction not only can reach the motion accuracy, but also can maintain the joint stability. Maximum joint strength is various with joint position and moving velocity due to the muscle length-force and loading-velocity relationship. For that reason, muscles around the joint should have different co-contraction condition to keep joint stability in different motion situation. The shoulder joint relies on muscles most around the joint to maintain the joint stability. The purpose of this study is to investigate the effect of joint position and moving velocity in muscles co-contraction in shoulder rotation. **Methods** Four healthy subjects, aged 20-23, without any upper limb injuries were recruited in the study. Before testing, the subjects were asked to warm up the shoulder and measured the muscle maximum voluntary contraction (MVC). Eight muscles including anterior deltoid, posterior deltoid, pectoralis major, supraspinatus, infraspinatus, teres major and teres minor were tested by the surface electromyography system (Trigno•, Delsys Inc, USA). In the isokinetic shoulder internal and external rotation test, the joint velocity was set by the dynamometer system (System 3, Biodex Medical Systems, USA) in 60°/sec, 120°/sec and 210°/sec at shoulder abduction 45°, 70° and 90°. **Results** During internal rotation, the teres minor, teres major, pectoralis major and anterior deltoid were more activated than in external rotation. However, the supraspinatus, infraspinatus and posterior deltoid were more activated in external rotation. Analyzed the effect of joint position in muscle activation, the teres minor, teres major, supraspinatus and infraspinatus had largest activation at shoulder abduction 70°, but the pectoralis major, posterior deltoid and anterior deltoid were more activated at shoulder abduction 90°. About the effect of moving velocity in muscle activation, the teres minor, supraspinatus and posterior deltoid have more activation at 210°/sec, and most of muscles had less activation at 60°/sec, except teres major and anterior deltoid. **Discussion** From this study, we had found that the joint angle and moving velocity did affect muscles activation during internal and external rotation. However, subjects in this study didn't show the consistent change in the different moving velocities at various joint positions. That may result from that we choose the maximum muscle contraction value for analysis during the test, however, the peak value for different muscles were not occurred at the same time. Only four subjects was also the limitation. More subjects tested will be required to define the muscle co-contraction change with motion velocity change at different joint position. These results will be helpful for athletes training for injury prevention and rehabilitation program design. References Walmsley RP, Szybbo C. (1987). *J Orthop Sports Phys Ther*, 9, 217-222. ### THE EFFECT OF HIGH-INTENSITY INTERVAL EXERCISE AND RESISTANCE EXERCISE ON BLOOD PRESSURE IN OBESE ADULTS

Shi, Q.1, Kong, Z.2, Lin, H.3, Tong, T.4, Choi, C.1, Nie, J.1

*Macao Polytechnic Institute*

1: MPI (Macao, China). 2: UMAC (Macao, China). 3: LNU (Dalian, China). 4: HKBU (Hong Kong, China). **Introduction** Current recommendations for blood pressure (BP) control involve performing prolonged endurance and resistance exercise. However, the general population fails to follow such regimes due to lack of time. Therefore, it is very important to develop time-efficient exercise intervention strategies. A growing body of evidence demonstrates that minimal volume of high-intensity interval training and resistance training can serve as effective alternatives to traditional time-consuming training, inducing similar or even superior physiological adaptations (Babraj et al., 2009). However, limited information is available regarding the impact of minimal volume exercise on BP. The study aimed to analyze BP responses in obese adults following minimal volume high-intensity interval exercise (HIE) and resistance exercise (RES). **Methods** Fifteen obese adults (age:  $21.7 \pm 2.4$  years; BMI:  $34.1 \pm 5.9$ ) underwent: (1) HIE: all-out cycling exercise 30 sec  $\times$  4, interspersed with 4 min of rest; (2) RES: a circuit of nine resistance exercise involved the large muscle groups with ten repetitions, interval with 1 min of rest; and (3) CON: a

control session of no exercise. Systolic (SBP), diastolic (DBP) and mean arterial (MAP) were measured by ambulatory blood pressure monitoring (ABPM) over a 15 hrs period following exercises and CON, including daytime and nighttime. Results SBP increased ( $P < 0.05$ ) immediately after both HIE (Pre vs. Post:  $135 \pm 11$  vs.  $158 \pm 21$  mmHg) and RES (Pre vs. Post:  $136 \pm 11$  vs.  $148 \pm 20$  mmHg), but returned to pre-exercise level since then. Only RES elicited post-exercise DBP (CON vs. RES:  $72 \pm 11$  vs.  $68 \pm 12$  mmHg) and MAP (CON vs. RES:  $94 \pm 11$  vs.  $91 \pm 12$  mmHg) reduction that lasted near 2 h after exercise ( $P < 0.05$ ). Compared with CON, no significant change in the BP was found during sleep post-exercise ( $P > 0.05$ ) after HIE or RES. Discussion The results of the present study demonstrate that, compared with no exercise and HIE, minimal volume RES (total exercise period of 14 min) was effective in promoting hypotension effects in DBP and MAP in normotensive adults, as measured by ABPM. It is known that responses to physical training are the result of cumulative acute effects over time (Thompson et al., 2001). Further, longer exercise-induced hypotensive effects may be observed in subjects with higher baseline levels compared with normotensive individuals (Cardoso et al., 2010). Therefore, the current findings led the authors to speculate that minimal volume resistance exercise involved the large muscle groups may represent a practical and time-efficient exercise strategy to BP control in individuals with baseline-elevated BP. \*The study was supported by a research grant from Macao Polytechnic Institute (RP/ESE FD-02/2012). ## AN INNOVATIVE TREATMENT CONCEPT FOR TRIATHLETES SUFFERING FROM ACHILLODYNIA

Fladischer, T., Hoeden, D., Titze, S.

*LKH Bruck/Mur*

INTRODUCTION: According to former published data up to 90% of active triathletes suffer at least one injury during their career.(1) Because of this high injury prevalence, our study group accomplished a survey, interrogating nearly 1200 long distance triathletes, concerning their injuries and training habits. The aim of our study was to detect risk factors for injuries to establish prevention and treatment concepts. We found a particularly high occurrence of Achillodynia (AD) (34%), and due to these findings we developed a treatment concept, especially for triathletes suffering from AD. METHODS: Our e-questionnaire - available in 5 languages - was sent to all members of the Austrian triathlon association and to participants of several Ironman events in Europe. 1158 athletes met our inclusion criteria and returned the questionnaire between July 2011 and February 2012. Chi square tests were applied to identify differences in risk factors between athletes with and without AD. RESULTS: We recommend a treatment concept based on a modified version of the EdUReP model, a tendinopathy treatment model emphasizing Education, Unloading of the Achilles Tendon and controlled reloading. (2) Week 1 -4: During the first 4 weeks a consistent unloading phase is scheduled. Within this period a rigorous running rest and key aspect on alternative training (e.g. strength training upper body, swimming, aquajogging,...) is intended. We also recommend an all day long heel pad supply for both legs. Additionally, anti-inflammatory and pain-relieving measures, implying the use of anti-inflammatory drugs, deep friction massage, physiotherapy, ice, therapeutic ultrasound and ESWT should be applied. If the athlete is free of pain after 4 weeks of unloading, a gradually reloading phase should be started for the next 8 weeks. Week 5-6: Intermittent relieve of heel pas during daily life, gain of alternative training, retain of running rest. Week 7-8: Start with Nordic walking training and moderate cycling sessions using heel pads. Eccentric training of the calf muscles should be entered to training. Week 9-10: Start with moderate running sessions on flat terrain using heel pads, gain of cycling training and eccentric calf muscle training. Week 11-12: Gain of running training with intermittent relieve of heel pads. After 12 weeks the athlete should return to the full training coverage. DISCUSSION: Due to our statistical analysis we found a long median time span of athletes suffering from AD until they return to training (mean 31 days) and high percentage of chronication. Because of these findings best possible treatment concepts should be applied. REFERENCES: (1)Egermann M, Brocai D, Lill CA, et al. ## DRINKING AD LIBITUM OF ELITE MALE RUNNERS DURING HALF MARATHON COMPETITION

Vukasinovic Vesic, M., Dikic, N., Andjelkovic, M., Antic, T., Baralic, I.

*Sports Medicine Association of Serbia*

Introduction Drinking ad libitum appears to optimize performance and safety during exercise in many situations. The presence of thirst, not of water loss, may be the biological signal that impairs exercise performance in those who drink less than their thirst dictates during exercise.(1) Method Twenty three runners were assessed during the official Serbian Championship on International Belgrade Marathon event. In order to estimate hydration status we collected urine samples of each athlete before and after the race, we measured body mass of all athletes before and after the race, as well as weather conditions in Belgrade on that day. Athletes were advised to drink ad libitum. Fluid intake estimated from fluid recall questionnaire after the race. Hydration status was evaluated by urine specific gravity (Usg), urine color (Ucol), sweat rate (SR), and fluid intake (FI). Results Runners age was  $26 \pm 5$  years. After the race body mass loss was  $2,2 \pm 1,3$  kg, percentage of dehydration  $3,6 \pm 1,5\%$ , total fluid intake  $322 \pm 302$  ml and sweat rate  $1,74 \pm 0,7$  L/h. Mean Usg before the race  $1017 \pm 8$  and after the race  $1013 \pm 8$  were obtained. Ambient temperature was  $23^\circ\text{C}$  and humidity 96%. 78% of the participants in this study used the water for rehydration, 13% of them used sports drink and 9% did not take any fluid during race. Statistically significant differences where found between body mass before and after the race ( $p < 0,05$ ) also we found significant negative correlations between fluid intake and body mass loss as well as positive correlations between body mass loss and result time of race. Discussion Drinking of fluids "ad libitum" of 23 runners was adequate for them to complete their race, while maintaining their hydration status. Drinking habits in our study does not corresponding with the ACSM guidelines for fluid intake for marathoners which suggested that fluid intake should be from 0.4 to 0.8 L/h.(2). Endurance athletics events always as a result have huge loss of fluid which does not necessary leads to dehydration. Most of the lost fluids in prolonged exercise come from the process of glycogen oxidation which means that there is no loss from extracellular fluid compartment.(3) References 1. Noakes D. ## INJURIES IN GERMAN ELITE MEN'S SOCCER – VIDEO ANALYSIS OF INJURY SITUATIONS

Klein, C., Luig, P., Henke, T.

*Ruhr-University Bochum*

**Introduction:** With about 6.8 million members the German soccer federation is one of the biggest sport federations of the world. In Germany, soccer is the most popular sport, but particularly on professional level a sport with a very high injury incidence (approx. 18.4 inj. / 1000h). During the seasons 2010/11 and 11/12 more than 3,500 injuries within the 1st and 2nd league led to about 50,500 days of disability and medical costs of almost 8 million. The purpose of this study was to identify typical injury situations in professional men's soccer and the illustration of resulting prevention measures. **Methods:** The observation period focused on the season 2010/11 and 11/12 of the two highest leagues in German men's soccer. To describe the sample of all professional soccer players who played at least once in a competitive match, soccer specific journals were consulted. Injury data including information about nature and severity of the injuries were provided by the German accident insurance of the athletes (VBG). The footage was available via the media library of the German Soccer League. With the aid of a validated checklist approx. 200 injuries of the given period were analysed. **Results:** Throughout the observation period 78 % of all athletes got injured at least once. In average each player sustained 2.5 injuries per season. About two-thirds of the injuries in German professional soccer concerned the lower limbs. Most of them were injuries of the thighs (19.5 %), the knees (16.0 %) and the ankles (12.4 %). Knee injuries showed the highest severity leading to nearly 7,500 days of disability and 1.6 million medical costs. In case of thigh injuries prevalently chronic injuries were monitored as a result of overuse effects during the season. Concerning knee injuries pivoting or coordination deficits in non-contact situations are common. Most of the ankle injuries are a result from direct contact with an opposing player. **Discussion:** At least on professional level soccer is a high risk sport. Most scientific preventive measures focus on physical preparation and training approaches. To increase applicability and acceptance of these approaches a sport specific implementation is recommended. Particularly to prevent injuries resulting from irregular contact situations approaches should focus on referee education and technique advises helping the athletes to withstand risk situations uninjured. Furthermore injury prevention modules should be included into education curricula of all trainer licenses.

## A META-ANALYSIS ON SPORTS INJURY PREVENTION IN CHILDREN AND ADOLESCENTS

Rößler, R., Donath, L., Schweizer, T., Faude, O.

*Institute of Exercise and Health Sciences*

**Introduction** Physical inactivity during childhood and adolescence has considerable detrimental health effects and thus the promotion of sports and physical activity during early years is widely recommended to support a healthy lifestyle (Mountjoy et al., 2011). Otherwise, being engaged in sports always bears the risk of sustaining an injury. Injuries, in turn, can lead to a reduction in current and future involvement in physical activity and, therefore, may negatively affect future health as well as quality of life (Emery, 2003). The aim of the present meta-analysis was to analyse the effectiveness of injury prevention programmes in organised sports in children and adolescents. **Methods** A computer based literature search was conducted in six databases (CINAHL, Cochrane, EMBASE, ISI Web of Science, PubMed, SPORTDiscus) using the search terms: sport\* injur\*, athletic injur\*, sport\* accident\* AND prevent\*, prophylaxis, avoidance AND child\*, adolescen\*, youth. Moreover, citation tracking and hand searching were carried out until February 2013. A total of 1556 articles were found. 22 studies met the inclusion criteria (analysing the effects of a prevention strategy on injury occurrence in children and/or adolescents during organised sport compared to a control group). Statistical analysis was conducted using a Mantel-Haenszel random effects model. Risk ratios (RR with 95% CI) were calculated by dividing the injury rate of the intervention group by the injury rate of the control group. **Results** The overall RR was 0.58 [0.44; 0.76] (P<0.001). 16 studies evaluated "active programmes" (e.g. neuromuscular training) and found a mean significant effect (RR=0.60 [0.49; 0.72], P<0.001). Of those, 9 studies aimed at reducing "global injuries" (RR=0.66 [0.53; 0.83], P<0.001) and 7 studies focused on "specific injuries" (e.g. knee, head) (RR=0.48 [0.32; 0.71], P<0.001). 6 studies evaluated "passive prevention" (e.g. safety equipment) and demonstrated a non-significant effect (RR=0.64 [0.29; 1.42], P=0.27). 2 of those studies focused on "global injuries" (RR=0.60 [0.38; 0.95], P=0.03) and 4 studies on "specific injuries" (RR=0.62 [0.19; 1.99], P=0.42). **Discussion** The present analysis clearly demonstrates the potential of preventive measures in youth sports. Depending on the mode of intervention and the specific aim, a reduction in injury rate of 40% seems possible. Active prevention focusing on specific injuries revealed the most promising effects. This is in line with Emery (2003) who emphasized the impact of modifiable risk factors like poor strength or endurance. **References** Emery, C. A. (2003). *Clin J Sport Med*, 13, 256-268. ### EXERCISE HYDRATION KNOWLEDGE OF SINGAPOREAN SCHOOL-GOING YOUTH ATHLETES

Chia, M., Mukherjee, S., Huang, S.H.D.

*National Institute of Education, Nanyang Technological University, Singapore*

**Introduction** Youth athletes in Singapore are at a higher risk of heat-associated disorders due to the exposure to outdoor co-curricular activities and sports training in hot and humid weather conditions all year round. To enhance sports safety and health, it is important to understand the baseline exercise hydration knowledge in this population before guidelines can be formalised and implemented. The study examined the exercise hydration knowledge of Singapore school-going youth athletes. **Methods** 586 youth athletes (13.91±2.53y, male=322, female=264) from primary schools, secondary schools and a junior college participated in the study. All participants completed a hydration knowledge questionnaire based upon the ACSM and NATA guidelines on fluid replacement for athletes (Casa et al. 2000; Sawka et al. 2007). The questionnaire consisted of pre-exercise, during-exercise and post-exercise hydration knowledge sections. Adequate hydration knowledge was accepted as a score of 80% and above (Ransone and Dunn-Bennett 1999). **Results** 82.3% of the participants were involved in team sports. The average knowledge scores of primary, secondary and junior college athletes were

41.08±11.84%, 43.10±14.07% and 53.27±13.86% respectively. Of the 586 participants, only one athlete from junior college could attain the passing score. Overall, the post exercise knowledge scores were lower compared to pre-and during exercise hydration knowledge (pre=47.2±22.0%, during=48.7±16.9%, post=36.3±18.3%). 46.9% responded that their teachers and coaches were their main source of hydration knowledge. Reliance on parent and coaches for hydration knowledge reduced with the age of the athletes (Coaches and teachers: Pri=52.8%, Sec=45.2%, JC=39.7%; Parents: Pri=52.4%, Sec=27.9%, JC=19.9%; Self-taught: Pri=21.6%, Sec=41.6%, JC=52.2%). Discussion The lack of hydration and fluid replacement knowledge in Singaporean youth athletes is a cause of concern and increases the risk of dehydration and heat-associated disorders. These athletes must be empowered with adequate hydration knowledge and practices, for enhanced sports safety and safeguarding health. Coaches, PE teachers and parents should play a major role in educating and facilitating learning among youth athletes. In addition, resources on hydration tips and strategies should be made freely available. The findings of this study can contribute to the development of formalised hydration guidelines for Singapore and the Southeast Asian region. References Casa DJ, Armstrong LE, et al. (2000). ### **POST-RESISTANCE EXERCISE HYPOTENSION IS NOT MEDIATED BY THE CENTRAL NERVOUS SYSTEM NOR INFLUENCED BY TRAINING METHOD**

Rodriguez, D., Pontes Jr, F.L., Bocalini, D.S., Charro, M., Figueira Jr, A.

*São Judas Tadeu University*

INTRODUCTION: Hypertension affects approximately 40% of the population over 40 years old; therefore it is extremely important to search strategies for prevention and treatment of this disease. Although the cardiovascular behavior is partially unknown, resistance exercise (RE) has been recommend for this population, especially, executed in circuit (C) and multiple sets (MS) training methods. PURPOSE: The aim of this investigation was to check the post RE hypotension (PREH) and heart rate variability (HVR) after different training methods (C and MS) in normotensive middle-aged men. METHODS: Volunteers (n= 15; 46,5 ± 4,9 years; BMI 27,9 ± 2,6 Kg/m<sup>2</sup>; MBP 96,4 ± 4,0 mmHg; HR 66,5 ± 4,7 bpm) performed two experimental RE sessions (C and MS) composed by 12 exercises (3 sets; 14-17 reps; 60 % of 1-RM) with the same total work. Blood pressure (BP) and HRV were monitored before (20 min) and after (90 min) the exercises sessions. Autonomic regulation was evaluated by normalized low-LFR-Rnu) and high-frequency (HFR-Rnu) components of the R-R variability. RESULTS: Data showed significant changes in HRV (P > 0,05). LFR-Rnu increased, while HFR-Rnu decreased in both exercise sessions. MBP results are presented on the table below: RESULTS: The MBP remained significantly reduced throughout the monitoring period after the end of the exercise in relation to rest values for both RE training methods (C = - 6,1 ± 1,3 mmHg and MS = - 6,3 ± 1,5 mmHg; p 0,05). There was no significant difference in the MBP when the methods were compared. Data showed significant changes in HRV (p < 0,05). LFR-Rnu increased, while HFR-Rnu decreased in both exercise sessions. DISCUSSION: Despite some evidences that the RE variables could influence the cardiovascular behavior after its end (Polito et al., 2003; Jones et al.,2007; Rodriguez et al., 2008), both training methods caused PREH similarly. Furthermore, PREH is accompanied by an increase in sympathetic modulation to the heart observed by the HFR-Rnu increase. This behavior has been previously described for the MS (Rezk et al., 2006) but not for the C method. Additionally we can speculate that the PREH is not determined by the central nervous system. Introduction The number of pets has been increasing in Japan, but the culture of pet ownership is different from other countries. Several reports associating the physical, psychological and social effects of human pet bonding exist in Japan. The objective of this study was to investigate the relationship between the presence of pets and the mental and physical health of their Japanese owners. Methods Persons selected at random voluntarily participated in this study. A questionnaire related to presence/absence of pet, animal breed, pet care, life change raising the pet and health-related QOL items was administered. Health-related QOL items assessed with the SF-36, the relationship between 4 scales (physical functioning:PF, general health perceptions:GH, vitality:VT, general mental health :MH) and pet ownership were analyzed. Results and Discussion The data sample consisted of 284 male and 714 female respondents. Score results of the 4 scales did not significantly differ between the pet owner group (POG) and non-pet owner group (NPOG). But GH scores in POG playing with pets were significantly higher than POG not-playing with pet and NPOG. MH scores in POG feeding to pets, grooming of pets, cleaning pet's cages were significantly higher than NPOG. It is suggested that regardless of the kind of pet, and contact pets have a good influence on the health of the owner. VT and MH scores in POG increased the opportunity for going at with pet breeding and POG increased the amount of physical activity with pet breeding were significantly higher than NPOG. 90% of POG was the dog owner. Moreover, the group with the increased amount of physical activity walking with dogs showed a tendency to increased VT scores. We could show the presence of dog play as a major role in promoting physical activity of the owner. The walking of a dog would bring benefits to the health of the owner by noticing that the walking of dogs helps to promote one's own health.

### **THE RELATIONSHIP BETWEEN PLASMA KLOTHO CONCENTRATION AND AEROBIC EXERCISE CAPACITY IN POST-MENOPAUSAL WOMEN**

Matsubara, T., Miyaki, A., Akazawa, N., Choi, Y., Ra, S.G., Higashino, R., Tanahashi, K., Kumagai, H., Oikawa, S., Ajisaka, R., Maeda, S.

*University of Tsukuba*

INTRODUCTION: The Klotho gene is a suppressor of the expression of aging-associated phenotypes (Kuro-o et al., 1997) and its plasma concentration decreases with aging (Yamazaki et al., 2010). It is also widely published that habitual aerobic exercise is an effective therapy for preventing aging-related diseases. However, little is known about the relationship between plasma Klotho concentration and aerobic exercise capacity. Therefore, the aim of this study was to determine whether plasma Klotho concentration is associated with aerobic exercise capacity. METHODS: Sixty-nine healthy, post-menopausal women aged from 50 to 76 years, participated in this study.

We measured physiological and hemodynamic characteristics, as well as oxygen consumption (VO<sub>2</sub>) at ventilatory threshold (VT), an index of aerobic exercise capacity. Plasma Klotho concentration was measured by enzyme-linked immunosorbent assay. The correlation between plasma Klotho concentration and VO<sub>2</sub> at VT was calculated by partial Pearson correlation analysis. Stepwise regression analysis was used to extract the significant parameters associated with plasma Klotho concentration. RESULTS: There was positive correlation between plasma Klotho concentration and the VO<sub>2</sub> at VT, adjusting for age and BMI ( $\beta = 0.329$ ,  $P < 0.01$ ). Furthermore, stepwise regression analysis showed that plasma Klotho concentration was significantly associated with VO<sub>2</sub> at VT. DISCUSSION: The present study found that plasma Klotho concentration was associated with aerobic exercise capacity in postmenopausal women. These results suggest that habitual aerobic exercise might increase plasma Klotho concentration. Therefore, the increase in plasma Klotho concentration may contribute to habitual aerobic exercise-induced anti-aging effect. REFERENCES: Kuro-o M, et al. ## DETERMINANTS OF PHYSICAL FUNCTION CHANGES AFTER A FALL-PREVENTION PROGRAM IN OLDER JAPANESE WOMEN

Jindo, T., Tsunoda, K., Soma, Y., Saghazadeh, M., Tsuji, T., Mitsuishi, Y., Kitano, N., Okura, T.

*University of Tsukuba, Japan*

**Introduction** Benefits to physical function (PF) induced by exercise training vary between adults. The purpose of this study was to investigate determinants of PF changes in older adults during a period of exercise training. **Methods** The subjects of this study were 68 community-dwelling older women (mean age:  $70.5 \pm 4.1$  years) in Kasama City, rural Japan. All subjects participated in a fall-prevention exercise called Square Stepping Exercise (SSE) (Shigematsu et al., 2008) conducted once a week for 11 weeks. To ascertain the PF benefits induced by the exercise program, we measured 9 physical performance tests: grip strength, one leg stand, sit and reach, functional reach, 5-time sit-to-stand, timed-up-and-go, 5-m habitual walk, manipulating pegs and choice-stepping reaction time. Additionally, we calculated a comprehensive score of the 9 physical performance tests using a principal component analysis. Change in comprehensive PF score between baseline and post test was used as a dependent variable, while baseline values of physical activity, the Lubben social network scale, the geriatric depression scale, the five cognitive function test and the comprehensive PF score were treated as independent variables. **Results** Stepwise multiple regression analysis revealed that the change in the comprehensive PF score correlated significantly with baseline values of comprehensive PF score ( $\beta = -0.448$ ) and the five cognitive function test ( $\beta = 0.257$ ). **Discussion** These results suggest that older women with a low level of PF at baseline are more likely to improve their PF with a period of exercise training. However, the improvement in PF would be less in older women with a low level of cognitive function than in older women with a high level of cognitive function. We recommend that researchers and physiotherapists consider this difference in PF improvement during exercise training programs when working with older women having a lower level of cognitive function. **References** Shigematsu R, Okura T, Nakagaichi M, Tanaka K, Sakai T, Kitazumi S, Rantanen T. Square-Stepping Exercise and Fall Risk Factors in Older Adults: A Single-Blind, Randomized Controlled Trial. *J Gerontol A Biol Sci Med Sci* (2008) 63 (1): 76-82.

## EFFECT OF EXERCISE HABIT ON DEPRESSION AND SENSE OF COHERENCE IN UNIVERSITY STUDENTS: FOCUS ON SEX DIFFERENCE

Omagari, M.1, Atin, S.1, Hayashi, N.2, Matsushita, T.2, Kumagai, S.2

*1: Graduate School of Human-Environment Studies, Kyushu University (Fukuoka, Japan), 2: Institute of Health Science, Kyushu University (Fukuoka, Japan)*

**Introduction** Mental health disorder such as depression is one of serious problems in university students worldwide (Kunugimoto and Yamasaki.2008; B  r   et al. 2011). However, students with mental disorder who received treatment are rather few (Eisenberg. 2012). Thus, constructing students' mental health care system on campus is necessary. Regular exercise habit has a preventive effect against physical and emotional health problems; however, few studies have shown the association of exercise with mental health among university students categorized by sex. The aim of this study was to examine the association among depression, sense of coherence and regular exercise habit by sex. **Methods** The study was carried out in freshmen ( $n=2631$ ) in May to June 2010 at one of government funding university in the southeast part of Japan. The study participants answered to the following questionnaires; Center for Epidemiologic Studies Depression scale (CES-D), Sense Of Coherence by 13 items scale (SOC), students health questionnaires on regular exercise habit ("very few", "sometimes" and "almost every day") and quality and nature of college life. Height, weight, age and sex of the students were collected from students' annual health checkup held on April, 2010. Data was analyzed using SAS statistical package. Logistic regression analysis was conducted by sex using depression and SOC as dependent variables and regular exercise habit as an independent variable to assess the interrelationship among depression, SOC and regular exercise. Odds ratio and its 95%CI were calculated with adjustment of quality and nature of college life factors. **Results** In males, the adjusted odds ratio for depression in the group having moderate exercise habit (G2) was 0.74 (95%CI, 0.56 - 0.98) , and that in the group having exercise habit almost everyday (G3) was 0.54 (0.35 - 0.83), compared to the group who had least exercise habit (G1). The adjusted odds ratio for high SOC score in G2 was 1.36 (1.05 - 1.76) , and that in G2 was 2.27 (1.56 - 3.29), compared to G1. In females, those ratios were not significant. The adjusted odds ratio for depression in G2 was 0.69 (0.46 - 1.03), and that in G3 was 0.39 (0.11 - 1.35), compared to G1. The adjusted odds ratio for high SOC in G2 was 2.0 (1.41 - 2.86), and G3 was 1.09 (0.48 - 2.48), compared to G1. **Discussion** In male, regular exercise habit was independently associated with both depression and SOC. Conversely in female, regular exercise was not significantly associated with depression, and solely G2 was associated with SOC after adjusting by quality and nature of college life factors. The findings of the current study indicated that exercise has favorable preventive effect against depression and for SOC, whereas other factors than regular exercise have rather greater impact on depression and SOC for women. **References** Kunugimoto N, Yamasaki K.(2008). *Shinrigaku Kenkyu*, 16( 2), 141-148. ## LOW FREE TESTOSTERONE LEVELS ARE ASSOCIATED WITH LOSS OF APPENDICULAR MUSCLE MASS IN JAPANESE COMMUNITY-DWELLING WOMEN

Yuki, A., Otsuka, R., Kozakai, R., Ando, F., Shimokata, H.

*National Center for Geriatrics and Gerontology*

**Introduction:** The relationship between endogenous testosterone (T) and age-related muscle loss among Japanese women is poorly understood. The objective was to demonstrate longitudinal relationships between baseline T levels and muscle mass changes in 477 community-living, middle-aged and elderly Japanese women. **Methods:** The subjects were 477 women who had participated in both the baseline and follow-up examinations (mean duration, 8.3 years). The subjects were not classified as having sarcopenia at the time of the baseline examination. Appendicular skeletal muscle mass (ASMM) was measured by dual-energy X-ray absorptiometry at baseline and follow-up examinations. The cut-off point for sarcopenia was defined as a skeletal muscle index (calculated by ASMM divided by height squared) of 5.46 kg/m<sup>2</sup> (Baumgartner et al., *Am J Epidemiol*, 1998; Sanada et al., *Eur J Appl Physiol*, 2010). Total T (TT) and free T (FT) were measured by radioimmunoassay at the baseline examination. The TT and FT were categorized approximately into tertiles. Multiple logistic regression models were fit to determine the association between TT or FT and sarcopenia while controlling for baseline age, body mass index, leisure-time physical activity, nutritional intakes (total energy, total protein, vitamin D), serum levels of C-reactive protein, medical histories (heart disease, osteoporosis, rheumatoid arthritis), menstruation, and smoking habit. The study protocol was approved by the Ethics Committee of the National Center for Geriatrics and Gerontology, and written, informed consent was obtained from all participants. **Results:** There were no significant relationships between sarcopenia and TT. The odds ratio of sarcopenia for the Low-FT group (<0.7 pg/mL) compared to the High-FT group (≥1.2 pg/mL) was 4.101 (95% confidence interval, 1.334-12.609). A significant negative trend ( $p$  for trend=0.0106) in the odds ratios of sarcopenia was found with increasing serum FT level. **Discussion:** The results indicate that endogenous FT levels are significant predictors of muscle loss over an 8-year period. Improvement of endogenous FT levels by appropriate therapies, such as androgen replacement therapy or lifestyle interventions, may reduce the risk of muscle loss during aging. **References:** Baumgartner RN, Koehler KM, Gallagher D et al., 1998 Epidemiology of sarcopenia among the elderly in New Mexico. *Am J Epidemiol* 147: 755-763. Sanada K, Miyachi M, Tanimoto M et al., 2010 A cross-sectional study of sarcopenia in Japanese men and women: reference values and association with cardiovascular risk factors. *Eur J Appl Physiol* 110: 57-65.

## PHYSICAL ACTIVITY AND FITNESS IN AFRICAN HIV POSITIVE WOMEN

Prista, A.1, Damasceno, A.2, Bhatt, N.3, Daca, T.1, Mangona, L.1, Tchonga, F.1

*1Physical Activity and Health Research Unity Faculty of Physical Education and Sports, Universidade Pedagógica, Mozambique; 2Maputo Central Hospital, Mozambique; 3Polana Caniço Research Health Center*

**INTRODUCTION** Physical activity (PA) has an important role on cardiovascular health. By turn, cardiorespiratory fitness (CRF) is and consensual indicator of cardiovascular health. High levels of CRF, expressed by VO<sub>2</sub>max, predicted lower risk of cardiorespiratory mobility and mortality. In this context PA and CRF in HIV positive population is an important issue since these population tend to drastic reduce PA physical levels as well as CRF. The aim of this study was to determine the levels of PA and CRF in a sample of HIV positive African women population from Mozambique which were submitted to antiretroviral therapy (ART) **METHODS:** 54 HIV positive Mozambican women (age=38,6±8,4 years) that were clinical controlled by ART participated on the study. Physical activity was assessed by accelerometer wearing, during 7 days, an accelerometer Actigraph model GT3X. Cardiorespiratory fitness were assessed by VO<sub>2</sub>max using a modified treadmill Balke protocol and a Cosmed K4 gas analyser. CRF classification criterion was made according to ACSM classification for healthy women's for the respective age. **RESULTS** Time spent in moderate to vigorous activity was higher than one hour per day in 66% of the subjects while 97.7% spent more than half hour on that activity level. Average percentile of VO<sub>2</sub>max relative to ACSM norms were 65±24. According to classification criteria 81,8% were classified as Healthy (10.9% Reasonable=; 29,1 % Good; 36.4% Exlent; 5.5% Superior). Only 18,2% did not attained the criterion value. **DISCUSSION** CRF levels were higher than expected for HIV positive women's. Associated with their healthy condition, levels of activity and consequently levels of fitness use to be reduced. Due to the socioeconomic conditions of this sample, levels of activity seems to be high related to survival activities like walking, carrying and non-mechanical households. Their lower levels of fat may also contribute for the high aerobic power. Further similar studies in African population are needed to explore our finding in different settings.

## RELATIONSHIPS AMONG SLEEP DURATION, BODY MASS INDEX AND ARTERIAL STIFFNESS IN 4TH TO 8TH GRADES JAPANESE CHILDREN

Morita, N., Oda, S.1, Kambayashi, I., Okuda, T., Nakajima, T.2, Ishizawa, N., Nakamichi, R., Fukuoka, R., Kamiie, S., Takahashi, M., Mizoguchi, H., Asakura, J., Narayama, S., Shide, N., Shinkaiya, H.

*Hokkaido Univ. Education, 1: Hokusho Univ., 2: Hokkaido Institute Tech.*

**Introduction:** The childhood obesity and high blood pressure are expected to increase cardiovascular disease risk in adulthood. Recently, some studies demonstrated that short sleep duration associated with obesity and high blood pressure even in children (Javaheri et al., 2008; Lytle et al., 2011). However, little is known about whether short sleep duration increases arterial stiffness in children. In this study, we investigated relationships between daily sleep duration and arterial stiffness indices in Japanese 4th to 8th grades children. **Methods:** This is a cross-sectional study of 113 elementary and junior high school children (63 boys and 50 girls). As noninvasive arterial stiffness indices, the children's cardio-ankle vascular index (CAVI; Vasera VS-1000, Fukuda Denshi Co., Tokyo; Shirai K et al., 2011) were measured in rest condition. During the measurement, brachial systolic blood pressure and heart rate were also obtained. When systolic blood pressure or heart rate were over 130 mmHg or 100 bpm, respectively, those children's data were excluded. Children answered questionnaires regarding their sleep habits (bedtime and wake-time on usual weekday) and then we obtained their sleep duration by difference between the bedtime and the wake-time. Body weight and height were measured, and then body mass index (BMI) z-score was calculated by using BMI reference data of Japanese children. Relationships among measures were analyzed by Pearson correlation and multiple regression analyses. **Results:** CAVI values were 4.8±0.9 in boys and 4.7±0.9 (arbitrary unit) in girls. CAVI values were correlated negatively with sleep duration (boys,  $r = -0.34$ ,  $p < 0.01$ ; girls,  $r = -0.24$ ,  $p = 0.10$ ). Significant linear correlations were shown between BMI z-score and CAVI values in both genders (boys,  $r = -0.56$ ; girls,  $r = -0.35$ , both  $p < 0.01$ ). In multiple regression analysis, when CAVI was used as the dependent variable and age, gender, BMI z-score and sleep duration as the independent variables, only CAVI and BMI z-score remained significant (R-square = 0.328,  $p < 0.001$ ). **Conclusion:** These results raise a possibility that short sleep duration in childhood

could lead to acceleration of arterial stiffening. References: Javaheri S, et al., (2008) *Circulation*, 118: 1034-1040. Lytle LA, et al., (2011) *Obesity*, 19: 324-331. Shirai K et al., (2011) *J Atheroscler Thromb*, 18: 924-938.

### SEASONAL DIFFERENCES IN THE LIFE-STYLE AND MENTAL HEALTH IN MIDDLE AND OLD AGE SPORTS CLUB MEMBERS LIVING IN A NORTHERN AREA

Sasaki, H., Oda, S., Kinoshita, N., Okita, K.

*Hokusho University*

**Introduction:** Seasonal affective disorder (SAD) which can manifest as depression from autumn to winter, is often associated with the shortening of sunlight hours in higher latitude areas (Magnusson et al., 2003). In addition, it has been reported that people living in northern areas have a decreased amount of daily activity in winter (Marchant et al., 2007). It has also been reported that sleep quality is improved by an increase of daily activity (King et al., 1997). However, there were few studies that examined the relationships between the amount of daily activity, sleeping habits, and mental health. The purpose of this study is to examine the seasonal differences of sleep habits and mental health in middle and old age sports club members living in a northern area. **Methods:** Subjects in this study were 226 people over the age of 40 with a mean age of  $61.0 \pm 7.4$ . All participants were members of comprehensive community sports club in a northern area of Japan. They participate in a fitness classes. To compare the seasonal differences, a questionnaire was given in spring and then again in autumn 2011. The questionnaire was composed of personal profiles about their life-style, including sleep and eating habits and psychological measurements. Sleep habits were assessed by the Japanese version of the Pittsburgh Sleep Quality Index (PSQI-J). Eating habits were assessed by a food intake frequency questionnaire (FFQ). The psychological measurement used a 30-item General Health Questionnaire (GHQ30). **Results:** Mean values of total points for PSQI-J were  $5.4 \pm 2.8$  in spring and  $5.1 \pm 3.0$  in autumn, while the total points for GHQ30 were  $3.6 \pm 3.8$  in spring and  $3.0 \pm 3.5$  in autumn. In comparing spring and autumn, there was no significant difference between the total score of PSQI-J and GHQ30. The ratio of high score to PSQI-J was 41.0% in spring and 35.1% in autumn. Two items of FFQ in autumn, exercise and health and eating behavior, were significantly higher than in the spring. **Discussion:** There were not seasonal differences in the sleep habits and mental health in middle and old age sports club members living in the northern area. There were however, seasonal differences in food intake behavior. These results suggest that people who have an active lifestyle are not affected by seasonal changes in regards to their sleep quality and mental health. Even though this study's population with active lifestyle was not affected by seasonal changes, it became clear that sleep problems still occur in over 30% of the population. **Acknowledgments:** This study was performed in part by a grant from MEXT-Supported Program for the Strategic Research Foundation at Private Universities, 2011-2013. **References:** King et al (1997) : Moderate-intensity Exercise and Self-rated Quality of Sleep in Older Adults, *JAMA*. 277(1), 32-37 Magnusson et al (2003) : Seasonal Affective Disorder: An Overview, *Chronobiol Int*, 20(2), 189-207 Marchant et al (2007): Seasonal Variation in Leisuretime Physical Activity Among Canadians, *Canadian J Public Health*, 98(3), 203-208

### ASSOCIATION BETWEEN PHYSICAL ACTIVITY INTENSITIES AND SLEEP HABITS IN JAPANESE WORKERS

Supartini, A., Honda, T., Kumagai, S.

*Kyushu University*

**ASSOCIATION BETWEEN PHYSICAL ACTIVITY INTENSITIES AND SLEEP HABITS IN JAPANESE WORKERS** 1) Graduate School of Human Environment Studies, Kyushu University, Japan 2) Institute of Health Science, Kyushu University, Japan **Introduction** Sleep is one of the most important factors in maintaining optimal health. Previous research showed that physical activity has impact on quality of sleep<sup>1)</sup>. However, few studies indicate the relationship between objective physical activity measures and sleep habits. The aim of this study is to evaluate the concordance between an accelerometer-derived physical activity and subjective sleep habits in Japanese workers. **Methods** Data was collected from a total 395 men and women, aged above 20 years who participated in the CRC Health Survey in the northwest of Japan. Physical activity during waking hours was measured by a single tri-axial accelerometer device (HJA-350IT; Omron Healthcare, Inc., Kyoto, Japan) placed on the waist for an average of 7 consecutive days. Physical activity rate indicators included the volume (METs hour/day) and time spent (minute). Sleep habits (sleep time, wake time and sleep latency) was evaluated by Pittsburgh Sleep Quality Index (PSQI) Descriptive statistics were carried out for all variables. A chi-square test was used to analyze a relationship among categorical variables. To calculate crude associations of sleep habits with physical activity intensities, a simple linear regression was run for each of the two physical activity intensities; light physical activity (LPA) and moderate-to-vigorous physical activity (MVPA). **Results** The study has shown insomnia prevalence rates of 28.8% with sleep time average of  $24.30 \pm 2.0$  (hour), wake time average of  $7.12 \pm 2.12$  (hour) and sleep latency average of  $16.30 \pm 14.30$  (minute). The association between the volume of LPA and sleep time was 4.15 ( $P < 0.05$ ), which shows that the volume of LPA and sleep time were statistically significant and positively associated. The volume of and time spent in LPA also was positively associated with wake time variable ( $P < 0.05$  in both), whereas MVPA was only inversely associated with sleep time ( $P < 0.05$ ). **Discussion** The primary finding of this study is that, the volume of and time spent in LPA showed positive association with sleep and wake time, which shows that sleep-wake cycle was affected by LPA. The significant association between the volume of MVPA and sleep time shows that MVPA might improve the sleep-wake cycle. Since the studies on objective measurements of physical activity intensities and sleep habits conducted in workers were relatively few, further studies are needed to confirm these results. **References** 1) Shelley S. Tworoger, et al. Effects of a Yearlong Moderate-Intensity Exercise and a Stretching Intervention on Sleep Quality in Postmenopausal Women. *SLEEP*, Vol. 26, No. 7, 2003

### MODELING SPORTS PARTICIPATION IN PORTUGUESE YOUNGSTERS USING A VARIANCE COMPONENTS APPROACH. A SIBLING STUDY

Maia, J.1, Gomes, T.1, Santos, F.1, Souza, M.1, Chaves, R.1, Santos, D.1, Borges, A.1, Pereira, S.1, Garganta, R.1, Gouveia, R.2, Teixeira, A.2, Freitas, D.2

*Faculdade de Desporto - Universidade do Porto 1: CIFI2D, FADEUP (Porto, Portugal) 2:*

**Introduction** It is well established that a vast majority of youngsters do not meet international guidelines for moderate-to-vigorous physical activity. Furthermore, it has been shown (Vilhena et al., 2012) that family is a potent correlate of physical activity and sports participation (SP) habits. Not many studies addressed the issue of sibling clustering in SP (Gomes et al., 2012), and if their age, birth order (BO), sex and body mass index (BMI) condition this healthy habit. This study addresses these issues. **Methods** We sampled 10 to 18 years old Portuguese siblings: 270 male, and 279 female pairs, as well as 499 opposite-sex pairs (totaling 2096 subjects). SP was assessed with the Baecke et al. (1982) questionnaire, using information from sports practiced, corresponding estimated energy expenditure, its duration,

and frequency. Furthermore, BMI and BO were also assessed. Siblings' correlations (rsibs) and modeling age, sex, BMI, and BO effects in SP were done in S.A.G.E. software, for variance components among family members. Results Sport participation prevalence in males is 68.3% (95%CI= 66.1-70.3), and in females is 42.3% (95%CI=40.1-44.6). Team sports are most prevalent than individual sports. No sex-specific correlations were found among siblings (Chi-Square=3.27,  $p=0.19$ ; rsibs=0.27±0.02,  $p<0.001$ ). Sibling dyads explained 30% of SP total variance. On average, boys are more sportive than girls (sex effect=0.39±0.036,  $p<0.001$ ); SP increases with increasing age (age=0.030±0.006,  $p<0.001$ ); first born siblings do more sports than second born siblings (BO=0.062±0.02,  $p=0.021$ ). No significant effects were found for BMI, or BO by sex interactions. Discussion On average, 55.2% of Portuguese youngsters practice sport, and boys are consistently more sportive than girls, which is consistent with international data, and public information from the Portuguese Institute of Sport (IDP, 2011). As expected older subjects do more sport, and birth order does significantly distinguish within dyads sports practice (Gomes et al., 2012). Siblings' variance component (30%) may be explained by genetic and shared family environment (Vilhena et al., 2012). The most important finding is that BMI does not condition sports practice – a true message that sport is for all. References Baecke JA, Burema J, Frijters JE (1982). *Am J Clin Nutr* 36: 936-942. ##### **INTEGRABILITY OF A COMPUTER-BASED EXERCISE PROGRAM IN PEDIATRIC ONCOLOGY AND EFFECTS ON QUALITY OF LIFE AND FATIGUE SYNDROME -TRIAL IN PROGRESS-**

Platschek, A.M.1, Wessely, N.1, Graf, C.1, Baumann, F.1, Berthold, F.2, Schönau, E.2, Strüder, H.K.1

*German Sport University Cologne*

**Introduction** The benefits of physical activity in cancer therapy in adults are well documented. In addition to an increase of physical performance there can be positive effects on quality of life and reduction in fatigue syndrome. In pediatric oncology this approach has not been sufficiently explored. The aim of this study is to research the integrability of a child-friendly computer-based exercise program in the pediatric oncology as well as the effects of the intervention on quality of life and fatigue syndrome. Results could underline the need for exercise therapy as a useful supportive therapy in pediatric oncology. **Methods** Thirty subjects with malignant neoplasm (ICD10 C00-C97) between 6-18 years will be included. The intervention involves a computerized exercise program over three months, twice a week. Intensity and duration of exercise program depends on individual day's form and consists of a fitness program and an active adventure game. Health-related quality of life (KINDL) and fatigue syndrome (PEDsQL multidimensional Fatigue-scale) will be assessed by questionnaire. During the intervention heart rate will be measured. Before and after every fourth intervention a brief emotional questionnaire (mood meter) will be answered. Integrability of the intervention will be determined by drop-out. **Discussion** Well-controlled studies about physical activity in pediatric oncology do not exist. Small uncontrolled interventions already shows that movement in any form and intensity in the acute phase in paediatric oncology can have positive effects on functional mobility, quality of life and self-confidence (San Juan et al. 2007). Studies about other chronic diseases could demonstrate that the use of a computer-aided fitness program was able to reduce fatigue (Yuen et al. 2011) and improve sensorimotor skills (Wuang et al. 2011). More studies exploring this approach in pediatric oncology and supporting natural need for movement will be needed. **Perspective** The findings of the this study suggest guidelines and recommendations about possibilities and contraindications of exercise therapies in pediatric oncology. ##### **THE EXPECT STUDY - EXERCISE DURING PREGNANCY EVALUATIVE CONTROLLED TRIAL**

Davies, R.E., D'Silva, L., Emery, S., Lewis, M.J.

*Swansea University*

Exercise is believed to be beneficial during pregnancy and is therefore recommended for healthy women with normal pregnancies (Artal & O'Toole, 2003). Antenatal exercise might also be important in the management of pregnancy-induced disease (Sorensen et al., 2003). However, no official exercise guidelines have been published in the UK, leading to conflicting advice and much confusion for pregnant women. This study aimed to examine the influence of regular exercise during pregnancy on cardiovascular, haemodynamic and autonomic nervous system (CHANS) parameters during and following pregnancy. Participants were randomly assigned to either one of two weekly exercise groups (water (w) or land (l) based class) or to a control group (n, no organised exercise) using a 2x2x2 design. Non-invasive monitoring of CHANS variables (Heart Rate (HR), Stroke Volume (SV), Left Ventricular Ejection Time (LVET), SDRR, RMSSDRR, LFn) were performed at 15.0±0.2 weeks (T1, n=47, l=12, w=5), 25.4±0.2 weeks (T2, n=43, l=5, w=2), 34.7±0.3 weeks (T3, n=36, l=0, w=1) and 13.5±0.5 weeks post partum (T4, n=22, l=0, w=0). 62 non-pregnant females (no organised exercise) were also assessed using the same protocol. Participants performed postural manoeuvres (supine, standing), stepping exercise, seated recovery (all 6 minute blocks), mental arithmetic and controlled and spontaneous breathing (all 3 minute blocks). Mixed between-within repeated measures ANOVA assessed the influence of main factors 'Protocol Stage', 'Trimester (T1-T4)' and 'Exercise Group' on each CHANS variable. Post-hoc analysis with Bonferroni correction identified the locations of significant differences. One way ANOVA assessed the stage-specific influence of trimester and exercise group on CHANS variables. Qualitative changes in HR, SV and LVET were observed with advancing gestation during the T1-T3 period. RMSSDRR was diminished between T1 and T3 compared with non-pregnant women during the standing and exercise transitions ( $p<0.0005$ ). A reduced LFn response to standing was observed throughout pregnancy ( $p<0.0005$ ). The SDRR response to standing was enhanced during T2 and T3 ( $p=0.041$ ,  $p=0.028$ ). Exercise influenced the trend in LVET and HR throughout the protocol ( $p=0.047$ ,

$p=0.050$ ). There was also a tendency towards an Exercise Group x Trimester interaction for HR ( $p=0.072$ ). HRV variables and SV were not affected by exercise. The results of this pilot study are limited by the fact that recruitment is still at an early stage, and so the number of participants in each of the exercise groups is low. However these initial findings suggest that HR and LVET might be influenced by antenatal exercise. Sorensen, T. K. et al (2003) Hypertension, 41:1273-80 Artal, R. & O'Toole, M. (2003) British Journal of Sports Medicine, 37:6 – 12

### ACTIVATING EVERYDAY LIFE OF GENERATION X – A RCT STUDY

Koskivaara, E.1, Helajärvi, H.2, Virtanen, P.3, Laukkanen, R.3,4, Heinonen, O.J.2

1: University of Turku, School of Economics (Turku, Finland), 2: University of Turku, Health and Physical Activity & Paavo Nurmi Centre (Turku, Finland), 3: Polar Electro Oy, 4: University of Oulu (Oulu)

**Introduction** Physical inactivity accounts for more than 3 million deaths annually (WHO 2011). Physical activity (PA) is a major contributor for both physical and mental wellbeing, and is needed to maintain public health. PA is not only about sports and exercise, but also being active at work, home, in commuting and during leisure time. Evidence-based interventions to promote PA are therefore of great importance. Many of us want to be physically more active, but have found it challenging. Activity monitors provide a means to set targets for daily activity and to follow the intensity, frequency, and duration of PA. Monitoring daily activity has been shown to motivate for PA. We studied the PA changes induced by Polar Active (Polar Electro Oy, Kempele, Finland) activity monitor during a 10-week randomized controlled trial. **Methods** Inclusion criteria for the study were: age 35 – 55, BMI < 30.1 and no sports engagement. The subjects also reported daily PA challenging and wanted to increase everyday PA. In total 60 females and 54 males were randomized into an intervention (30 females, 28 males) and control group (30 females, 26 males). During a 1 week run-in period all subjects used a blinded PA monitor for baseline PA recording. During the following eight week period the intervention group used PA monitor with display and diary functions while the control group continued with the blinded PA monitor. All subjects downloaded their PA data biweekly via an internet interface. The effect of intervention was evaluated by comparing baseline PA to week 8 PA estimated in METs. **Results** Both groups increased their weekday daily mean PA (> 2 MET); intervention group by  $62 \pm 114$  min ( $p < 0.001$ ) and control group by  $47 \pm 104$  min ( $p < 0.001$ ). The mean increase was 40 min higher in females in the intervention group ( $73 \pm 119$  min) than in the control group ( $34 \pm 103$  min;  $p = 0.003$ ). There was no difference between groups in males. Also the weekday mean of more vigorous PA (> 3.5 MET) increased in both groups but there was no difference between the groups. No change was seen in more vigorous PA (> 3.5 MET) during weekend even though PA > 2 MET increased similarly in both groups during weekends. **Discussion** Pretty light intervention, a wrist-worn activity monitor and a biweekly email reminder together with activity data downloads increased the > 2 MET PA with an hour per weekday in the intervention group. Such increase, if durable, has a positive impact on health. The results also confirm that female daily PA may differ from the one of males and that PA monitoring tool may have a stronger effect on females.

### RELATIONSHIP OF CARDIORESPIRATORY FITNESS WITH HEALTH-RELATED QUALITY OF LIFE IN MOROCCAN ADULT WOMEN

Aparicio, V.A., Carbonell-Baeza, A., Senhaji, M., Ruíz-Cabello, P., Camiletti-Moirón, D., Fernández, M., Andrade, A., Delgado-Fernández, M., Aranda, P.

University of Granada.

**Introduction** Due to religion and socioeconomic factors, Moroccan women's health is understudied, especially regarding fitness. The purpose of this study was to analyze the association of cardiorespiratory fitness with health-related quality of life in Moroccan adult women. **Methods** The study comprised 151 women from the North of Morocco (Tetouan and close villages) with an age ranged 45-65 years ( $52.5 \pm 3.8$  years). The 6-min walking test was used to assess cardiorespiratory fitness. Quality of life was assessed by means of the Arabic version of the Short-Form-36 Health Survey (SF36). **Results** The 6-min walking test showed a weak relationship with physical function ( $=0.002$ ), physical role ( $=0.005$ ) and bodily pain ( $=0.003$ ) subscales from the SF-36 ( $p$  ranged 0.241-0.263), and a low relationship with vitality ( $=0.023$ ) and emotional role ( $=0.044$ ) ( $p$  ranged 0.173-0.194). General health, social function and mental health subscales did not show significant correlations. **Discussion** We have found associations between cardiorespiratory fitness and most of the subscales from the quality of life questionnaire employed (SF36). In agreement with our results, Karelis et al. (2008) examined the psychosocial correlates of cardiorespiratory fitness ( $VO_{2peak}$ ) in 137 overweight and obese sedentary post-menopausal women and observed almost the same correlations than us for all the SF36 subscales. The association of cardiorespiratory fitness with mental health is gaining importance in the last years. Therefore, Ortega et al. (2010) observed as individuals with both a low level of negative emotion and a high level of cardiorespiratory fitness had a 63% lower risk of premature death than those with higher levels of negative emotion and a low level of cardiorespiratory fitness. **References** Karelis, A.D., Fontaine, J., Messier, V., Messier, L., Blanchard, C., Rabasa-Lhoret, R., Strychar, I., 2008. ### SELF-ADMINISTRATED VESTIBULAR REHABILITATION TREATMENT FOR DIZZY PATIENTS

Ruzic, L.1, Bencic, I.2, Madjarevic, T.3

1:Dpt. of Sport and Exercise Medicine, School of Kinesiology, Univ. of Zagreb, 2:Dpt. of Otorinolaringology, Univ. Hospital Center Rijeka, 3: Univ. Hospital for Orthop. Surgery, Lovran, Croatia

**Introduction** The aim of this study was to evaluate the effectiveness of the physiotherapy manipulation treatment for dizzy patients that could also be home-based. The so-called vestibular gymnastics protocol involving various head, neck and whole body exercises was conducted throughout the period of 5 weeks 5 times a week. Indication areas for this type of physiotherapy are all types of vertigo and dizziness no matter if it is central or peripheral. The designed exercises were aimed to provoke the vestibular apparatus response. Apart from the first educational session, all of the patients received the information leaflet describing and depicting the exercise protocol in details. **Methods** For the purpose of the study the data of 130 patients (age 23-67;  $49.6 \pm 12.2$ ; 72 male and 58 female) with vestibular vertigo symptoms treated during the 2007 and 2008 were analyzed. Two 1-20 point symptoms scales FreqSymp and IntSymp (frequency and intensity of the disturbances) were designed for this purpose and were used in order to obtain subjective evaluation. The peripheral impairments were diagnosed by Fitzgerald-Hallpike caloric test while the central impairments as well as the differentiation between both were diagnosed by electronystagmography. **Results** Altogether 86.03% of the patients gained some benefits from the treatment. The group of the patients in which the improvement was not observed consisted mostly of the older patients, all with central impairments

(N=17). On the contrary, only 21% of the controls were evaluated as improved. There was a small but significant correlation observed between the age and the results while no correlation was seen between the gender and the improvements. Unfortunately there was also a high correlation between the intensity and the frequency of the symptoms meaning that the patients who had the most severe symptoms had them also the most often. Conclusions We have demonstrated that the very simple modified vestibular rehabilitation program, which could easily be home-based, might decrease the frequency and the intensity of symptoms in dizzy patient. It seems that in this type of rehabilitation the improvements may be achieved no matter if symptoms were acute or chronic or if the etiology was central or peripheral. References 1. Bittar RS et al. ## COMPARISON OF STATIC BALANCE WITH VISUAL CONTROL IN ELDERLY PERSONS

Gomes-Silva, B.A.1, Ferreira, D.L.1, Bessa, A.1, Costa, G.A.1

*Universidade Federal de Uberlândia*

Introduction Balance is fundamental functional capacity in elderly to carry out their daily living activities (DLA). Over the time the elderly tend to lose this functional capacity, increasing the risk of injury from falls. Therefore, the goal of this research is to compare the visual static balance control in elderly people. Methods The sample consisted of 202 older adults with a mean age of 68 years and standard deviation of  $\pm 8$ . For the analysis of visually controlled static balance the volunteers performed the static balance battery by Grene Williams (1990). Results Statistics demonstrated the predictive effect of the percentage of seniors who completed the test between variables: Man / Woman (Men = 43.75% - 16.96% = Women), active / non-active (Assets = 23 28% - No Assets = 21.42%), AFRID / non-AFRID (AFRID = 26.47 - 20.48 = Not AFRID). And we noted a higher rate of occurrence of seniors who completed the test in the range 60-69 years (58.62%). Another fact that was observed: only 23.26% of the total sample reached the 30 seconds of the test. Conclusion We found that men had a higher percentage of visually controlled static balance than women, active subjects also had a small advantage over non-active subjects, and the group that trained supervised by the University trainers had an advantage over the group that trained without supervision. The age range with the highest occurrence of visually controlled static balance was the 60-69 years, ahead of the 70-79 and 80-89 years. We concluded that the static balance training should be taken into consideration in gyms and clubs, because physical activity to prevent falls should be included in elderly training programs to help them carry out their DLA. ## SUBSTRATE OXIDATION FOLLOWING CONCENTRIC AND ECCENTRIC ENDURANCE EXERCISE IN OLDER ADULTS

Gault, M., Willems, M.E.T.

*University of Chichester*

Introduction A lower ability to oxidise fat is associated with ageing and several disease states (Jeukendrup & Wallis, 2005; Sial et al., 1996). However, participation in endurance based exercise has been shown to decrease carbohydrate utilization and increase lipid oxidation when tested at the same absolute exercise intensity (Carter et al., 2001). We examined substrate oxidation in elderly adults, at a constant self-selected walking speed, following a program of regular level and downhill treadmill walking (i.e. concentric or eccentric endurance exercise) at self-selected walking speeds. Methods 18 healthy elderly adults (67 $\pm$ 5 yrs, 170 $\pm$ 9 cm, 77 $\pm$ 14 kg) volunteered. Participants completed 12-weeks of level [LW: 0% gradient (n=8)] or downhill [DW: -10% gradient (n=10)] treadmill walking (30-mins, 3x week) at a self-selected walking speed (SSWS, re-adjusted every 4-wk). Gas exchange measurements were obtained using the Douglas bag method during the last 3-minutes of a 15-minute level treadmill walk (Baseline SSWS: 1.24  $\pm$  0.13 m/s-1) before and after the exercise intervention. Substrate oxidation (carbohydrate, CHO; Fat, F) was calculated using the equations presented by Peronnet & Massicotte (1991). A two way repeated measures ANOVA with post-hoc pre-planned t-tests were used for data analysis (P<0.05). Results Baseline absolute VO<sub>2</sub> (LTW: 0.94  $\pm$  0.29 L/min-1; DTW: 0.98  $\pm$  0.22 L/min-1) and VCO<sub>2</sub> (LTW: 0.85  $\pm$  0.24 L/min-1; DTW: 0.86  $\pm$  0.19 L/min-1) were similar for both exercise groups walking on a level gradient at SSWS (P>0.05). Following 12-weeks of treadmill walking, VO<sub>2</sub> and VCO<sub>2</sub> decreased by 9% and 8 % respectively at SSWS, for both LTW (VO<sub>2</sub>: 0.85  $\pm$  0.22 L/min-1; VCO<sub>2</sub>: 0.77  $\pm$  0.22 L/min-1) and DTW (VO<sub>2</sub>: 0.84  $\pm$  0.16 L/min-1; VCO<sub>2</sub>: 0.81  $\pm$  0.16 L/min-1; P<0.05). Substrate oxidation during the level treadmill walk was similar between exercise groups at baseline (P>0.05) and did not change following 12-weeks of LTW (CHO: 0.88  $\pm$  0.34 g/min-1; F: 0.14  $\pm$  0.14 g/min-1) or DTW (CHO: 0.96  $\pm$  0.35 g/min-1; F: 0.10  $\pm$  0.09 g/min-1; P>0.05). Discussion Regular level and downhill treadmill walking at a self-selected walking speed resulted in lower oxygen consumption and carbon dioxide production for the same intensity (1.24  $\pm$  0.13 m/s-1). However, there was no increase in fat oxidation or decrease in carbohydrate oxidation as demonstrated following exercise training in older adults (Sial et al., 1998). This could be due to the lower intensity of the training programme (% age-predicted maximum heart rate = range 56-74). Additionally, the exercise period during which substrate oxidation was measured (15-minutes) was lower than previous studies (60 – 90 minutes) (Carter et al., 2001; Sial et al., 1998). ## CROSS-COUNTRY SKIING IN KIDNEY TRANSPLANT RECIPIENTS

Totti, V., Trerotola, M., Nanni Costa, A., Roi, G.S.

*Isokinetic Medical Group (Bologna, Italy), FITOT Onlus (Padua, Italy), Italian National Transplant Center (Rome, Italy)*

Introduction Cross-country skiing is an endurance sporting activity that stimulates aerobic performance capabilities. In chronic diseases aerobic metabolism is impaired particularly in patients waiting for solid organ transplantation. After successful transplantation, patients can recover their physical fitness utilizing endurance sporting activities, however limited information has been published about sporting activities in organ Transplant Recipients (TR). The aim of this preliminary study is to evaluate "in the field" the metabolic response and the performance capacities of a group of kidney TR during a cross-country skiing competition. Methods Eight kidney TR (one of which with combined kidney-pancreas transplant) aged 45 $\pm$ 13yrs, participated in a cross-country skiing race (3 km long, flat) at an altitude of 1,520

m above sea level (air temperature: 3°C). They undergone transplant 179±98 months before, all were under immunosuppressive therapy, with creatinine 1.2±0.3 mg/dL. The energy expenditure (EE) was measured by a multi-sensor device recording physiological body signals (skin temperature, heat flux, galvanic skin resistance, the pattern of movement; Armband, Body Media, Pittsburg, PA) worn on the lateral head of the right triceps brachii. The Heart Rate (HR) was measured by heart rate monitors (Polar, Finland). Between the 3rd and the 5th minute after the finish each skier was took a sample of capillary blood from the earlobe which was immediately analyzed with Arkray portable Lactate Analyzer for blood lactate concentration [La]. Results All the transplanted skiers complete the race without problems. The mean time taken for completing the cross-country skiing race was 9:27±3:14 (mm:ss). During the race the mean HR was 80±9% of the theoretical maximum HR (220-years) and the mean [La] measured at the end of the competition was 7.1±1.2 mmol/L. The mean EE during the race was 458±219 kcal/h. Conclusions Kidney TR may participate in a cross-country skiing race choosing the technique (skating or classical) according to their capabilities and are able to stress the cardiovascular system up to intensities around the anaerobic threshold. Obviously there are a wide range of performances but the metabolic involvement can be considered normal and roughly comparable to that of amateur cross-country skiers. These patients represent the upper limit of performance currently available for kidney transplant patients and in any way can not be considered representative of the entire TR population. However, data collected on patients who practice sports activities can help us to understand their potential performance and thus to promote physical activity and sport for all the transplant patients.

### EFFECTS OF HIGH AND MODERATE INTENSITY AEROBIC EXERCISE ON EXCESS POST-EXERCISE OXYGEN CONSUMPTION IN MEN WITH METABOLIC SYNDROME

Larsen, I., Welde, B., Martins, C., Tjønnå, A.E.

*Høgskolen i Nord Trøndelag*

**Introduction** Physical activity is central in the prevention and treatment of metabolic syndrome, as effective weight reduction and increased physical activity levels reduce risk factors associated with metabolic syndrome (Katzmarzyk et al., 2005). It may also induce larger energy expenditure during post-exercise recovery. The primary aim of this study was to compare the excess post-exercise oxygen consumption (EPOC) between three sessions of aerobic exercises with different intensity and duration. **Methods** Seven men (age: 39-70 yrs) with metabolic syndrome participated in this crossover study. Three aerobic exercise sessions were performed as: four aerobic intervals (4-AIT) at 85-95% of HRmax, one aerobic intervals (1-AIT) at 85-95% of HRmax, and 47 minutes of continuous moderate exercise (CME) at 70% of HRmax in separate days, with at least 48 hours between each test day. Resting metabolic rate (RMR) was measured pre-exercise before each exercise session and used as baseline value. EPOC was measured until baseline metabolic rate was re-established. Results 4-AIT showed a significant longer period of EPOC than both 1-AIT (mean diff.: 35 min,  $P < 0.001$ ) and CME (mean diff.: 25 min,  $P = 0.04$ ). 4-AIT had a significantly higher accumulated O<sub>2</sub>-uptake during the EPOC period as compared to the 1-AIT (mean diff.: 1.5 l O<sub>2</sub>,  $P = 0.05$ ). **Discussion** The results of this study suggest that 4-AIT induces a larger EPOC compared with and, hence it seems appropriate to recommend high intensity interval exercise with regards to prevention and treatment of metabolic syndrome. Higher exercise intensity training has been shown to be more effective in decreasing risk and preventing metabolic syndrome compared to lower intensity training. A previous study demonstrated that high intensity exercise training was superior to moderate-intensity training in reversing risk factors of metabolic syndrome (Tjønnå et al. 2005). An increased EPOC in addition to reversing risk factors of metabolic syndrome makes high intensity intervals beneficial in preventing the metabolic syndrome. In addition to the exercise intensity, this study also highlights the importance of the duration of the training stimuli, i.e. 4-AIT significantly increased EPOC as compared to 1-AIT. Notwithstanding the higher EPOC for 4-AIT, the major contribution of both treatments to weight loss is via the energy expended during the actual exercise, and the exercise should likely be undertaken regularly for EPOC to have an increasing effect on weight reduction. **References** Katzmarzyk PT, Church TS, Janssen I, Ross R, Blair SN. (2005). *Diabetes Care*, 28, 391-397. Tjønnå, A.E, Lee, S. J., Rognum, O., Stølen, T.O, Bye, A., Haram, P.M., Loennechen, J. P., et al. ### THE EFFECT OF AN 8-WEEK GREEN EXERCISE PROGRAMME ON MARKERS OF MENTAL AND VASCULAR HEALTH

Thompson, J.E.S., Webb, R., Llewellyn, D., Hewlett, P., McDonnell, B.J.

*Cardiff Metropolitan University*

**Introduction** Green exercise is defined as any exercise that takes place in a relatively natural environment. Therefore, it is considered cheap and available to almost the whole population. Current literature illustrates the effects of acute bouts of green exercise on mental health (Pretty et al., 2005). However, no literature to date has demonstrated the effect of a long-term, green exercise programme upon markers of mental and vascular health. The current study aims to investigate the effects of community-based walking groups, as a mode of green exercise, upon markers of mental health (mood state) and vascular health (blood pressure and wave reflection). **Methods** Thirty six healthy, sedentary individuals (43±14 yrs), not taking any cardiovascular-acting or psychiatric medication, joining an aerobic, moderate-intensity, green exercise programme, were recruited. Physical activity (measured in MET-minutes, using IPAQ), constructs of mood (measured using POMS), supine blood pressure and augmentation Index (AIx), a measure of wave reflection (SphygmoCor, Atcor Medical) were obtained at baseline and following eight weeks of participation in a green exercise programme. Participants were split into those who adhered to the proposed green exercise programme (AD) (n=17) and those who did not (NAD) (n=19). Results Participants in the AD group significantly increased their physical activity over the eight week period, compared to those participants in the NAD group ( $p < 0.001$ ). Constructs of the POMS questionnaire; 'anger-hostility', 'depression', 'tension-anxiety' and 'total mood disturbance' were all significantly reduced ( $p=0.046$ ,  $p=0.007$ ,  $p=0.001$  and  $p=0.023$ , respectively) in the AD group following the eight weeks when compared to the NAD group. Mean arterial pressure and AIx were significantly reduced in the AD group when compared to the NAD group ( $p=0.044$  and  $p=0.045$ , respectively), over the eight weeks. **Discussion** These data illustrates for the first time that an eight week, green exercise programme has been shown to improve markers of mental and vascular health in sedentary, healthy individuals. These data demonstrate that unstructured, moderate-intensity exercise that is free and accessible to all, elicits many of the benefits that are associated with structured exercise programmes. The impact of green exercise programmes upon systemic markers of health needs to be investigated further. These preliminary data suggest that a moderate-intensity, green exercise programme may be a method by which low physical activity levels and poor health in areas of low socio-economic status could be addressed. **References** Pretty J, Peacock J, Sellens M, Griffin M (2005). *Int J of Environ Health Res*, 15(5), 319-337.

## PSYCHOSOCIAL WORK RISKS, EXERCISE AND MENTAL HEALTH: DOES EXERCISE SERVE AS A BUFFER AGAINST CONSEQUENCES OF PSYCHOSOCIAL WORK RISKS?

de Vries, J.D., Claessens, B.J.C., Van Hooff, M.L.M., Kompier, M.A.J.  
*Radboud University Nijmegen*

Psychosocial work risks, exercise and mental health: does exercise serve as a buffer against consequences of psychosocial work risks? Introduction Work factors may cause or contribute to adverse mental health and mental health complaints affect participation in both the work and non-work areas. In this study, we aimed to identify the role of exercise in the relationship between psychosocial work characteristics and indicators of mental health. Specifically, hypotheses were: 1) Psychosocial work risks will be associated with higher level of mental health complaints; 2) Regular exercise will be associated with lower level of mental health complaints; 3) Exercise will attenuate the relationship between psychosocial work risks and mental health complaints. Methods In this longitudinal study, we used two waves (T1: 2008 and T2: 2009) of the Netherlands Working Conditions-Cohort Study (N=708, Koppes et al., 2010), a survey on the quality of work, health and well-being of Dutch employees. Three work characteristics (autonomy, task demands and emotional demands) and two indicators of mental health (emotional exhaustion and depression) were measured. Exercise was assessed as number of days a week complying to 30 minutes of moderate-intensity exercise. Results Regression analyses revealed that autonomy T1 was negatively related to emotional exhaustion T2 ( $\beta = -.057$ ,  $p < .05$ ) and depressive complaints T2 ( $\beta = -.088$ ,  $p < .05$ ), but we found no relation between task and emotional demands and the two indicators of mental health. Furthermore, we found that exercise T1 negatively related to levels of emotional exhaustion T2 ( $\beta = -.069$ ,  $p < .05$ ), but not to depression. Finally, moderated regression analysis showed that exercise T1 attenuated the relationship between autonomy T1 and emotional exhaustion T2. Simple slope analyses revealed that the relationship between autonomy and emotional exhaustion was stronger for individuals with a lower level of exercise ( $\beta = -.088$ ,  $p < .05$ ) than for individuals with a higher level of exercise ( $\beta = -.022$ ,  $p > .05$ ). Discussion Results partly supported our hypotheses. We found evidence for the relation between autonomy and the two indicators of mental health. In addition, we found that exercise was related to less emotional exhaustion and that exercise attenuated the effect of autonomy on emotional exhaustion. The finding that exercise was not related depressive complaints was surprising, because many studies indicate that exercise benefits depression in particular. It might be that decrease in depression requires different modes of exercise (i.e. intensity, type and frequency). However, this current study indicates that at least moderate-intensity exercise is a buffer for work-related emotional exhaustion. ## THE EFFECTS OF PHYSICAL FITNESS ON CHILDREN WITH PREVIOUS NEOPLASIA

Patti, A.1,2, Palma, R.1,1, Thomas, E.1, Guadagna, P.3, Maggio, M.C.1,2, Corsello, G.1,2, Caramazza, G.2, Battaglia, G.1,2, Bianco, A.1,2, Palma, A.1,2

Introduction: There is a lack of data investigating the effects of physical activity (PA) on adolescent and young adults survivors of childhood leukemia, moreover some authors suggest that children with diagnosis of leukemia (LK) are showing decreased level of fitness and a moderate risk for developing neuromuscular and musculoskeletal complications. We aim to verify if, in children involved in an individualized physical exercise program, the above-mentioned low fitness level may be prevented or at least reduced. Subjects and methods: We assessed the level of physical fitness on children with diagnosis of leukemia during the post-chemotherapy period. We evaluated the fitness in 9 children ( $8.3 \pm 2.7$  yrs), off-therapy by  $\geq 6$  months (group GOT) at the end of a physical activity program (13 weeks length). Few validated fitness tests (Ruiz et al., 2011) were adopted and then administered three times in 2 weeks: standing broad jump, 4 x 10 m shuttle test, sit-up test and handgrip strength test. The tests were also administered to a sedentary control group (CG) of 32 children ( $8.12 \pm 1.56$  yrs) with no diagnosis of neoplasia. The scores from the performances were used for statistical purposes. Results: Standing broad jump results showed  $112.55 \pm 32.80$  cm in GOT and  $124.18 \pm 22.19$  cm in CG, without remarkable differences ( $p = 0.11$ ). An interesting finding comes from 4 x 10 m shuttle run test with GOT that revealed  $16.27 \pm 0.83$  seconds, while CG performed the same test in  $14.02 \pm 0.25$  seconds ( $p = 0.001$ ). No differences were found when comparing sit-up performances (0.25) and handgrip performances (0.08 left arm and 0.15 right arm). Conclusions: After 13 weeks of properly PA program, the level of GOT's physical fitness appears to be in line with control group results. These preliminary findings are confirming the eligibility of GOT to start a specific exercise program in order to reduce cardiovascular and muscular complications and improve their quality of life. The only concern is about the agility test (4 x 10 SRT) that showed very high significant differences ( $\Delta = 2s$ ). The sample is not adequate to make conclusions. More data coming from a bigger sample size of GOT are necessary to confirm this pilot. References Gohar, S.F., Comito, M., Price, J., and Marchese, V. (2011). ## PERCEIVED INFLUENCE OF HORMONE CONTROL AND MENSTRUAL SYMPTOMS ON PHYSICAL ACTIVITY PARTICIPATION IN ACTIVE FEMALES

Schaumberg, M., Jenkins, D., Janse de Jonge, X., Emmerton, L., Burton, N., Skinner, T.  
*The University of Queensland*

Introduction Hormone control (HC) habits of competitive athletes and physically active females are not known, nor is it clear whether these females believe whether HC use influences their capacity to exercise. Given that hormone control through oral contraceptive (OC) use has been shown to reduce exercise capacity in both highly trained (Lebrun et al., 2003) and recreationally active (Casazza et al., 2002; Notelovitz, 1987) females, the present study investigated whether perceived changes in exercise ability with HC use influences involvement in physical activity (PA). Methods 97 active females (age  $25 \pm 4$  years; BMI  $22 \pm 2.4$  kg/m<sup>2</sup>; physical activity levels  $360 \pm 290$  min/week) completed a 32-page questionnaire booklet, designed to assess previous and current use of HC, hormone-specific barriers to PA, as well as PA status. Results Prevalence of OC use was 64%, with 4% reporting use of other HC. Of the 32% not using any form of HC, 65% had previously taken an OC. 0% of HC users reported 'often' or 'very often' avoidance of PA due to pill side-effects and/or menstrual symptoms, yet 25% of non-HC users reported avoiding PA 'often' or 'very often' in the previous year due to menstrual symptoms. Only

13% of HC users reported avoiding PA 'often' or 'very often' in the previous year because of menstrual bleeding, yet 47% of non-HC users reported the same behaviour. Additionally, respondents perceived that OC use 'never' or 'rarely' affected their ability to train (85%) compared to non-HC users (34%), and 'never' or 'rarely' reduce their involvement in PA (90%), compared to non-HC users (40%). Discussion The reported prevalence of HC use in active females is similar to use reported from previous Australian population surveys (Greig et al., 2010). Preliminary results suggest that HC users are less-likely to avoid PA due to menstrual symptoms or menstrual bleeding than non-HC users, and are less likely to feel that they cannot train or exercise to their full potential or reduce their involvement in PA due to menstrual symptoms. This suggests that HC use potentially reduces the impact of female hormone-related barriers to PA involvement. References Casazza, GA, Suh, SH, Miller, BF, Navazio, FM, Brooks, GA. (2002). ## PHYSICAL ACTIVITY, HEALTH-RELATED QUALITY OF LIFE AND SALIVARY BIOMARKERS OF ADOLESCENTS IN DISASTER AREA

Sakamoto, Y.1, Suzuki, K.2, Okazaki, K.2, Sasaki, K.2, Ueki, S.3

1: Tohoku Institute of Technology (JAPAN), 2: Tohoku Gakuin University (JAPAN), 3: Tohoku Bunka Gakuen University (JAPAN)

Introduction In ECSS2012, we reported that the physical activity level of adolescents living in disaster areas is decreased by tsunami and earthquake hit regardless of the damage situation (Suzuki, et al. 2012). The decrease of the physical activity in the adolescents of growth period may have an influence to psychosomatic health. The purpose of this study is to examine the time-dependent change of salivary biomarkers (saliva flow (ml/min), cortisol concentration ( $\mu\text{g}/\text{dL}$ )) and association with physical activity and health-related quality of life (QoL) in adolescents living in a town affected by the earthquake and tsunami 2011. Methods The participants were 178 adolescents aged 11-13 (91 boys, and 87 girls) in the town of Onagawa (where housing damage affected 60% of participants). The survey was performed in September 2011 (the disaster after 6 months) and March 2012 (after 1 year). Survey items included time spent on physical activity (PAwk (min/week)), QoL (the 23-item Pediatric Quality of Life Inventory Version 4.0 Generic Core Scales). In addition, whole saliva samples were collected, and saliva flow rate (SF: ml/min) and salivary cortisol concentration (COR:  $\mu\text{g}/\text{dL}$ ) were determined. Results The SF was significantly increased after one year in comparison with the disaster after six months ( $P<0.05$ ), but COR, PAwk and QoL did not have the significant change. In the boys, the COR was significantly decreased after one year, but SF and COR have the no significant change in the girls. When PAwk of Sep. 2011 were divided into two groups based on the median and compared each groups, SF was significantly increased in the PAwk-high group after one year, but there were not significantly changed for SF and COR in the PAwk-low group. In addition, when QoL of Sep. 2011 were divided into two groups based on the median and compared each groups, SF was significantly increased in the QoL-low group after one year, but there were not significant changed in SF and COR in the QoL-high group. Conclusion These results show that they are different in the subsequent change of the basal saliva flow levels by the state of physical activity and health-related quality of life of adolescents living in disaster area. #### PHYSICALLY ACTIVE = HEALTHY? - ACTIVITY TYPES AND HEALTH STATUS AMONG GERMAN CHILDREN

Grützmaier, N., Blumenthal, K., Wagner, P.

Leipzig University

Introduction In today's society, even children have to deal with various demands of everyday life and developmental aspects to maintain individual wellbeing. In this context, physical activity as well as psychosocial determinants have to be considered as health-enhancing resources (Brandl-Bredenbeck & Brettschneider, 2010). However, there is a lack of studies regarding the causal relationship of the children's level of physical activity and their health status (Ottevaere et al., 2011). Therefore, the purpose of the present study was to investigate whether specific types of activity levels can be differentiated among German children and whether these activity types are characterized by distinctive health-enhancing resources. Methods The present cross sectional study included 385 children (f: 192, m: 193) with an average of 11.86 years of age and their parents. With the help of a children fitness test (KATS-K) and a questionnaire, we collected data giving evidence about anthropometric (BMI-SDS), physical, and psychosocial aspects (KINDL, FSKI, social support) as well as data concerning the level of physical activity and inactivity (HBSC-index). The different clusters regarding specific activity types have been calculated with a hierarchical cluster analysis and an additional z-transformation. Results For each gender (boys and girls), the results indicate four specific activity types (2 examples each: inactive media freaks: boys = 11.7%, girls = 22.7%; athletic actives: boys = 33.9%, girls = 29.1%), which significantly differ in various physical and psychosocial resources (e.g. HBSC-index – boys:  $F=10.44$ ,  $p<0.001$ , girls:  $F=5.97$ ,  $p=0.001$ ; self-concept – boys:  $F=50.24$ ,  $p<0.001$ , girls:  $F=33.74$ ,  $p<0.001$ ; family support – boys:  $F=5.46$ ,  $p=0.001$ , girls:  $F=10.99$ ,  $p<0.001$ ). Additionally, we found differences concerning the activity types and their health status (boys:  $F=6.40$ ,  $p<0.001$ ; girls:  $F=6.62$ ,  $p<0.001$ ). Discussion One of the main goals of health-enhancing physical activity programs is the promotion of individual resources to improve quality of life levels. By identifying different activity types and related psychosocial determinants, there is the possibility to improve the necessary individualization of these programs. Consequently, these individualized interventions reach more people who are threatened by risk factors (concerning their health status) and improve the program's sustainability. ## JOINT ASSOCIATIONS OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIORS WITH OBESITY INDICES AND DIETARY HABITS AMONG SAUDI ADOLESCENTS

Al-Hazzaa, H.M.1, Al-Sobayel, H.2, Abahussain, N.3, Qahwaji, D.4

1: King Saud University, 2: King Saud University, 3: Education Ministry, Eastern Province, 4: King Abdulaziz University

**Introduction** Physical inactivity and sedentary behaviors appear to be independent entities (Ekelund et al, 2006) and differently associate with adverse health outcomes (Tremblay et al. 2010). Physical activity is related more to healthy food choices, whereas sedentary behaviors are linked more to unhealthy dietary choices (Plataat et al. 2006). Thus, the aim of this study was to investigate the joint associations of physical activity and sedentary behaviors with obesity indices and dietary habits among Saudi adolescents aged 14-19 years. **Methods** Data were from the Arab Teens Lifestyle Study (ATLS), a school based, cross-sectional lifestyle study involving Arab adolescents (Al-Hazzaa et al., 2011). The present analysis included 2822 secondary-school students (51.2% females) aged 14-19 years, randomly selected from three major cities in Saudi Arabia, using a multistage stratified cluster sampling technique. Participants were classified into four categories based on cut off scores of 60 minutes daily physical activity and 3 hours of screen time/day (high activity-low screen time, high activity-high screen time, low activity-low screen time and low activity- high screen time. Results One-way ANOVA tests indicated that there were no significant differences in age ( $p = 0.103$ ), body mass index ( $p = 0.472$ ) or waist to height ratio ( $p = 0.116$ ) between the four categories. However, body weight ( $p = 0.002$ ), and consumption (day/week) of breakfast ( $p = 0.012$ ), vegetables ( $p = 0.000$ ), fruit ( $p = 0.000$ ), milk ( $p = 0.000$ ), sugar-sweetened beverages ( $p = 0.000$ ), fast food ( $p = 0.000$ ), French fries/potato chips ( $p = 0.000$ ), and sweets ( $p = 0.000$ ) were all significantly different among the four categories. **Discussion** Adolescents with high activity and low screen time tend to consume breakfast more frequently than their low activity and high screen time peers. Intakes of vegetables, fruit and milk were higher among high activity group whether they have high screen time or not. Less healthy foods like fast food, potato chips, sweets and sugar-sweetened beverages tend to associate with those adolescents with high screen time. It can be concluded that adolescents with high activity and low sedentary behaviors tend to have healthy dietary habits, whereas low activity and high sedentary behaviors increases adolescent's risk of having unhealthy dietary habits. **References** Al-Hazzaa HM, Musaiger AO; ATLS group. ## ADOLESCENTS' PERCEIVED LIFESTYLE PATTERNS IN SELECTED SECONDARY SCHOOLS IN THE WESTERN CAPE, SOUTH AFRICA

Van Deventer, K., Malan, P.E.

*Stellenbosch University*

**Introduction** Holistic enhancement during adolescence not only refers to physical growth and development, it also entails the emancipation process. Cognitive development entails the accumulation of knowledge, self-knowledge and reasoning, whereas emotional growth refers to a realistic identity formation, which can be divided in the self-concept and self-esteem. The primary aim of the study was to determine adolescent lifestyle patterns, while the secondary aim was to determine personal and social reasons for participating in sport. **Methods** Quantitative data was captured by a questionnaire, obtained from the International Committee of Sport Pedagogy (ICSP). The questionnaire covered the following: biographical information; preferences and dislikes; and patterns of participation in sport and leisure activities. The secondary schools ( $N=30$ ) and the learners ( $N=60$ ) were randomly selected from Grade 9 and 11. Twenty-two schools ( $N=22$ ) responded providing a sample of 880 participants. The data were processed with Statsoft Statistica version 10. Descriptive statistics were used. The comparison of ordinal scales between groups was done with the non-parametric Mann-Whitney test. The level of significance was set at 5% ( $p \leq 0.05$ ). **Results** There were significant differences according to race regarding reasons for sport participation. The most important reasons were: it is good for my health ( $p=0.03$ ); to be fit ( $p=0.04$ ); and to relax ( $p=0.05$ ). Both genders, although not significant, placed the highest premium on their health. Significant differences were found between the genders on the following reasons for sport participation: to be fit ( $p=0.02$ ); I want my body to be in good condition ( $p=0.05$ ); it makes my body look good ( $p=0.02$ ); I have the opportunity to prove myself ( $p=0.01$ ); to relax ( $p=0.01$ ); and I like competition ( $p=0.01$ ). Significant differences for feeling successful in sport participation according to race were: when I notice that a new skill I have learned works ( $p=0.01$ ); when I practice really hard ( $p=0.05$ ); and when I am the only one that can play the sport ( $p=0.02$ ). Regarding gender, significant differences were found for the following: when I practise really hard ( $p=0.01$ ); when I learn new sports ( $p=0.01$ ); when I can do something better than my friends ( $p=0.02$ ); and when I am the only one that can play the sport ( $p=0.03$ ). **Discussion** The race and gender groupings indicated that the most significant personal reason for sport participation was health. However, boys also wanted to look good, competitive and relax. The key reasons for being successful in sport by the race and gender were of a personal nature. Something that was noticeable regarding success in sport was that although adolescents, especially boys, were very competitive in nature it was not to the disadvantage of their peers. Both race and gender groupings did not feel being successful in sport when others are not as good as I am and when other makes mistakes and not me indicating that they held a high social esteem for their peers.

## ENERGY EXPENDITURE AT CONSTANT SPEED IN DIFFERENT SLOPES IN CHILDREN WITH OVERWEIGHT AND OBESITY

Serra, N.1, Ensenyat, A.1, Castro, I.2, Mur, J.M.2, Rotger, A.2, Blanco, A.1

1: INEFC Lleida (Lleida, Spain), 2: Nereus Association. Food and healthy physical exercise. Health Region of Lleida (Lleida, Spain)

**Introduction** The amount of energy expended during physical activity plays a significant role in the prevention of overweight and obesity and in the process of weight loss (Peyrot, 2009). The main objectives of the present study are to evaluate the progression of energy expenditure (EE) with the increase of slope in a treadmill test at constant speed and the interrelation with the degree of adiposity, in overweight and obese children. **Methods** In the study participated 11 boys and 9 girls who were divided into two groups depending on their degree of obesity, by the International Obesity Task Force Criteria: Overweight group ( $n = 10$ ; age =  $9.7 \pm 1.34$ ) and obese group ( $n = 10$ ; age =  $10.40 \pm 1.43$ ). Both groups performed a submaximal exercise test on a treadmill. Speed was kept constant at  $1.53 \text{ m}\cdot\text{s}^{-1}$  and the slope increased every 3 minutes following the sequence 0-4-8%. During the test  $\text{VO}_2$  and RER were measured by means of breath-by-breath gas exchange. The EE was calculated according the equation of Robergs (1997):  $\text{EE} (\text{kcal}\cdot\text{min}^{-1}) = \text{VO}_2 (\text{L}\cdot\text{min}^{-1}) \times (\text{RER} \times 1.232 + 3.815)$ . **Results** EE in each group increased significantly with slope. The EE in the three slopes was significantly ( $p < 0.001$ ) superior in obese children in relation to overweight ones. This differences at 0% slope were  $3.32 \pm 0.80$  vs.  $5.33 \pm 0.77 \text{ Kcal}\cdot\text{min}^{-1}$ ; at 4% slope were  $4.28 \pm 0.76$  vs.  $6.54 \pm 0.88 \text{ Kcal}\cdot\text{min}^{-1}$ ; and at 8% were  $5.16 \pm 0.86$  vs.  $7.89 \pm 0.95 \text{ Kcal}\cdot\text{min}^{-1}$ . Differences at each slope disappeared when EE was adjusted by weight. But, were still present when EE was adjusted by Fat Free Mass. Correlation index between weight and EE

indicates that weight can explain a 68% of the variance of EE. Discussion These results indicate that increases of slope, as speed (Lazzer et al., 2003), raise EE. Moreover, children with greater body mass were penalized by the excess of fat mass. In the present study weight mass is the most influential parameter on EE. ### **USING GPS TO TRACK THE COMMUTE HOME FROM SCHOOL: ESTABLISHING THE CONTRIBUTION TO FREE-LIVING PHYSICAL ACTIVITY.**

Collins, P., Al-Nakeeb, Y., Lyons, M.

1. Newman University, Birmingham., 2. Qatar University., 3. University of Limerick

**Introduction** Active school commuting is widely regarded as a key opportunity for youth to participate in physical activity (PA). Whilst young people's school commuting patterns have been widely researched, inconsistencies and inaccuracies in the measurement of commute type and commute journey are a major limitation in many previous studies (Lubans et al., 2011). Using global positioning system (GPS) technology, the current study aims to accurately track the commute journey home from school and its contribution to total free-living moderate-to-vigorous PA (MVPA) in youth. **Methods** 75 adolescents (38 males, 37 females) wore an integrated GPS and heart-rate device during after-school hours for four consecutive weekdays. Descriptive statistics and analyses of variance were utilised to explore differences in the commute patterns of youth according to mode of transport, gender and socio-economic status (SES). **Results** The commute journey home of walkers and cyclists on average contributed 35% of their total free-living PA. Active commuters were significantly more active (11.72 minutes MVPA) than passive commuters (3.5 minutes MVPA) during their commute home from school ( $p=0.001$ ). However, there was no significant difference in the overall free-living PA levels of passive and active commuters ( $p>0.05$ ). 92.7% of youth living within 1.5 miles of the school actively commuted, compared to just 16.7% of youth who lived further away. SES differences in commuting patterns were also evident, with a higher proportion of low SES youth (74%) actively commuting compared to high SES youth (57%). **Discussion** The findings highlighted the significant proportion of total free-living PA that was attributed to active commuting home from school. Furthermore, the utilisation of GPS monitors allowed for the accurate tracking of young people's commute journey, and provided a detailed account of important commute information such as travel mode, speed, distance, directness, and deviations. The study provides a valuable insight into the complex methods utilised and intriguing comparisons between youth from different demographic backgrounds. The findings highlight commute distance as a major determinant for commute mode in youth, although the high proportion of youth who lived within 1.5 miles of the school and actively commuted was encouraging. Future research and intervention studies may wish to focus on the promotion of cycling as a means of encouraging youth who live further than 1.5 miles away from the school to actively commute. **Reference** Lubans DR, Boreham CA, Kelly P, Foster CE. *Int J Behav Nutr Phys Act*. 2011; 8:5.

### **EFFECT OF PHYSICAL TRAINING ON HEART RATE VARIABILITY IN HEALTHY CHILDREN: SYSTEMATIC REVIEW WITH META-ANALYSIS**

Silva, C.C., Pereira, L.M., Cardoso, J.R., Moore, J.P., Nakamura, F.Y.

Universidade Estadual de Londrina

**Introduction** Studies have demonstrated that reduction of heart rate variability (HRV) is associated with increased risk of cardiac events and premature death. Therefore, analysis of HRV in childhood and adolescence may provide early indication of future cardiovascular disease risk. Furthermore, whilst it is reported that the cardioprotective effects of exercise in adults includes a beneficial effect on HRV, the effect of exercise in children remains unclear. Thus, the aim of this study was to undertake a systematic review of available literature to determine whether physical training positively impacts upon HRV in prepubertal healthy children. **Methods** Systematic computerized searches were performed in 9 databases from 1950 to 2012. The key words used were: heart rate variability, autonomic nervous system, exercise training, physical activity, continuous exercise, intermittent exercise, children, prepubescent and adolescents healthy. This systematic review followed the recommendations of the PRISMA Statement. According to the recommendations proposed by the Cochrane Collaboration, only randomized controlled trials were included. **Results** Searches identified 6164 articles from which 2 studies (Mandigout et al., 2002; Gamelin et al. 2009) satisfied the inclusion criteria of this systematic review. **Meta-analysis** compared the experimental group to control group for parameters of HRV: R-R intervals, SDNN, RMSSD, pNN50, LF (log), HF (log), LF/HF and Total Power (log). The total number of children in the intervention group was 29, while 28 were in the control group. The meta-analysis did not demonstrate significant differences between groups for any of indexes of HRV. **Discussion** Exercise training did not affect indices of HRV. Although there is a high risk of bias in each of the studies admitted to the analysis, we conclude that currently there is insufficient evidence to suggest that physical training in healthy children has an effect on HRV. **References** Gamelin FX, Baquet G, Berthoin S, Thevenet D, Nourry C, Nottin S, et al. Effect of high intensity intermittent training on heart rate variability in prepubescent children. *Eur J Appl Physiol*. 2009;105(5):731-8. ### **AN INVESTIGATION OF THE DIFFERENCES BETWEEN PLAYING SPORTS, WATCHING TELEVISION AND USING COMPUTER IN ADOLESCENTS**

Kabadayi, M., Bostanci, O., Imamoglu, O., Oktas, R.

ONDOKUZ MAYIS UNIVERSITY

**Aim:** The aim of this study is to investigate the effects of factors of playing sports, watching television and using computer on the balanced height and weight development of 11-17 years old boys and girls. **Material and Method:** This study was conducted on a total of 13761 students, 6927 girls and 6834 boys, studying at secondary schools and high schools in different cities of Turkey during the 2009-2011 Academic Year. The students' weights were measured with 0.1 kg precision scale and their heights were measured with 0.1 cm precision metal bar. The measurements were taken before noon during a week. The students' habits of playing sports, watching TV and using computer were determined through a questionnaire. One way analysis of variance and Tukey HSD were used for statistical processes. **Findings:** For boys, average height was found to be 162,42 cm and average weight was found to be 53,92 kg while the average height was 159,72 cm and average weight was 50,78 kg for the girls. HWI values were found to be 20,22 kg/m<sup>2</sup> for boys and 19,78 kg/m<sup>2</sup> for girls. The difference between height, weight and HWI values by sex was statistically significant ( $p<0.001$ ). The average age for the students who played sports was 14,31 years and 14,88 years for the students who didn't. The average height of the students who didn't play

sports was 160,42 cm while the average height of the students who played sports was 162,03 cm. for weight, the students who didn't play sports were lighter than those who did (51,63 kg versus 53,42 kg). The difference between age, height, weight and HWI values between the students who played and didn't play sports was statistically significant ( $p < 0.001$ ). The students who watched TV for an hour or less had more weight and higher HWI values than those who watched TV for 2-3 and 4-5 hours ( $p < 0.001$ ). The students who didn't use computer and the ones who did for 1-2 hours had less weight and HWI values than those who used computer for 3-5 hours and more than 5 hours ( $p < 0.001$ ). Result: The results of this study show that for the students to have balanced weight and height development, they should have a more controlled TV and computer use and their habits of playing sports should be increased.

### **LONGITUDINAL CHANGES IN PHYSICAL FITNESS FROM ADOLESCENCE TO MIDDLE AGE. THE SWEDISH PHYSICAL ACTIVITY AND FITNESS COHORT STUDY SPAF**

Westerståhl, M., Aasa, U.

*Karolinska institutet*

**Aim** To study the longitudinal changes in aerobic power, muscular endurance and strength, flexibility and balance in men and women from 16 and/or 34 to 52 years of age. Further, factors in younger age that could predict the changes was studied. **Background** Longitudinal studies on the changes in physical capacity during the life span with a long follow-up period are very rare. The focus of the SPAF study is multidisciplinary and involves physical and psychological variables that are related to a wide range of health outcomes. The unique feature of the SPAF study is that physical activity, physical capacity, CVD risk factors, health habits and health are measured over 36 years. Here the results from the longitudinal changes in, and indicators for, physical capacity are presented. **Subjects and Methods** The same men and women were followed for 36 years in three waves of data collection (1974, 1992 and 2010). The test battery was partly the same as baseline and partly supplemented at the two follow-ups. **Baseline:** A group of 425 randomly selected Swedish boys and girls from strategically selected cities in Sweden at 16 years of age. **Follow-up I:** 65% of the original sample participated in tests and measurements at 34 years of age. **Follow-up II:** 50% of the original sample participated in tests and measurements at 52 years of age. Physical capacity was objectively measured with field tests of muscular endurance, maximal strength, aerobic capacity, balance and flexibility. The Regional Ethical Review Board in Umeå approved the study. **Statistics** The longitudinal changes were analyzed using linear mixed model with covariates. A full model with all significant covariates was created for each measure of physical capacity. **Results** There was an increase or no change from 34 to 52 years of age in balance, lower body flexibility, thoracic back extension or muscular endurance of the abdomen. There was a decrease from 34 to 52 years of age in flexion and rotation of the neck, in muscular endurance of the back and in aerobic capacity. There was an increase from 16 to 52 years of age in muscular endurance of the arms. Maximal static lifting strength increased in men but decreased in women from 16 to 52 years of age. The longitudinal changes in physical capacity were often predicted by background characteristics at baseline. **Discussion** Decreasing flexibility of the neck and strength of the back could be a predictor or a symptom of back pain and will be further explored in this study. Background characteristics already in adolescence seem to predict capacity in middle age which is important knowledge for the understanding of life time physical capacity.

### **VERIFICATION OF DELAYED MENARCHE EVALUATION IN FEMALE ATHLETES BY WAVELET INTERPOLATION METHOD**

Fujii, K.

*Aichi Institute of Technology*

**Introduction** To improve the accuracy of the evaluation of delayed menarche proposed by Fujii and Demura (2005), data on general Korean females were obtained and the validity of the polynomial from the first to the fourth order was examined with regard to the regression evaluation of the age at menarche for age at MPV of height. A delayed menarche evaluation chart was constructed by deriving a regression evaluation of the most appropriate order. This regression evaluation was applied to various sports to judge delayed menarche in athletes. Specifically, by investigating delayed menarche and menstrual status in individuals in this study, the relation between delayed menarche and menstrual status in female athletes was examined for the first time. **Methods :** The subjects were 124 second year female students at a physical education high school in the suburbs of Busan, South Korea. A questionnaire survey of these girls was conducted, from which their date of birth, age at menarche, and athletic activities in elementary, junior high, and high school were obtained. In addition, health check records were examined retrospectively, and longitudinal growth data for height were obtained from the 1st year of elementary school (7 years old) until the second year of high school (17 years old). Next, the same survey as above was also done for second year students at a general high school in the same area, as a control group. Three hundred forty-five non-athletes for whom all data were available were selected. **Results** The third order polynomial was found to be most suitable for the regression polynomial. When it was applied to individual female Korean athletes with respect to the regression evaluation, positive scores were obtained for many athletes and an overall delay in menarche was seen. Delayed menarche was not seen, however, in archery athletes. A strong delay in menarche was thus found in Korean athletes. **Discussion** This study was the first to attempt this kind of analysis. Menstrual status was judged by the intensity of menstrual pain in this study. A judgment of delayed menarche may be a warning for continuing training in female athletes. The delayed menarche evaluation in Korean female athletes in this study further advances the delayed menarche evaluation established by Fujii (2008) in Japanese girls, and leads to a relation with menstrual status following delayed menarche. The present findings will be useful for resolving problems related to menstrual abnormalities in female athletes. **References** Fujii K, and Demura S (2005) An Approach to Verifying Delayed Menarche in Japanese Female Athletes —Analysis by wavelet interpolation method—, *The Journal of Sports Medicine and Physical Fitness*, 45, 580-593. ### **MENSTRUAL ATTITUDE OF COLLEGIATE ATHLETE**

Sahin Ozdemir, F., Kızılyıllı, M.

*ankara universitesi*

**Introduction:** Cultural environment and religion play an important role at attitude toward menstruation. Most of the former female athletes believe that menstruation affects their performance negatively and recently many girl and women refuse to join physical activities during menstruation. Most women who are professional or non-professional athletes probably form their attitudes toward "menstruation and sport" in their elementary school gym classes. Current studies indicated that perceptions and severity of psychological and physical symptoms during menstruation mostly affected by negative or positive attitudes toward menstruation (Marván.2005). The aim of this study was to evaluate the attitudes of collegiate athletes (CA) toward menstruation and compare them with their sedentary college students (CS)

counterparts. Methods : Female CA (n=181) and female CS (n=148) and total 329 volunteers participated in this study. Menstrual Attitude Questionnaire (MAQ) was used as a data collection device in this study. The original MAQ developed by Brook-Gunn and Ruble is the gold standard measurement of menstruation (Brooks-Gunn, 1980). Results: The mean age of the sample (n= 329) was found  $20.5 \pm 1.9$ . The mean menarche age of CA was  $13.70 \pm 1.07$  and CS was  $13.50 \pm 1.12$  and there is no significant differences between menarche age of groups since  $p=0.09 \geq 0.05$ . The total of 74.5 % participants stated that they have a regular menstrual cycle and there is no significant differences between menstrual cycle order of athletes and sedentaries since  $p=0.65 \geq 0.05$ . By looking at the average overall score of CA and CS (X(CA)=3,13 and X(CS) =3,17), it can be said that both groups have positive attitudes toward menstruation. When we look at the lower scales, menstruation as a "bothersome event" has highest score and "anticipation and prediction of onset of menstruation" sub-scale has lowest score for both groups. In the perception of menstruation as a debilitating event and as a natural event there is significant differences between athlete and sedentary group. Discussion: The results of this study reported that 49.7% of college athletes do not believe in that menstruation is negatively effect their sport performance, on the other hand this negative perception is still more common between non-athletes. Despite this high frequency, menstruation is still perceived by athletes as something that they have to put up with. While attitudes toward menstruation is positive for athletes and non-athletes, non-athletes perceived menstruation more debilitating. References Marván M, Cortés-Iniestra S, Gonzáles R. Beliefs about and attitudes toward menstruation among young and middle-aged Mexicans. *Sex Roles* 2005;53:273- Brooks-Gunn J, Ruble D, (1980), The Menstrual Attitude Questionnaire, *Psychosomatic Medicine*, 42(45):503-512

## PHYSICAL ACTIVITY AND CARDIOVASCULAR FITNESS IN PERIPUBERTAL BOYS WITH DIFFERENT WEIGHT STATUS

Lätt, E.1, Mäestu, J.1, Rääsk, T.1, Rubin, D.A.2, Purge, P.1, Jürimäe, J.1, Jürimäe, T.1

1:UT (Tartu, Estonia), 2:CSUF (Fullerton, USA)

Introduction Low physical activity (PA), poor cardiovascular fitness (CVF), increasing overweight and obesity in children are the major health problems nowadays (Blair 2009). There are limited data on the relationship between objectively measured PA and directly measured peak oxygen uptake ( $VO_{2peak}$ ) from a stepwise incremental exercise test using a cycle ergometer. The aim of the present study was to examine the relationship between PA and CVF in peripubertal boys and to determine if differences in weight status affect this association. Methods In total 265 boys were analysed (age  $12.04 \pm 0.77$  y). On the basis of body mass index (BMI), the children were grouped as normal-weight ( $<19.8-22.6$ ), overweight ( $\geq 19.8-22.6$  and  $<24-27.6$ ) and obese ( $\geq 24-27.6$ ), according to the age-adjusted cut-offs (Cole et al. 2000). CVF was determined on cycle ergometer for  $VO_{2peak}$  and  $VO_{2peak}$  per kilogram of body mass ( $VO_{2peak}/kg$ ) and maximal power output ( $W_{max}$ ) and  $W_{max}/kg$ . PA was assessed by accelerometer for seven consecutive days. Time spent in moderate PA and vigorous PA were calculated based on cut-offs of 2000 and 4000 counts per minute, respectively. Time spent in moderate-to-vigorous PA (MVPA) was calculated as the sum of moderate PA and vigorous PA. Results Normal weight group had a significantly higher vigorous PA and MVPA levels compared to overweight group ( $p < 0.05$ ) and had significantly higher moderate PA, vigorous PA, MVPA and total PA compared to obese group ( $p < 0.05$ ). No differences were found in PA levels between the overweight and obese. Obese group had significantly lower values of  $VO_{2peak}$ ,  $VO_{2peak}/kg$  and  $W_{max}/kg$  compared to normal weights and significantly lower values  $VO_{2peak}/kg$  and  $W_{max}/kg$  compared to overweight ( $p < 0.05$ ). Measured PA levels (except vigorous PA in obese boys) were significant predictors of  $W_{max}/kg$  in normal weight and obese boys. Vigorous PA, MVPA, total PA in normal weight and vigorous PA in obese were significant predictors of  $W_{max}$ . Variation in  $VO_{2peak}/kg$  was significantly explained by moderate PA, vigorous PA, MVPA and total PA in normal weight only. Discussion In normal weight boys, total amount of activity and intensity are important in prediction of CVF and also for relative workload ( $W/kg$ ), respectively in obese subjects in general. It was interesting to note that in the overweight group, PA was not associated with any of the fitness parameters, that could be explained to higher-energy intake, which affects body composition and therefore also CVF. Therefore, if studying interactions between PA and CVF, the weight status, especially between normal and overweight boys should be taken into account. References Blair SN. (2009). *Br J Sports Med*, 43, 1-2. Cole TJ, Bellizzi MC, Flegal KM, Dietz WH. (2000). *BMJ*, 320, 1-6.

### PP-PM04 Adapted Physical Activity [AP] 4

#### EXCESSIVE BODY WEIGHT INFLUENCE ON PROPRIOCEPTION IN POSTURAL CONTROL IN YOUNG SUBJECTS

Barthélemy, J.1, Duclos, N.C.1, Mercier, C.S.2, Nicol, C.1, Mesure, S.1

1 : ISM UMR 7287 (Marseille, France), 2 : AJO@ Les oiseaux (Sanary-sur-Mer, France)

Introduction Excessive body weight is repeatedly reported to increase postural instability and to lead to fall-induced injury (Hue et al., 2007). In most studies balance stability has been evaluated in a constrained feet position, with and without vision. The present research questioned, first, the influence of a pre-set feet position on the postural instability reported for obese subjects and, secondly, the relative influence of the proprioceptive information on their postural control. Methods This study included a total of 136 children and adolescents: 68 obese (Ob) and 68 non-obese (NOB) subjects. To investigate the feet position influence, each group of subjects was divided into two subgroups examined in either 'standardized' (St) or 'natural' (Nat) feet position. Each subject was tested in 3 conditions: with vision (Vis), without vision (NVis), without vision and Achilles tendon vibration (Vib). The postural test lasted 51.2 sec in a standing position on two combined force-plates (acquisition frequency of 40 Hz). In the Vib condition, each Achilles tendon was equipped with a neuromuscular vibrator (VB115, Techno-Concept ©). The 80 Hz vibration stimulus started 5 to 15 sec after the beginning of the postural test and lasted for 20 sec. Appropriate MANOVA and Student-t tests were used, with statistical significance set at  $p < 0.05$ . Results Independently of feet position (St or Nat), all parameters indicate a decreased stability in the Ob subjects when compared to NOB ones, except for the length of medio-lateral displacements. All the subjects were more stable in the Nat feet position. For the Ob subjects only, the antero-posterior length of displacements was not reduced when switching from the St to the Nat feet position. The Romberg coefficient (NVis/Vis surface) was  $> 1$ , and did not differ between Ob and NOB subjects. The Ob subjects were more sensitive to the vibration stimulus than the NOB subjects (antero-posterior difference). Among Ob subjects, the sensitivity to vibration was enhanced in the St feet position. Discussion This

demonstrates that evaluation of Ob subjects should be performed in a more natural testing position, although inter-feet position should be controlled. The absence of inter-group difference in the Romberg coefficient (NVis/Vis surface) contrasts with the results obtained with the vibratory stimulus. This suggests that Ob subjects would rely more on proprioceptive than on visual cues as compared to NOb subjects. Considering the potential effect of body mass on proprioception, their combined changes along treatment should be considered as favoring potentially to the occurrence of injuries. ### **USE OF COMPUTER OPTICAL TOPOGRAPHY IN POSTURAL DISORDERS AND SPINAL DEFORMITIES DIAGNOSIS AND CORRECTION IN CHILDREN AND ADOLESCENTS**

Kovalenko, T., Shklyarenko, A., Ulyanov, D.

*Volgograd State University, Krasnodar State University, Russia.*

Continuity Postural disorders fall under an important group of diverse in nature and manifestations pathological spinal deformities of the musculoskeletal apparatus in children, so the issues of its early diagnosis, treatment and effectiveness control refer to this research actual continuity [1, 2]. In recent years, new estimation methods and techniques based on three-dimensional evaluation of postural disorders have appeared. Based on numerous children and adolescents examinations, an effective system of identifying posture and spinal deformities followed by recreational activities has been worked out in the children's orthopedic sanatorium. Methods We used computer optical topography method that was developed at the Novosibirsk Institute of Traumatology and Orthopedics. The topography is harmless, accurate and provides images of the dorsal surface of the body in three dimensions: lateral analysis characterizes the deviation in the frontal plane and the parameters of scoliotic arcs; sagittal analysis describes the severity of physiological sagittal curves; and horizontal analysis shows the relative rotation of shoulder girdle pelvic. Topographic screening results were analyzed for postural disorders and spinal deformities in three dimensions: frontal, sagittal and horizontal. After image processing and results interpretation we distribute all examined patients in three groups: I - healthy, II - children with functional disorders of posture, III - patients with structural scoliosis and kyphosis. Results We recommended the healthy children to be active, control body posture and have monitoring survey in one year. For the second group of children in addition to the above recommendations we prescribe corrigent gymnastics exercises, laying on the rollers at an increased thoracic kyphosis and flattening of the lumbar lordosis, back muscles massage in absence of contraindications, as well as computer optical topography re-examination in three or six months (depending on the disorder gravity). In case of revealed signs of structural pathology, pelvic tilt, twist expressed in the horizontal plane (III group), the patient is sent to an orthopedist for further examination and clinical survey. Once the diagnosis is confirmed, the child is assigned with combined treatment with mandatory computer topography control. Discussion The experience in examination of more than 1,300 patients allows us to assume the screening ensures timely diagnosis of existing abnormalities and give correct recommendations to form a group of children in need of an orthopedic consultation and a group of patients who can start immediately corrigent gymnastics exercises (in absence of somatic contraindications) and further control by computer topography. ### **PHYSICAL EXERCISE FOR THE PREVENTION OF DEMENTIA : A RANDOMIZED, PARALLEL-GROUP, OBSERVER-BLINDED CLINICAL TRIALS**

Aquino, G., Iuliano, E., Mignogna, P., Di Cagno, A., Cristofano, A., Fiorilli, G., Calcagno, G., Tagliatela, M., Di Costanzo, A.  
*university of molise*

Molise University (Campobasso, Italy) Introduction Several observational studies have shown that physical activity reduces the risk of cognitive decline in subjects at risk of dementia; however, evidences from well-conducted randomized controlled trials are scanty (Lautenschlager et al, 2012). The aim of the study is determine whether physical exercise reduce the rate of cognitive decline in the older adults at risk of dementia. Methods A Randomized controlled trial of 24 months of monitored physical activity was conducted in Campobasso, Italy. Two hundred thirty-five subjects aged 50 years and over were screened for eligibility, 18 were not eligible for health problems, 28 refused to participate and 10 could not be recontacted. Subjects who reported memory problems but did not meet criteria for dementia were also included. A total of 180 subjects were recruited and 111 of these have completed 24 months of the study. Subjects were randomly assigned to a control group (n = 90), which has not received the treatment, or to an intervention group (n = 90) which has been subjected to a physical exercise program for 24 months. Outcome measures were Mini-Mental State Examination (MMSE), Frontal Assessment Battery (FAB), Rey's word list immediate and delayed recall tests, Attentional Matrices, Raven's Progressive Matrices, Stroop test, Prose memory immediate and delayed test, Copying of Drawings with and without landmarks, Trial Making Test (TMT) version A and B. Results: At baseline, the two groups were homogeneous in terms of age, education and scores on tests of cognitive performance. At 24-month assessment, Repeated Measures Analysis of Variance (RM-ANOVA) showed significant differences between the two groups in both Rey's word list immediate and delayed recall tests (p<0.05) and in the Prose memory immediate test (p<0.05). No significant difference was found in the other tests. Conclusion Preliminary results show that, in elderly patients with memory disorder, a controlled physical exercise program, lasting 24 months, leads to significant improvements in memory performances. References Lautenschlager NT, Cox K, Cyarto EV. (2012). *Biochim Biophys Acta*, 1822, 474-81.

### **EFFECTS ON V-WAVE WITH SKIN AND MUSCLE COOLING DURING %MVC**

Yona, M., Tadano, C., Sakamoto, M., Naito, Y., Seki, H., Muro, M.

*Tokyo University of Pharmacy and Life Science*

Introduction We have demonstrated that with skin cooling the amplitude of H-reflex is unchanged and the amplitude of V-wave increases more than under normal skin temperature conditions in the latter half of the %MVC. However, there is no clear effect of muscle cooling. The purpose of this study was to investigate the effects of muscle cooling on spinal and neural drive by analyzing V-wave. Methods Six healthy adults volunteered for this study. The force of the isometric contraction and twitch of the triceps surae muscle were measured with a force transducer attached to a footplate apparatus. Electric signals were picked up by surface electrodes (10mm) on the belly of the soleus (SOL). This experiment was performed under three conditions that consisted of skin cooling (skin temp. 26 deg.; SC), muscle cooling (muscle temp. about 2 deg. less than normal: MC) and control (skin temp. about 33 deg.; NSC). A cooling pad, attached to the skin (SC: 3 minutes, MC: 5min), was used in the cooling conditions. Two 3 second maximal voluntary isometric contractions (MVC) were per-

formed at the control temperature. The force at every 10%MVC was calculated using the MVC under control temperature. H-reflexes, M-wave and V-wave were evoked in the soleus muscle by electrical stimulation of the posterior tibial nerve via a cathode ball electrode (5mm in diameter) pressed into the popliteal fossa. H-reflex and Mmax were obtained under the three conditions at rest. During sub-maximal contractions (10, 20, 30, 40, 50, 60, 70, 80 and 90% of one MVC) and MVC performance, a supra-maximal stimulus was delivered at supra-maximal intensity, which allowed us to record the superimposed M-wave (Msup) and V-wave of the SOL. Results and Discussion There was no significant difference in Hmax, Mmax and H/M ratio under each condition. M-wave amplitude recorded during maximal voluntary plantar flexor contractions (Msup) was significantly greater than that recorded at rest (Mmax) in each condition. However, there was no significant difference between SC, MC and NSC. The amplitude of V-wave increased gradually with increased %MVC under the three conditions. The polynomial relationship indicated with skin cooling was higher than that of MC and NSC over 80%MVC ( $p < 0.05$ ). However, there was no significant difference between MC and NSC. These results suggest that the increase in V-wave response with skin cooling is related to elevated motorneuron excitability due to the influence of cutaneous inputs, especially cold receptors.

### LONGITUDINAL CHANGES OF DEPRESSIVE SYMPTOMS IN PATIENTS WITH MULTIPLE SCLEROSIS AFTER EXERCISE IN DEPENDENCY TO THE SEVERITY OF FATIGUE

Wonneberger, M.1, Froböse, I.1, Schmidt, S.2

1: DSHS (Cologne), 2: Ambulance of neurology (Bonn)

**Introduction** Fatigue is a frequent and often disabling symptom in patients with multiple sclerosis (MS) and severity of fatigue is further increased by co-existing depressive symptoms (Bradshaw und Rose 2008). Here, we investigated the impact of endurance training on depressive symptoms in relation to the extent of fatigue. **Methods** Untrained patients with relapsing-remitting MS were included (n=44, mean age 38.7 +/-8.5 yrs) with a mean EDSS of 1.9 +/-0.6. At the beginning of the examination all participants were rated according to the 'fatigue severity scale' (FSS) and the German version of the 'Center for epidemiological studies depression scale' questionnaire (ADS) (Krupp et al., 1989; Hautzinger et al., 2012). The patients were then assigned to either a non-fatigue group (nFG: n=20; FSS<4.0) or a fatigue group (FG: n=24; FSS≥4.0). Subsequently, all subjects completed a treadmill exercise test and afterwards a home-based exercise training for twelve months. Details of the treadmill test and the exercise program have already been published (Wonneberger et al., 2012). **Results** The mixed-model ANOVA with repeated measurements showed neither a significant group by time effect nor a time effect ( $p > .05$ ). However, the group effect was significant over the entire observation period and constantly higher for the FG ( $F(1;42)=7.13$ ;  $p \leq .01$ ;  $\text{part.}\eta\text{-square}=0.15$ ). **Discussion** We assume that the low mean ADS score for both groups at baseline (nFG: 10.1; FG: 16.0) mainly accounts for the fact that no treatment effects were detectable. When comparing the ADS-Score for the FG to a German general population (11.7) the difference is statistically significant ( $p < .05$ ), but still below the cut-off value for depressive disorders ( $>22.0$ ) (Hautzinger et al., 2012). It is also possible that the lack of constant supervision could also lead to no changes (Romberg et al., 2005). However, the results of our study further confirm the interdependence of fatigue and depressive symptoms. We propose to select patients with higher ADS scores at baseline for further studies to detect possible treatment effects of exercise interventions on depressive symptoms in MS patients. **Bradshaw J; Rose A (2008):** Cognition, Depression and Fatigue in Multiple Sclerosis. ### INTENSIVE PHYSICAL RETRAINING PROGRAM FOR PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Calcagno, G.1, Aquino, G.1, Vardaro, A.2, Iuliano, E.1, Di Gioia, C.2, Verlingieri, G.1, Di Cagno, A.1, De Simone, G.2

1: Molise University; 2: CDC Villa Margherita BN

**Introduction** COPD is clinically characterized by a functional respiratory deficit and reduced capacity for exercise. These symptoms determine physical deconditioning as well as a decreased in cognitive function and health related quality of life (J.W. Dodd, 2010). Exercise training is fundamental for the management of COPD patients, inducing improvement in physical performance and quality of life (Wadella K., 2004). Different training types have been evaluated, but the most effective training for COPD patients has not yet been defined. The aim of this study was to examine the effects of a high intensity retraining on exercise tolerance, cognitive decline and quality of life. **Methods** Seven COPD male patients (aged 60.8±12.8), hospitalized in a rehabilitation centre, were recruited. Retraining program provided one session per day of 60 minutes, for 5 day per week, for 3 weeks. It consisted of endurance, strength and respiratory exercises at high intensity (70-90 % of baseline capacity). Before and after the experimental retraining protocol, the patients were evaluated for anthropometric parameters, laboratory test, blood gases, respiratory tests, dyspnea scales, physical exercise tests, mental deterioration battery (MDB) and S. George Questionnaire to assess the quality of life. **Results** The results showed a significant reduction of total cholesterol and glucose values. The physical exercise tests, some tests of MBD and level of quality life were also significantly improved. All patients showed a significant reduction of dyspnea scales, increased maximal inspiratory pressure (Pimax), and improvement of oxygen flow rate (PaO2). No significant changes were found for other respiratory tests. **Discussion** The preliminary results of the study confirm the beneficial effects of the high intensity retraining on physical performance, dyspnea and quality of life, limiting the progression of the disease. Moreover, due to increased cerebral oxygenation produced by high intensity exercises, this protocol may prevent some aspects of cognitive decline, characteristic in severe COPD patients (William W. et al., 2010) These preliminary results seems an optimal strategy for patients with COPD and may contribute to optimizing training and to provide guidance for the design of retraining exercise programs (Subin et al., 2010). **References** Wadella K, Sundelina G, Henriksson-Lars K, Rune L.(2004). *Respiratory Medicine*, 98, 428–38 **Dodd JW, Getov SV, Jones PW.** (2010). *Eur Respir J*, 35, 913–22 **William W, Hung JP, Wisnivesky, Albert LS, Joseph SR.**(2009). *Am J Respir Crit Care Med*, 180, 134–7 **Subin, Vaishali R, Prem V, Shaoo.** (2010). *Lung India*, 27(1), 4–7.

### PHYSICAL ACTIVITY LEVELS IN ADULTS WITH INTELLECTUAL DISABILITIES

Guerra, M.1, Javierre, C.2, Oviedo, G.R.1, Barnet, S.1, Carbó, M.1, Fernhall, B.3

1-FPCEE-Blanquerna (University Ramon Llull), 2-University of Barcelona (Spain), 3-University of Illinois at Chicago (IL)

**Introduction** Individuals with intellectual disabilities (ID) have low physical activity (PA) levels and total energy expenditure (TEE). Purpose To evaluate the total physical activity (TPA), the quantity of moderate to vigorous PA (MVPA), daily steps (DS) and TEE of an active and a sedentary group of adults with ID during the intervention period. **Methods** Two groups of adults with moderate to severe ID, with and without Down Syndrome, participated in this study. The intervention group (IG) (17 women, 22 men, age=40±11 years) followed an aerobic and strength training program during 14 weeks, 1 hour 3 times per week and the control group (CG) (13 women; 15 men; age=45±12 years) did not train. TPA, MVPA, DS and TEE were obtained through triaxial accelerometry during 7 consecutive days of the intervention period. Body Mass Index (BMI), TPA, MVPA, DS and TEE differences between groups were analyzed using the student t-test ( $p < 0.05$ ). **Results** The BMI was  $27.6 \pm 5.4$  and  $28.4 \pm 6.6$  in the IG and the CG respectively. TPA and MVPA in the IG were  $297.2 \pm 143.4$  counts/min and  $155.5 \pm 132.7$  min respectively and in the CG  $223.2 \pm 109.6$  counts/min and  $87.7 \pm 81.4$  min respectively. TEE in the IG was  $2205.6 \pm 1245.4$  kcal and  $1605.5 \pm 779.2$  kcal in the CG. The IG exhibited a significant higher number of daily steps ( $7086.7 \pm 3038.6$  steps) than the CG ( $5164.45 \pm 2307.3$  steps) ( $p = 0.033$ ). No significant difference was founded between groups in BMI. The IG presents significant higher values in TPA ( $p = 0.036$ ), MVPA ( $p = 0.029$ ) and TEE ( $p = 0.039$ ) than the CG. **Discussion** Even though the TPA and MVPA of the IG was higher than the CG, neither group achieved the recommendations of 10000 DS, while the IG achieved the 150 minutes/week of MVPA recommended by the WHO, 2010. More research is needed. **References** Fernhall, B., Pitetti, K. H., Rimmer, J. H., McCubbin, J. A., Rintala, P., Millar, A. L., Burkett, L. N. (1996). ### IMPACT OF A PHYSICAL ACTIVITY PROGRAM TO IMPROVE BALANCE AND MOBILITY PERFORMANCE IN ADULTS WITH INTELLECTUAL DISABILITY

Cabedo, J., Giné-Garriga, M., Fortuño, J., Oviedo, G., Carbó, M., Barnet, S., Martín-Borràs, C., Guerra, M.

University Ramon Llull

**Introduction:** Balance and mobility limitations are common in persons with intellectual disability (ID). Differences in balance and mobility between persons with ID and controls have mainly been demonstrated by instrumented assessments (e.g. posturography and gait analysis), which require sophisticated and expensive equipment such as force plates or a 3D motion analysis system. Most physicians and allied healthcare professionals working with persons with ID do not have such equipment at their disposal, so they must rely on clinical tests to determine whether mobility is affected. There is insufficient evidence to demonstrate that there is improvement in physical performance outcomes such as balance and mobility in adults with ID (Andriolo et al., 2010). This descriptive study investigated the impact of a physical activity (PA) program in improving balance and mobility performance in older adults with ID. **Methods:** A descriptive design was developed. Thirty seven (15 women, 22 men) adults,  $39.7 \pm 11.4$  years old with mild to moderate ID, from an Occupational Day Center placed in Girona, followed an aerobic, strength and balance training program during 14 weeks, 1 hour 3 times per week. All subjects were measured while doing a Timed Up and Go Test, a Flamingo balance test and a Gesell bar test. Balance and mobility descriptive data were compared between the groups using paired-sample t-tests. **Results:** Between the first test (T1) and the second test (T2) there were only significant differences ( $p < 0.05$ ) for dynamic balance (Gesell bar: T1= $14.92 \pm 11.23$ s vs T2= $6.84 \pm 4.51$ s). However, no significant differences ( $p < 0.05$ ) were found for static balance and mobility (Flamingo: T1= $10.64 \pm 11.61$ s vs T2= $12.47 \pm 10.05$ s and Timed Up and Go: T1= $15.27 \pm 3.78$ s vs T2= $14.38 \pm 3.54$ s) **Discussion:** Results showed significant differences in dynamic balance. A different pattern of results emerged for static balance and mobility where no statistically significant differences were found. It is possible to speculate that the balance-based exercises included in our training program could be responsible for the statistically better dynamic balance. More research is needed to understand why so few differences exist in static balance and mobility performance in adults with intellectual disability. **References:** Andriolo RB, El Dib RP, Ramos L, Atallah AN, da Silva EM. #### INFERIOR MUSCULARITY OF THE RECTUS FEMORIS TO VASTI IN CYCLISTS BUT NOT IN LACROSSE PLAYERS

Ema, R., Wakahara, T., Kanehisa, H., Kawakami, Y.

Waseda University

**Introduction** We have reported inferior muscularity of the rectus femoris (RF) to vasti (vastus lateralis (VL), vastus medialis (VM), and vastus intermedius (VI)) in oarsmen (Ema et al., 2012). This was assumed to be due to muscle-specific adaptation to the rowing motions, which include cyclic leg extensions (combination of knee and hip extensions). However, it is unknown whether the inferior muscularity of RF, observed in oarsmen, can be generalized to other athletes who mainly perform cyclic leg extensions in their competitive and training activities. We examined this subject by comparing the muscularity of four constituents of the quadriceps femoris among cyclists, lacrosse players and non-athletes. **Methods** T1-weighted magnetic resonance (MR) images of the thigh were obtained from seven male cyclists, 13 male lacrosse players and 21 non-athlete men. From the MR images, muscle volume of each muscle of the quadriceps femoris was determined. The muscle volume relative to body mass and to that of the total quadriceps femoris were calculated for each muscle.

Results The muscle volume relative to body mass of the total quadriceps femoris, VL, VM, and VI was significantly larger in the cyclists than in the lacrosse players and non-athletes, whereas that of RF was significantly smaller in the cyclists and non-athletes than in the lacrosse players. The relative value of RF to the total quadriceps femoris in volume was significantly lower in the cyclists than in the lacrosse players and non-athletes. Discussion The present study demonstrated inferior muscularity of RF to the vasti in the cyclists. This result was consistent with our finding in oarsmen (Ema et al., 2012). This may be attributable to the difference in muscle activation between RF and the vasti during cycling motions (Chin et al., 2011). The current results indicate, regardless of sport events, that inferior muscularity of RF to the vasti is common to the athletes who mainly perform cyclic leg extensions. On the other hand, larger size of RF in the lacrosse players may be partly due to repeated sprint activities during field sports (Spencer et al., 2005), which include hip flexions during the swing phase. The present findings suggest that chronic participation in sport activities that require cyclic leg extensions results in inferior muscular hypertrophy of RF compared to the vasti. ## NEUROMUSCULAR FATIGUE OF THE QUADRICEPS FOLLOWING CONCENTRIC ISOLOAD VS ISOKINETIC FATIGUE PROTOCOL

Plautard, M., Cornu, C., Guevel, A.

*University of Nantes*

Introduction Isolead (against a constant load, IL) and isokinetic (at constant angular velocity, IK) movements are commonly used in rehabilitation and training programs. IL and IK contractions exhibit specific mechanical constraints that influence EMG activity of the quadriceps muscle (Guilhem et al., 2011; Remaud et al., 2009). In the same time, fatigue has been shown to be task dependent and to depend on mechanical features and motor unit activation (Babault et al., 2006). Our study aimed to compare neuromuscular fatigue of the knee extensors induced by concentric IL and IK standardized fatigue protocols. Methods 12 subjects participated in IL and IK test sessions. Each session comprised a fatigue protocol performed in the tested contraction mode and neuromuscular tests carried out before, immediately after and 5-min after the fatiguing exercise. In order to compare the effects of contraction mode on neuromuscular response, IL and IK fatigue protocols were standardized by equalizing total amount of work and mean angular velocity. During the tests, peak torque (Pt), rate force development (RFD) and voluntary activation (VA) were assessed through isometric maximal voluntary contraction. Contractile properties were estimated from the mechanical response to supramaximal paired stimuli, i.e. the maximal rate of force development, the peak torque and the maximal rate of torque development. The statistical differences between contraction mode and/or tests were computed using a two-way ANOVA with repeated measures. Results Our results indicated similar Pt decrease consecutive to both IL and IK exercises (respectively -20 and -17%;  $p < 0.005$ ). In the same way, VA did not demonstrate differences between the two sessions. On the contrary, RFD decrease (-29%;  $p < 0.005$ ) and contractile properties impairment (-25% on average for corresponding parameters;  $p < 0.005$ ) were specifically induced by IL fatigue protocol. Discussion Our study highlighted that neuromuscular fatigue was different when protocol was made of IL or IK contractions. Contractile properties impairment probably originated in modifications of excitation-contraction coupling processes, while RFD decrease could be linked with both neural and muscular changes. EMG analysis of maximal voluntary and electrically evoked contraction is in progress and will be presented at the ECSS conference. References Babault N, Desbrosses K, Fabre MS, Michaut A, Pousson M. ## HOW MANY HEALTHY INDIVIDUALS RESPOND TO WIDE-PULSE, HIGH-FREQUENCY NEUROMUSCULAR STIMULATION BY GENERATING "EXTRA FORCE"?

Wegrzyk, J.1, Fouré, A.1, Vilmen, C.1, Maffioletti, N.A.3, Place, N.2, Mattei, J.P.1, Bendahan, D.1, Gondin, J.1

*Aix Marseille University*

Introduction In contrast to conventional (CONV) NMES, the use of "wide-pulse, high-frequency" (WP-HF) NMES has been reported to generate up to five times higher forces than expected from the direct activation of motor axons alone [1]. This "extra force" (EF) phenomenon has been mostly ascribed to central mechanisms and observed in 80-85% of healthy individuals (i.e., responders) [2, 3]. The latter calculation, however, was based on small samples (5-15 subjects) using a single criterion analysis. In the present study, we aimed at determining the number of responders to the EF phenomenon on the basis of a large sample size and an original methodological approach. Methods Electrically evoked isometric force of the plantar flexor muscles was recorded in 42 healthy subjects (20 men, 22 women; age:  $28 \pm 6$  years). CONV (25Hz, 0.05ms) and WP-HF (100Hz, 1ms) NMES consisted of  $5 \times 20$  s constant-frequency stimulation trains at 5% of the maximal voluntary contraction (MVC) force. A three step calculation process was applied to classify responders, i.e., S1) inclusion of subjects for whom the force difference between 0-2 s and 18-20 s of WP-HF was significantly greater than zero, S2) exclusion of subjects showing no significant difference in force output between the two protocols, S3) inclusion of subjects for whom peak force occurred before 18-20 s. Results After S1, 25 subjects were classified as potential responders from whom two were excluded after S2, and to whom three were added after S3. Overall, 26 subjects i.e. 62% were classified as responders. For this group, the mean force increased significantly from  $4.4 \pm 1.5$  to  $14.1 \pm 3.4$  % MVC for WP-HF whereas it remained constant for the non-responders ( $4.7 \pm 1.0$  to  $4.4 \pm 1.3$  % MVC). No significant effect of age, sex, height, weight, caffeine intake and stimulation intensity (mA) on EF was found. Discussion Although the extent of EF (i.e. threefold force increment) was comparable to former studies, the relative amount of responders i.e. 62% was considerably lower than the 80-85% value [2,3] previously reported. The use of multiple selection criteria allowed us to discard false-responders and to include false non-responders who would have been wrongly classified on the basis of a single criterion. Overall, this methodological approach provides a framework for unraveling the physiological mechanisms involved in EF generation. References 1 Collins DF. et al. (2002). *J Physiol* 538(1), 289-301. 2 Lagerquist O. et al. (2009). *J Appl Physiol* 107(1), 161-167. 3 Dean JC et al. (2007). *J Appl Physiol* 103, 170-176.

## ENGINEERING INNERVATED SKELETAL MUSCLE IN VITRO

Martin, N.R.W., Passey, S.L., Mudera, V., Baar, K., Greensmith, L., Lewis, M.P.

*Loughborough University*

Introduction: In vitro skeletal muscle cultures have provided a novel method for investigations into mechanisms governing skeletal muscle maturation and adaptation to exercise in an isolated environment. However, typically such in vitro cultures have limited utility for such

investigations due to the fact that they are not cultured in a biologically relevant niche, and they lack innervation which inhibits physiologically correct stimulation. We aimed to create 3-dimensional skeletal muscle with an extracellular matrix and subsequently co-culture these skeletal muscle models with primary motoneurons to determine if a neuromuscular junction (NMJ) can be created in vitro. Methods: Primary rat muscle derived cells (MDCs) were isolated from P1 neonates by enzymatic digestion, and seeded on to fibrin based hydrogels as previously reported (Huang et al. 2005). After 4 days in culture, primary rat motoneurons were isolated from the ventral horn of spinal cords from 14 day old embryos and were seeded on to the muscle derived cells and maintained for a further 7-10 days. At the end of the culture period constructs were fixed and immunostained for markers of muscle, motoneurons and NMJs. Results: Over 14 days in culture, the hydrogels self-assembled into 3-dimensional constructs with a maximum width of <500µm. Immunohistochemistry of cross-sections of these muscles displayed that muscle fibres expressing the cytoskeletal protein desmin were present throughout the core of the constructs. Furthermore, longitudinal immunostaining displayed the structural biomimicry as evidenced by densely packed fascicular bundles of myotubes. When co-cultures were immunostained for MAP-2, there was clear evidence for motoneuron survival and extension of neurites/axons from neuronal cell bodies. Furthermore, co-localisation of pre- and post-synaptic proteins gives evidence to suggest that NMJs can be formed in this system. Conclusions: We have succeeded in creating a system for the co-culture of skeletal muscle with motoneurons and have evidence of NMJs. Stimulation through these motor nerves will allow for both phenotypic and molecular skeletal muscle regulation of exercise adaptation to be explored in a model which closely recapitulates native skeletal muscle. ### **DYNAMOGRAM IN ANTIOQUIA'S TEAM FINSWIMMING ATHLETES, COLOMBIA: COMPARATIVE CHARACTERISTICS**

Marino, F.E.1, Romero, L.J.P.2, Valbuena, L.H.1, Orozco, A.3, Escobar, N.3

*INDEPORTES ANTIOQUIA - UNIVERSIDAD PONTIFICIA BOLIVARIANA UPB*

Introduction Training done by athletes produces metabolic and physiological adaptations which are related to execution of sports movements and increasing of strength, agility, flexibility, power, speed, intra or intermuscular recruitment and metabolic pathways of energy production. The determination of force-velocity musculoskeletal system characteristics is one of the most widely method used to analyze and evaluate these variables. This uses technological devices and computers applied by means of dynamometry and electromyography. Dynamometer is used to measure developed force in a maximum isometric contraction and to determine fast characteristics of muscle contraction strength, by force curve graphic or dynamogram. The aim of this study was measure dynamometric variables in Antioquia Team Finswimming athletes, Colombia. The measurements were performed at Exercise Physiology Laboratory of Indeportes Antioquia. Two measurements were taken of each athlete and calculated with software designed to calculate and graph the dynamogram. Latency, first peak force, first peak time, maximum force, maximum force time, relaxation latency, relaxation time, relaxation force, maximum gradient strength and relaxation coefficient were measured. Results The results show differences between genders in the evaluated parameters. The intra and intergroup differences could be due to different forms of training or muscle imbalances that have not been corrected. Tables are presented with the results and statistical analysis. Discussion Assessing neuromuscular variables in athletes helps to build a more suitable training system. Obtained values for latency in both genders related to those reported in the literature (250 to 320 ms). The relationship between extensor and flexor strength is near to 2:1 but is not related to body weight or sport modality according data obtained in our laboratory. It provides a comparison between genders to see their statistical significance. References 1. Alonso Hernández, J; Iznaga Dapresa, A. ### **PERFORMANCE AND POWER OUTPUT IN VERTICAL JUMPS PERFORMED WITH POSITIVE AND NEGATIVE LOADING**

Jaric, S.1, Suzovic, D.2, Pasic, M.2, Markovic, G.3

*University of Delaware*

Department of Kinesiology and Applied Physiology, University of Delaware, Newark, USA, 2Faculty of Sport and Physical Education, University of Belgrade, Serbia, 3Faculty of Kinesiology, University of Zagreb, Croatia Introduction The aim of the study was to explore the effects of positive and negative load on the differences in performance and power output of the maximum vertical jumps (VJ) performed with and without the stretch-shortening cycle (SSC). In line with the Maximum Dynamic Output Hypothesis (Markovic, Jaric, 2009), we predicted that the maximum advantage of the SSC would be revealed under no-load (i.e., body mass only) conditions. Methods Thirteen physically active participants (age: 21.2 ± 1.3 yr, body mass: 79.5 ± 10.8 kg, height: 1.84 ± 0.06 m; mean ± SD) performed maximum squat jump (i.e., VJ without SSC) and various counter movement jumps (i.e., VJ with SSC) when loaded by a pulley system exerting a vertical force upon the body within the range between -40% and +40% of body weight (BW). Results The differences in performance between VJ executed with and without SSC revealed maxima strikingly close to no-load conditions (0%-2%BW), while the same differences in the power output were observed under relatively low positive loads (14%-25%BW). Discussion The obtained results support the Maximum Dynamic Output Hypothesis and suggest that all neuro-mechanical processes that enhance SSC associated performance could be optimized for one's own body weight. Future studies should extend this line of research both to different ballistic movements and different loading methods. Acknowledgments This work was supported in part by a National Institutes of Health grant R21AR06065, grants from the Serbian Research Council (#175037), and Croatian Ministry of Science, Education and Sport (034-0342607-2623). ## SHORT-TERM DISUSE AND SUBSEQUENT RECOVERY INDUCE AGE-SPECIFIC ALTERATIONS IN NEUROMUSCULAR ACTIVATION

Hvid, L.G., Suetta, C., Ørtenblad, N., Kjaer, M., Aagaard, P.

*University of Southern Denmark*

**Introduction** An optimal efferent neural drive (neuromuscular activation) is a governing factor for the ability to develop maximal muscle strength. However, it remains unknown how short-term disuse (< 7 days) and subsequent recovery affects neuromuscular activation in young compared to old individuals. The purpose of the study was to investigate this. **Methods** Eleven young (~24 yrs) and 11 old (~67 yrs) recreationally active healthy men underwent 4 days of unilateral lower limb disuse (locked knee brace, ambulation using crutches) followed by 7 days of recovery (free ambulation including one session of resistance training). Assessment of knee extensor maximal voluntary isometric contraction (MVC) and neuromuscular activation (NA) using superimposed twitch interpolation were carried out in a custom-built dynamometer (Suetta et al. 2009) before and after disuse as well as after recovery. **Results** Prior to disuse, old demonstrated lower MVC than young (159±11 vs. 208±12Nm, respectively) as well as reduced NA (89.2±2.2 vs. 94.0±0.8%, respectively). Following disuse, MVC decreased in old (135±12Nm, -16%) and young (188±12Nm, -10%), while NA decreased in old only (81.8±3.9%, -8%) and remained unaffected in young (92.9±1.1%). Following recovery, MVC and NA increased both in old (147±12Nm, +11%; 87.2±2.6%, +8%) and in young (205±13Nm, +10%; 95.6±0.7%, +3%). Notably, compared to pre disuse levels, MVC remained suppressed in old whereas NA increased in young following 7 days of recovery. **Correlations** were observed between relative changes in MVC and NA induced by disuse (old:  $r=0.83$ ) and recovery (young:  $r=0.65$ , old:  $r=0.66$ ). **Discussion** While short-term disuse and subsequent recovery caused similar changes in MVC in young and old, respectively, these changes were accomplished through different mechanisms. Hence, old demonstrated more marked alterations in NA compared to young, in accordance with longer lasting (7-14 days) disuse studies (Deschenes et al. 2008, Suetta et al. 2009). **In conclusion**, short-term disuse and subsequent recovery induce age-specific alterations in lower limb neuromuscular function. ## TWITCH POTENTIATION INDUCED BY NEUROMUSCULAR ELECTRICAL STIMULATION IS NOT AFFECTED BY STIMULATION PARAMETERS.

Silva, S.R.D.1,2, Maffiuletti, N.A.3, Gondin, J.4, Neyroud, D.2, Place, N.2

*University of São Paulo*

**1**School of Physical Education and Sport of Ribeirão Preto, USP, Brazil **2**ISMMS, University of Geneva, Switzerland **3**NRL, Schulthess Clinic, Zurich, Switzerland **4**CRMBM, Aix-Marseille University, Marseille, France. **Introduction** Neuromuscular electrical stimulation (NMES) recruits motor units in a nonselective, spatially fixed and temporally synchronous pattern (1). It has recently been suggested that the use of wide-pulse (1 ms) high-frequency (> 80 Hz) NMES can additionally recruit motor units through a "central" mechanism (2), which would be similar or close to the orderly recruitment observed in voluntary contractions. The increase in twitch force after a conditioning contraction (twitch potentiation) is affected by the activation history of the muscle but has also been shown to be greater for fast-twitch muscle fibers (3). Thus, the aim of the present study was to compare the extent of twitch potentiation after three different conditioning contractions: conventional NMES (CONV); wide-pulse high-frequency NMES (WPHF) and voluntary (VOL). A lower potentiation for WPHF in comparison to CONV would indicate that proportionally more slow-twitch motor units are recruited during WPHF. **Methods** Thirteen healthy subjects (nine men and four women) aged  $30 \pm 7$  yrs sat in a custom-built chair with the dominant foot placed on a pedal equipped with a strain gauge. Knee angle was 140° (180° = full extension) and ankle angle was 90°. Peak twitch (Pt) was evoked by supramaximal stimulation of the tibial nerve before and immediately after the three following conditioning contractions (duration 10 s): WPHF (1-ms pulse width/100-Hz frequency), CONV (50- $\mu$ s pulse width/25-Hz frequency) and VOL. Each condition was separated by 5-10 min. NMES was delivered by two large electrodes positioned over the triceps surae muscle belly, and stimulation intensity was set to produce an initial force of 10% MVC for the WPHF modality. Force-time integral was then matched for the two other 10-s contractions. **Results** The force time integral was comparable ( $p>0.05$ ) for WPHF ( $958 \pm 614$  N.s), CONV ( $958 \pm 559$  N.s) and VOL ( $968 \pm 544$  N.s). Peak twitch force was similarly potentiated after WPHF (from  $112 \pm 26$  N to  $116 \pm 29$  N,  $p<0.05$ ) and CONV (from  $105 \pm 25$  N to  $109 \pm 27$  N,  $p<0.05$ ), whereas no potentiation was observed for VOL (from  $103 \pm 26$  N to  $103 \pm 26$  N,  $p>0.05$ ). **Conclusion** The main finding of the present study is that low-intensity WPHF and CONV NMES of the triceps surae potentiated the twitch response to a similar extent. These results do not lend support to the theory that WPHF NMES can result in different motor unit recruitment compared to CONV NMES. **References** (1) Bickel CS et al. *Eur J Appl Physiol* 111, 2399-2407, 2011 (2) Collins DF et al. *J Physiol* 538, 289-301, 2002 (3) Moore RL & Stull JT. *Am J Physiol* 247, 462-471, 1984

## FREQUENCY DEPENDENCE OF JOINT VISCOELASTICITY BY SINUSOIDAL ANALYSIS

Shin, H.I, Motoki, K.1

*1: Human and environmental studies, Kyoto university*

**Introduction** In addition to muscle activation, joint viscoelasticity is important element for motor control. Although joint viscoelasticity is variable related displacement and velocity, recent study has not considered frequency dependence of joint viscoelasticity. To investigate the frequency dependence of joint viscoelasticity, sinusoidal analysis (Kawai M 1978) was applied in which the complex stiffness was calculated by relationship between displacement and force when the sinusoidal displacement was given. The purpose of the present study was to examine the frequency dependence of joint viscoelasticity by sinusoidal analysis. **Methods** Eight subjects were participated in this study. The vibratory stimulation on the index finger of left hand in which the amplitude was 1 deg and the frequency was 14 levels (0.25 Hz ~ 66 Hz) was given in direction of adduction-abduction. The force transducer was attached to the left index finger and the adduction-abduction torque was calculated. Using the high resolution (10  $\mu$ m) laser displacement sensor, adduction-abduction angular displacement was measured. Surface EMG was recorded from first dorsal interosseous in order to monitor the muscle activities. Then, to investigate the frequency dependence of joint viscoelasticity, sinusoidal analysis was applied and the procedure was as bellow. 1) Five cycles in which there were no reflex activities was selected as the analysis period at each trial. 2) The time series of angle and torque were fitted to the sinusoidal wave by the least-squares method. 3) From the amplitude ratio of torque and angle ( $T_0/\theta_0$ ) and the phase shift ( $\delta$ ) of torque and angle, the complex stiffness ( $G^* = T_0/\theta_0 \cdot e^{i\delta}$ ) was calculated and plotted in complex plane. This index has the property that real part shows the elastic component and the imaginary part shows the viscos component. 4) Elastic coefficient (K) and

viscos coefficient (B) were the quantified using the Results The complex stiffness existed in not only first quadrant but also second quadrant, because the obtained torque data contained the torque proportional to angular acceleration. Combining the model and the complex stiffness in order to extract the information of joint viscoelasticity, it was found that elastic coefficient (K) largely increased and the viscos coefficient (B) largely decreased, as the frequency became high. Discussions Main result that elastic coefficient increased and viscos coefficient decreased as the frequency became high corresponded to the resent study (Kawai M 1978) in which muscle preparation of rabbit psoas had been used. In conclusion, frequency dependence of joint viscoelasticity is verified. Reference Kawai M (1978). edited by Haruo Sugi and Gerald H.Pollack: 149-169

## STRUCTURE OF PROXIMAL AND DISTAL COMPARTMENTS IN RAT MEDIAL GASTROCNEMIUS MUSCLE

Taborowska, M., Celichowski, J., Bukowska, D.

*University School of Physical Education in Poznan*

**Introduction** Muscle compartments are subvolumes of the skeletal muscle which are innervated by primary extramuscular nerve branches and are documented in several muscles of mammals. These regions are innervated by unique sets of motoneurons, contain characteristic proportions of muscle fiber types and thus have various contractile and histochemical profiles. Rat medial gastrocnemius is composed of two subvolumes: the proximal compartment containing predominantly fast twitch oxidative fibers and the distal compartment with mainly fast twitch glycolytic fibers. The aim of this study was to determine the histological structure of muscle fibers (number and diameter) in the two medial gastrocnemius compartments on various levels along the muscle. **Methods** Adult female Wistar rats of the same age were studied. To diversify muscle compartments, glycogen depletion technique based on a stimulation protocol of one of the two primary nerve branches to medial gastrocnemius was applied. The area of compartments, number and diameters of muscle fibers in the two distinct subvolumes on five muscle levels (about 10, 25, 50, 75 and 90% of the muscle length) were determined from serial cross sections. For analysis the Nikon DS-Fi1c Camera and NIS-Elements Basic Research software were used. **Results** It was shown that the two smallest, opposite serial sections: close to the knee (about 10% of muscle length) and close to the Achilles tendon (about 90% of muscle length) are occupied by only one compartment: proximal and distal, respectively. The largest section (at about 50% of muscle length, 27.8 – 29.5 mm<sup>2</sup>), the proximal compartment constituted 27 – 33% of the muscle area. Maximal number of muscle fibers in the proximal compartment was 5,008 – 6,698, while in the distal one 4,773 – 6,241. The mean muscle fibers diameter in the proximal and the distal subvolumes ranged: 36.9 – 48.9  $\mu$ m and 46.5 – 63.5  $\mu$ m, respectively. Moreover, the diameter muscle fibers revealed a tendency visible within each of the two compartments to increase along the muscle. **Conclusion** It is concluded that size and number of muscle fibers in proximal and distal compartments of the medial gastrocnemius are different. In comparison to the distal compartment, the proximal one has smaller cross-section area but contains slightly higher number of muscle fibers which are smaller in diameter.

## EFFECTS OF REDUCED PLANTAR SENSATION ON MAXIMUM FOOT GRIP STRENGTH

Horiuchi, K.1, Yamauchi, J.1,2

*1:Tokyo Metropolitan University, 2:Future Institute for Sport Sciences*

**Effects of reduced plantar sensation on maximum foot grip strength [Introduction]** A better understanding of the functional role of the foot is the major key to understand regulatory mechanisms of human bipedal locomotion and postural control. It has been suggested that the foot muscle strength is an important role in motor task of the human movements (Goldmann et al. 2012). Also, it has been reported that greater sensory loss of the foot is related to loss of postural control (Wang and Lin 2008). This impairment of postural stability might be related to the decrease in muscle force production of foot after desensitization of foot if foot muscle strength is also required to maintain a whole body balance. However, no studies were investigated to the effects of reduced plantar sensation on the force generating capacity of foot muscle. **[Purpose]** The aim of the present study was to investigate the effects of reduced plantar sensation on maximum foot grip strength. **[Methods]** Twenty young healthy individuals (age 21.2 $\pm$ 3.4years, body height 1.67 $\pm$ 0.1m, body mass 56.9 $\pm$ 10.6kg, mean $\pm$ S.D) were participated and their maximum foot grip force (FGF), postural control, skin temperature (ST) and the cutaneous light-pressure thresholds (CPT) were measured with the foot grip dynamometer, Kistler force plate, thermography and Semmes-Weinstein monofilament, respectively, before and after the intervention (normal and reduced plantar sensation). For maximum isometric force measurement of foot grip, subjects optimally grabbed the grip-handle bar of the dynamometer by toe and fingers of foot in a sitting and standing position and exerted maximum force, and then, the highest value among the 3 trials was used for a further analysis. Postural control was assessed during double and single leg quiet standing in open eyes condition, using force plate to quantify center of pressure (COP) dynamics. Intraclass correlation coefficient (ICC) were used as estimates of reliability and precision. The right foot was placed into cold water (0°C) for 20 minutes, while the left foot was stayed outside of water as a control. The room temperature was maintained at 20°C. **[Results and Discussion]** After cold water immersion, FGF, ST and CPT significantly decreased, while the control foot did not changed. ICC values before and after intervention for the control foot was 0.95. The results of this study suggest that a desensitization of foot induces an impairment of foot muscle functions. Also, cold water immersion might cause to decrease muscle temperature itself and such lowered muscle temperature could imparted the force generating capacity of muscle. **[Reference]** Goldmann JP et al., The potential of toe flexor muscles to enhance performance, *J Sports Sci.* 2012; in press Wang TY and Lin SI, Sensitivity of plantar cutaneous sensation and postural stability, *Gait Posture* 2008; 23(4):493-499.

## PRESYNAPTIC CONTROL IN THE REGULATION OF THE VOLUNTARY MOVEMENT IN PERSONS OF DIFFERENT AGE

Chelnokov, A.

*Velikiye Luki State Academy of Physical Education and Sports*

The purpose of our research was in studying the role of presynaptic inhibition (PI) of Ia afferents in regulation of a voluntary muscle contraction in persons of different ages. **Methods** 9-12 year-old boys (n=15), 14-15 (n=15) and 17-18 year-old teenagers (n=15), and 22-27 year-old men took part in the research. PI of Ia afferents were evaluated according to the degree suppression m. soleus H-reflex amplitude of a testing person in conditioning stimulation of n. peroneus profundus (Mizuno et al., 1971). The lower the m. soleus H-reflex amplitude of a testing suppression is in relation to H-reflex amplitude of a control, the stronger is the PI. The interval between the conditioning and testing stimuli in 9-12 year-old boys was 40 ms, in 14-15 year-old teenagers was 70 ms, in 17-18 year-old teenagers and 22-27 year-old men 100 ms in rest and during isometric contraction on 1st, 15th and 30th seconds. The subjects performed an isometric muscle contraction (plantar flexion) with a 25% of maximal voluntary contraction effort in a sitting position in the dynamographic system Biodex (Biodex Medical System, USA). **Results** It is shown that without dependence from age at all groups in the conditions of static effort expres-

sion of PI decreased in comparison with the background data received in rest. The higher expression of PI at performance of isometric contraction throughout 30 seconds of effort is characteristic for 14-15 year-old teenagers, and the least for children of 9-12 years. Unlike previous age groups of 9-12 year-old boys and 14-15 year-old teenagers, at of 17-18 year-old teenager's expression of PI at performance of any movement is characterized by weakening and comes nearer to level of 22-27 year-old men. We consider the activity of PI to be not only under the influence of afferent, but also corticospinal and the cortical ones depending on the degree of spinal and cortical structures of maturation at different ontogenesis period of the human. ### LONG-TERM SPORTS ACTIVITIES MAY INDUCE PLASTICITY IN SPINAL MOTOR CONTROL SYSTEMS

Andriyanova, E., Lanskaya, O.

*Velikiye Luki State Academy of Physical Education and Sports*

**Introduction** More active skeletal muscle contractions significantly change work of central and peripheral sections of the nervous system. Therefore, research of the spinal cord plastic changes, connected with specific sport training, is of great importance. Methods and subjects 18 non-athletes, 13 basketball-players and 13 ski-racers (aged 18-22) were involved into the investigation. We used the technique of registration of posterior root-muscle reflexes (PRM-reflexes) (Minassian K., Persy I., Rattay F. et al., 2007) which were evoked by percutaneous surface electric spinal cord stimulation at the cervical levels (C2-C7). These responses are equivalents of the H-reflex. There were investigated PRM-reflex thresholds and maximal amplitudes of bilateral biceps brachii, triceps brachii, brachioradialis, extensor digitorum muscles. Results The lowest thresholds and the highest amplitudes of the PRM-reflexes of the studied muscles were revealed at C4-C7 level stimulation in both groups of the athletes, while the same data in the non-athletes were received in a narrower area - at C6-C7 level. At all levels of the stimulation PRM-reflex thresholds and maximal amplitudes in the basketball-players and the ski-racers were significantly different from those in the non-athletes. Practically at all levels alpha-motorneuron reflex excitability of biceps brachii and brachioradialis muscles was much higher in the ski-racers than in the basketball-players. It indicates more pronounced motorneuron plasticity of spinal cord cervical enlargement in ski-racers in comparison with basketball-players. Conclusion The studied long-term sport activities led to plastic changes of spinal cord structures affecting motor control. Further the type sport activity defines the nature and extent of the plasticity. References Minassian K., Persy I., Rattay F., Dimitrijevic M.R., Hofer C., Kern H. ### EFFECTS OF ELECTRICAL NOISE TO A TIBIAL NERVE ON SOLUES H-REFLEX

Taki, C., Kimura, T., Shiozawa, N.

*Ritsumeikan University*

**Introduction** A recent study (Kouzaki et al. 2012) showed that a minute electrical noise to an afferent nerve reduced force fluctuation during a force matching task, accompanied with the decreased variability of motor units inter-spike intervals. This may be accounted for by the stochastic resonance in the spinal neurons. The aim of this study was to verify the effect of subthreshold electrical noise of afferent nerve on the static and dynamic properties of the alpha motor neuron excitability. Methods The subjects were 12 healthy young men. They sat on a chair and were given subthreshold electrical noise stimulation (5-1000 Hz) (Kimura et al. in press) on a tibial nerve (80% of M-wave threshold) in the right leg. At the same time, a series of single twitch stimulation were injected to the tibial nerve, in order to induce H-waves at the frequency of 1 Hz. In each subject, trials with (ES) and without (CON) noise for 20 min were performed in random order. The H-wave was recorded in the soleus muscle. The time series data of the peak-to-peak amplitudes of 1200 H-waves was obtained for each trial. The variability of the fluctuation was quantified by coefficient of variance (CV). The detrended fluctuation analysis (DFA), based on the long-range correlation (Peng et al. 1995), was also performed to assess its dynamic property. Results The averages of H-wave amplitudes were not different between CON (average (SD), 5.14 (2.99) mV) and ES trials (5.50 (3.15) mV) ( $P > 0.05$ ). On the other hand, CV of the amplitudes in ES (14.0 (7.4) %) was significantly smaller than that in CON (16.7 (8.3) %) ( $P < 0.05$ ). In the DFA, the self-similarity parameter  $\alpha$  was significantly decreased by the injected noise (0.85 (0.06) and 0.98 (0.10) in ES and CON, respectively) ( $P < 0.05$ ). Discussion These results indicate that the static and dynamic properties of alpha motor neuron excitability are changed by a minute electrical noise to an afferent nerve. In terms of the static property, the fluctuation seemed to be attenuated by the noise. However, the DFA indicated that the fluctuation in ES trial became closer to the white noise ( $\alpha = 0.5$ ), not to the  $1/f$  fluctuation ( $\alpha = 1$ ). Further study is required to assess the physiological implication of the changes in dynamic property. References Kouzaki M et al. *Neurosci Lett*, 513:146-150, 2012. #### SLACKLINE TRAINING TO PROMOTE BALANCE, GAIT AND STRENGTH PERFORMANCE IN HEALTHY SENIORS

Donath, L., Roth, R., Zahner, L., Faude, O.

*University of Basel*

**Introduction** Aging-induced deteriorations of neuromuscular performance account for higher fall risks in seniors. Balance and strength training, in turn, improve neuromuscular performance and reduce fall rates up to 50% (Gillespie et al. 2009). Slackline training (balancing over nylon ropes) may be regarded as an appealing and challenging approach to train balance and was recently employed in young adults (Granacher et al. 2010) and children (Donath et al. 2013). As comparable studies are lacking in seniors, the present study examined effects of slackline training on standing balance, spatio-temporal gait characteristics and strength performance in seniors. Methods 24 seniors were stratified (strata: age, gender, physical activity (PA)) to an intervention [INT, n=12, 6 women, 6 men, age: 62±6y, PA: 8.7±3.5h/week] or control [CON, n=11, x women, y men, CON: age: 61±6y, PA: 8.5±3.5h/week] group. Slackline training was performed

within 6 weeks (3 times/week, 1 hour/session). INT comprised e.g. double and single limb standing, swinging; walking, turning; backwards walking. Training attendance was 97% (1 drop out in CON due to illness). Before and after the intervention, balance, gait and strength was assessed by (a) tandem and single limb stance (30s) on the slackline and a force plate (sway path of the center of pressure), (b) normal overground walking to obtain spatio-temporal gait characteristics during single, dual (+cognitive interference) and multi (+cognitive and motor interference) task conditions and (c) lower extremity strength (plantar flexion, dorsal extension, maximal force and force development). Results Large group (INT vs. CON) x time (pre vs. post) interactions were found for tandem ( $p=0.049$ ,  $\eta^2=0.17$ , INT, pre,  $1.4\pm 0.7$  s vs. post,  $4.5\pm 4.1$  s,  $p<0.001$ ; CON, pre  $1.5\pm 0.6$  s vs. post,  $2.3\pm 0.9$  s) and left-leg ( $p=0.04$ ,  $\eta^2=0.16$ , INT, pre,  $4.6\pm 3.6$  s vs. post,  $26.5\pm 29.1$  s,  $p<0.01$ ; CON, pre  $3.0\pm 1.4$  s vs. post,  $3.0\pm 1.8$  s) slackline standing. Right-leg slackline standing (INT, pre,  $3.8\pm 2.4$  s vs. post,  $12.9\pm 21.8$  s; CON, pre  $4.5\pm 3.5$  s vs. post,  $3.3\pm 4.2$  s) was slightly affected ( $p=0.12$ ,  $\eta^2=0.11$ ). Static upright stance on the force-plate, spatio-temporal gait characteristic and explosive and maximal strength were not relevantly affected (0.06

## RELIABILITY AND VALIDITY OF THE CHAIR SIT-AND-REACH TEST IN JAPANESE ELDERLY ADULTS

Nakatani, T.I., Terada, K.I., Nadamoto, M.2, Murakami, K.I., Shiraishi, A.I, Umesaki, S.I

1: Tenri University (Nara, Japan), 2: Poole Gakuin University (Osaka, Japan)

**Introduction** The sit-and-reach test is the most commonly used approach for measurement of lower back and hamstring muscle flexibility. The test is important because tightness in these muscles is responsible for musculoskeletal injuries and lower back problems (Stutchfield and Coleman, 2006), especially in older adults. The newly designed chair sit-and-reach (CSR) test has been used to measure hamstring flexibility in elderly individuals (Jones et al., 1998). However, the reliability and validity of this test in Japanese elderly adults has not yet been evaluated. We aimed to investigate the test-retest reliability and criterion-related validity of the CSR test in healthy Japanese elderly adults. **Subjects and Methods** A total of 1426 elderly subjects (419 men and 1007 women) aged 60–93 years participated in this study. The results of the CSR test were compared with those obtained using the passive straight leg raise (PSLR) test. The CSR values were also compared to standing trunk flexion (STF) and sit-and-reach (SR) measurements. **Results** The intraclass correlation coefficient (ICC) for the CSR test values was very high (ICC = 0.88–0.96). Significant differences in Pearson correlation coefficients ( $P < 0.05$ ) were observed between CSR values and the values obtained in PSLR ( $r = 0.66$  for men;  $r = 0.28$  for women), STF ( $r = 0.84$  for men;  $r = 0.85$  for women), and SR ( $r = 0.71$  for men;  $r = 0.74$  for women) assessments of hamstring flexibility. Two-way analysis of variance showed a significant interaction between age and gender. No age-related changes were observed in the CSR values in men. However, among female participants, a significant difference was observed between subjects aged 60–69 years and <70 years ( $P < 0.05$ ). Moreover, significant gender-related differences in CSR values were observed across all age groups. **Discussion** The high reliability values for the CSR test in Japanese elderly adults in this study were consistent with the results reported by Jones et al. (1998) in their assessment of the CSR test. The criterion-related validity coefficients (0.28 to 0.85) found in our study were accepted to be consistent with the results of previous studies. These findings suggest that the CSR test is a reliable approach and provides an acceptable measure of hamstring flexibility in Japanese elderly adults. **References** Jones C.J., et al. (1998). ## REPEATED SPRINT ABILITY IN YOUNG SOCCER PLAYERS AT DIFFERENT GAME STAGES

Meckel, Y., Einy, A., Gottlieb, R., Eliakim, A.

Zinman College for Physical Education and Sport Sciences

**Introduction** In previous studies, repeated sprint ability (RSA) was usually measured when participants were fresh following an appropriate warm-up (Bishop et al., 2001; Meckel et al., 2009). However, in soccer players are required to perform repeated sequences of sprints under fatigue conditions throughout the 90 min game. Therefore, the aim of this study was to determine young ( $16.9\pm 0.5$  yr) soccer players' RSA at different game stages, and to examine the relationships between the player's aerobic fitness ( $VO_2$  max) and the difference in RSA indices between the different stages. **Methods** Twenty players performed three repeated sprint test (RST) (12X20 m) after warm-up prior to the game, at half-time and after a full soccer game, each on a different day, at random order. The players performed also an aerobic power test (twenty-meter shuttle run test). **Results** Ideal (fastest) sprint time (IS) and total (accumulative) sprint time (TS) were significantly slower at the end of the game compared to after the warm-up prior to the game ( $p<0.01$  for each). The difference between IS and TS after the warm-up prior to the game and at half-time, and between IS and TS at half-time and the end of the game, did not reach statistical significance. There was no significant difference in the performance decrement (PD) during the RST after warm-up prior to the game, at half-time, and at the end of the game. Significant negative correlation was found between predicted  $VO_2$  and the difference between TS prior to the game and at the end of the game ( $r=-0.52$ ), but not between predicted  $VO_2$  and the difference between IS and PD prior to the game and end of the game. There were no significant correlations between predicted  $VO_2$  and the difference in any of the RST performance indices between prior to the game and half-time, or between half-time and the end of the game. **Discussion** The findings indicate that RSA of young soccer players is reduced as the game progress (Mohr et al., 2005). However, while fatigue can be recovered and RSA maintained during half-time, a significant long-lasting fatigue and RSA reduction is noticed at the end of a soccer game. The results also indicate that the involvement of aerobic energy sources in intermittent-type activity increases as the amount of work and fatigue level is increased. Therefore, the contribution of the aerobic system to soccer game intensity maintenance seems to be crucial mainly during the final stages of the game. **References** Bishop D, Spencer M, Duffield R, Lawrence S. ## NON CONVENTIONAL METHODS FOR ASSESSING STANDING BALANCE: RELIABILITY EVALUATION OF THE NINTENDO WII BALANCE BOARD

Carraro, A.I, Cardaioli, M.2, Pavan, A.I, Ferri, I.I, Gobbi, E.I, Pavan, P.2

1: FISPPA, University of Padua (Italy); 2: DII, University of Padua, (Italy)

**Introduction** Standing balance assessment represents a problem in field-based health-related fitness test battery and the research of low cost, portable and widely available measure tools is an important issue (Clark et al., 2010; Clark et al., 2011). Therefore, the aim of this study was contributing to analyse the validity and reliability of Wii Nintendo Balance Board (WBB) compared with a laboratory-grade force platform (FP) in evaluating subjects balance. The method adopted for comparing WBB and FP was intentionally simple in order to provide

a user friendly calibration, in line with the low cost approach to the problem. Method Four unmodified WBB were placed upon the FP and correctly aligned in order to avoid relative rotation of the respective intrinsic coordinate systems. Data from WBB with standard sampling frequency of 30 Hz were treated by an open source software and compared with the set of data obtained by the FP. WBB were tested in determining the centre of pressure (COP) in different static and dynamic tests. The static test consisted in the evaluation of COP over time for a mass of 64 kg placed on WBB, while dynamic tests involved thirty individuals (17 female, 13 male, age 23.8 ± 2.7 years). Dynamic tests consisted in double limb standing of 30 s with open and close eyes. Each subject performed 4 trials (2 with opened eyes, 2 with closed eyes). Results In static tests the variation of the COP over time for the WBB with respect to the effective COP position estimated with the FP was limited and similar for all the tools. In dynamic tests it was found a constant offset between COP position on the medio-lateral or anterior-posterior axis that can be related to the effect of horizontal forces on the effective position (Bobbert & Schamhardt, 1990). It was shown that this offset can be easily compensated for each WBB and, after compensation, values of sway path and sway area measures obtained by WBB and FP were comparable. Discussion Frequency sampling of unmodified WBB (30 Hz) is lower than usual frequency sampling of laboratory-grade force platforms (100 Hz) but this does not appear as a limit in evaluating the position of COP over time. Therefore, COP related measures such as sway path and sway area can be estimated in reliable way also by using a low cost set up based on WBB. This can represent a valid and easy-to-use tool for assessing standing balance control. References Clark R, Bryant A, Pua Y, McCroy P, Bennell K, Hunt M (2010). *Gait Posture*, 31, 307-310. ### RELIABILITY OF ANAEROBIC LACTATE THRESHOLD CONCEPTS IN RUNNING.

Prettin, S., Schnabel, A., Pottgiesser, T., Roecker, K., Ahlgrim, C.

*University Hospital of Freiburg, Hochschule Furtwangen University*

Introduction: Testing aerobic performance using blood lactate kinetics is a routine procedure in sports medicine and sports science. Several threshold models have been proposed and are routinely applied. Quantification of the test-retest-reliability of the respective concepts is necessary to differentiate between analytical and/or biological variation of the respective test results and real improvements or deteriorations e.g. after training interventions. In the present study we present a reliability analysis of commonly applied lactate threshold concepts in a healthy study group. Methods: 59 healthy subjects (40m, 19f, age: 41.7±12.6 yrs) performed three graded exercise tests on a treadmill (start 6km/h, increased by 2km/h every 3 min) until volitional exhaustion within 7 days. The initial test was performed to adjust to the test procedure; data for the analysis was obtained from the second and third exercise test. Lactate samples were taken from the hyperaemised earlobe during the last 20 sec of each step and 2, 3, 5 and 10 minutes after the test. Velocities and heart rates at conventional 4mmol (AT-4mmol) [Mader et al., 1976] and individual anaerobic thresholds as proposed by Stegman (IAT-ST) [Stegmann et al., 1981] and by lactate net-increase (IAT-DI) [Aunola et al., 1988] were determined. Typical errors (TE) of the velocities and the heart rates at the respective thresholds were calculated [Hopkins et al., 2001]. Results: For all subjects, mean velocity at AT-4mmol was 13.3 (± 2.0) km/h (TE: 2.4% (95%-CI: 2.0-3.0%)). Mean heart rate at AT-4mmol was 171.6 (± 11.3) bpm (TE: 1.9% (1.6-2.3%)). Mean velocity at IAT-ST was 12.3 (± 1.9) km/h (TE: 5.4% (4.1-7.5%)). Mean heart rate at IAT-ST was 161.2 (± 13.3) bpm (TE: 3.9% (3.1-5.4%)). For IAT-DI mean velocity was 12.4 (± 1.8) km/h (TE 2.6% (2.3-3.2%)) and mean heart rate was 164.8 (± 1.4) bpm (TE 2.4% (2.1-3.0%)). Discussion: Typical error for IAT-DI and AT-4mmol are of similar magnitude whereas TE for IAT-ST showed values almost twice the width and hence less reliability. This could lead to the conclusion, that AT-4mmol and IAT-DI are more sensitive to detect real changes than IAT-ST. Given that significant changes can be concluded when the difference between two values exceeds 2.77\*TE (95% CI), which means a difference of 0.89 km/h on average for velocity at IAT-DI, this illustrates that reliability of the respective measures have to be taken into account before 'real' improvements can be assumed.

### LACTATE CONCENTRATION IN GRECO-ROMAN WRESTLERS BEFORE AND AFTER FINAL MATCHES

Drid, P., Galovic, Z., Jovancevic, A., Trivic, T., Drapsin, M., Vujkov, S.

*Faculty of Sport and Physical Education, University of Novi Sad, Serbia*

Introduction As a result of recent rules changes in a match duration modern wrestling takes more the anaerobic energy system, elevates heart rates to maximal level (Kraemer et al., 2001) and accumulates moderate to high lactate concentrations (10-20 mmol•L<sup>-1</sup>) following competition. Up to date, level of lactate in athletes during intense training or competition has been used for assessing level of acidosis and muscle fatigue (Karninčić et al., 2009). The aim of this study was to investigate differences in blood lactate levels between wrestlers that have ended final matches in different rounds. Methods Study was conducted on three groups of wrestlers divided based on match duration. First group included wrestlers who ended their match after first round, second group included wrestlers who ended their match after two rounds and third group was made of wrestlers who ended their match after three rounds. All measurements were taken after final bouts during team championship of Serbia. Blood samples for lactate control were collected at two intervals: before the first round (after warm-up) and third minute after the end of a bout. T-test and one-way ANOVA were used for analyzing differences between groups and measuring time intervals. LSD test was used for post-hoc comparison. Results Results obtained in this study showed statistically significant differences between groups, divided on the basis of match duration. Third group of wrestlers (15.55±4.05 mmol•L<sup>-1</sup>) had statistically significant higher lactate level than first (8.06±2.35 mmol•L<sup>-1</sup>) and second group (11.10±2.27 mmol•L<sup>-1</sup>). Discussion Unlike findings of Kraemer et al. (2001) that showed resting lactate level concentrations before warmup between 1.7 mmol•L<sup>-1</sup> to 2.3 mmol•L<sup>-1</sup> this study showed higher lactate level values of first measurement (2.61-2.68 mmol•L<sup>-1</sup>). However, results of this study are in line with research of Karninčić et al. (2009) that reported lactate level of 2.61-2.63 mmol•L<sup>-1</sup> after warm-up as well. On the other hand, lactate concentration presented in this study is a bit lower than same values reported by Kraemer et al. (2001), where lactate concentration at the end of the wrestling match ranged from 17.1 to 20.0 mmol•L<sup>-1</sup>. References 1. Karninčić, H., Tocilj, Z., Uljević, O., Erceg, M. (2010). ## YOUNG SWIMMERS SHOULDER STRENGTH PROFILE: INTERNAL AND EXTERNAL ROTATION ISOKINETIC EVALUATION. A CONTRIBUTION TO NORMATIVE DATA

Batalha, N.1,2, Raimundo, A.1,2, Tomas-Carus, P.1,2, Marmeleira, J.1,2, Silva, A.J.2,3

1:UE (Évora, Portugal), 2:CIDESD (Portugal), 3:UTAD (Vila Real, Portugal)

**Introduction** The high incidence of overuse shoulder injuries in competitive swimmers is often attributed to both the high repetitive stresses inherent in the sport, as well as muscular imbalances in the humeral rotators (O'Donnell et al., 2005). The purpose of this study was to measure concentric glenohumeral joint internal and external rotation strength, to develop a bilateral descriptive profile in young competitive swimmers, contributing to the creation of normative data. **Methods** This was a cross-sectional study in which 60 male swimmers (age:  $14.55 \pm 0.5$  years old; body mass:  $61.16 \pm 7.08$  kg) were assessed. The peak torque of the external rotator (ER), internal rotators (IR) and the ER/IR ratio were evaluated with concentric actions. A seated position was used ( $90^\circ$  abduction and elbow flexion) at  $60^\circ$ .s<sup>-1</sup> and  $180^\circ$ .s<sup>-1</sup> angular speeds using an isokinetic dynamometer (Biodex System 3). Both dominant (DS) and non-dominant shoulder (NDS) were assessed. Descriptive statistics was performed for all variables using means and standard deviations. Calculations were performed using the SPSS software, version 19.0. **Results** The peak torque of IR ranged from  $34.81 \pm 9.33$ Nm to  $31.15 \pm 9.33$ Nm; the ER values were from  $26.39 \pm 5.66$ Nm to  $22.07 \pm 3.87$ Nm. Swimmers showed unilateral ratios of  $77.89 \pm 15.23\%$  in the DS and  $73.39 \pm 17.26\%$  in the NDS for assessments at  $60^\circ$ .s<sup>-1</sup>. At  $180^\circ$ .s<sup>-1</sup>, ratios were  $74.77 \pm 13.99\%$  for DS and  $70.11 \pm 14.57\%$  for NDS. **Discussion** Our results confirm that the IR ability to produce power is invariably superior to that of their antagonists. Regarding the shoulder rotators muscle balance, despite the fact that no normative data were available for young swimmers, some authors who evaluated older overhead athletes found values of ER/IR ratios between 66-75% (Ellenbecker & Roetert, 2003; Cingel et al., 2007). In our study, swimmers ER/IR ratios ranged from  $70.11 \pm 14.57\%$  to  $77.89 \pm 15.23\%$ , values that are close to, but slightly higher, than the normative values previously described. Since the unilateral ratios distinguish the quality of muscle balance (Ellenbecker & Roetert, 2003), these data can serve as a normative reference to shoulder rotators balance in young swimmers. **References** 1. ## STRATEGY BUILDING IN SOCCER

Cordes, O., Lames, M.

*University of Augsburg*

**Introduction/ Problem** One of the central tasks of sports teams' coaches is the generation of a suitable game strategy for the next competition. So far, the conception, the methodology and the effectiveness of this process have hardly been processed and documented by sport scientists. The aim of this work is to accompany and support the coaches at their usual strategy building and analysis and hence to generate a model of strategy building. **Methods** Before the season and over a period of one season (34 match days), the coaches of a team of the second division of the German Bundesliga were interviewed before and after every league game (by means of semi-structured interviews) so that their strategy building techniques could be reconstructed. Out of these interviews, an observation system was designed, which helps to analyze the tactics shown in the game in a systematic (Lames, 1994) and qualitative (Dreckmann et al, 2009) way. **Results** The first result was a model of strategy building which was generated according to concepts of applied economics. It shows the various sources of information and provides an overview of the steps of an idealized strategy building and analysis, including newly designed feedback loop. The empirical results of the study prove on the one hand the effectiveness of the developed game strategies, on the other hand, they show a strong bias of the coaches when it comes to the perception of the match performance, which is strongly influenced by the outcome of the match. Thus, the method and the results of the study (Cordes et al., 2012) offer the coaching staff the chance to optimize their work and their expertise. **Discussion** Methodologically, the combination of quantitative and qualitative methods has proven to be profitable when it comes to analyzing the development and the adherence to game strategies (Cordes, 2011). The study indicates that the strategic preparation could be more effective if carried out on the basis of conceptual rules and controlled by scientific methods (Cordes, unpub.).

## MAXIMAL EFFORT INTERVAL AND CONSTANT-RATE RUNNING USE SIMILAR AMOUNTS OF OXYGEN

O'Brien, B.J., Pratt, D.

*University of Ballarat*

**Introduction** The question of whether interval or constant-rate training has the greater potential to improve 5 km run performance remains unresolved. Interval running facilitates more oxygen consumption (VO<sub>2</sub>) than a constant-rate run when matched for average speed, and the physiological adaptations of interval training have been shown to be superior. However the constant rate efforts of these experiments have been sub-maximal and do not reflect athlete training practice. To address the question of which training strategy has the greater potential to enhance endurance performance, this study compared the VO<sub>2</sub> of a maximal effort interval run to a maximal effort constant-rate run at lactate threshold matched for time. **Methods** The VO<sub>2</sub> of 10 recreational runners (VO<sub>2</sub> max :  $4158 \pm 390$  mL.kg<sup>-1</sup>.min<sup>-1</sup>) were compared between three different 20 minute treadmill runs. The runners performed a maximal effort constant-rate run approximating lactate threshold (CRLT), a maximal effort interval run (INT) consisting of 2 min @ VO<sub>2</sub> speed with 2 minutes at 50% of VO<sub>2</sub> max repeated 5 times, and a run at the average speed sustained during the interval run (CR sub-max). Initial interval running speeds were determined from the treadmill speed corresponding to VO<sub>2</sub> max determined by an incremental test, and the lactate threshold speed from a 5 km time trial. To ensure a maximal effort, after successful completion of a 20 minute run – on another day participants would repeat the run 0.2 km.h<sup>-1</sup> faster. If the participant could sustain this speed and reported they could sustain a faster speed, treadmill velocity was raised a further 0.2 km.h<sup>-1</sup> in the next run to approximate a maximal effort. **Results** The average VO<sub>2</sub> for INT was  $3451$  mL.kg<sup>-1</sup>.min<sup>-1</sup> (3269-3633) - 83% VO<sub>2</sub> max; CRLT was  $3464$  mL.kg<sup>-1</sup>.min<sup>-1</sup> (3285-3643) - 84% VO<sub>2</sub> max and CR sub-max was  $3464$  mL.kg<sup>-1</sup>.min<sup>-1</sup> (3285-3643) - 76% VO<sub>2</sub> max. There was no significant difference in VO<sub>2</sub> between INT and CRLT, but the VO<sub>2</sub> was significantly greater in both treatments compared to CR sub-max ( $p < 0.05$ ). The distance covered was 4070 m (3831-4309), 4070 m (3831-4309), 4431 m (4202-3731) in INT, CR sub-max and CRLT respectively. Distance covered was significantly greater in CLRT ( $p < 0.05$ ) compared to INT and CL sub-max. Data are presented as mean and 95% confidence intervals. **Discussion** The novel finding of the present study is a 20 minute maximal effort constant rate run uses similar amounts of oxygen as a 20 minute maximal effort interval run, despite the greater distance covered in the maximal effort constant-rate run. An investigation comparing the impact of several training sessions

of maximal effort interval and constant-rate training would address which, or if any strategy is superior to improve a 5 km time trial.  
Introduction

### **GRIP STRENGTH-ENDURANCE IN AMBITIOUS AND RECREATIONAL CLIMBERS: DOES THE STRENGTH DECREMENT INDEX SERVE AS AN APPROPRIATE MEASURE?**

Donath, L.1, Faude, O.1, Zahner, L.1, Schöffl, V.2,3

*University of Basel*

Do not insert Introduction Hand-grip measures are serving as a simple low-cost method to assess fore-arm strength in the general population and in climbers as well. Since intermittent isometric handgrip exercises about 340 N lead to occluded fore-arm blood flow and average handgrip forces of >300 N for each hand were observed on a vertical wall (Quaine et al. 1999), it appeared interesting to examine the time course of maximal isometric grip strength in climbers, depending on testing position, laterality and climbing level. Therewith, we intended to provide a feasible maximal strength-endurance parameter. Methods Seventeen recreational (RC: climbing level (CL): 6.8±0.5 UIAA metric scale, 25±7 y; 70±9 kg; 21.5±2.0 kg/m<sup>2</sup>) and eleven ambitious (AC: climbing level: 8.7±0.6; 30±8 y; 72±8 kg; 21.8±1.9 kg/m<sup>2</sup>) climbers participated in the present study. All participants completed maximal isometric handgrip strength tests in four positions: Left and right hand beside the trunk as well as left and right hand above the shoulder. Each testing consisted of twelve repetitive work-relief cycles, applying a work-relief ratio of 5 and 1 second(s) (Donath et al. 2011) where isometric strength, heart rate and perceived exertion were recorded. Results A side x position x time x group interaction was found for the time series data of isometric grip strength ( $p = 0.009$ ,  $\eta^2=0.71$ ). Post hoc testing revealed significant differences between the left and right side for the ambitious (left: 55±8 kg vs. right: 62±9,  $p=0.01$ ) and recreation group (left: 47±8 vs. right: 51±9,  $p=0.04$ ). The upper grip position did not differ for the ambitious (left: 55±10 vs. right: 62±10) and the recreation group (left: 49±9 vs. right: 52±10). A group difference for heart rates was merely found for the bottom right position (AC, pre: 91±19 to post: 106±24; RC, pre: 91±21 to post: 124±32). Perceived exertion did not differ between both groups. Correlation analysis between asymmetry (left vs. right) and climbing level showed an inverse relationship for the lower position in ambitious climbers ( $r = -0.70$ ). Discussion The slope of grip strength decline did not relevantly differ between ambitious and recreational climbers. Thus, the time course of grip strength endurance seems to mainly depend on the amount of maximal isometric strength values. From a diagnostically point of view, it appears sufficient to evaluate maximal grip strength level in recreational and ambitious climbers. References Quaine et al. (1999). Gait Posture, 10:233-239. #### **STUDY OF STRESS MARKERS AND HEART RATE VARIABILITY IN BASKETBALL PLAYERS SUBJECTED TO THE IVE LOADS PERIODIZATION SYSTEM**

Souza, H., Mazon, J.E.

*University of Sao Paulo*

Introduction: To improve performance in sports, athletes are subjected to intense training loads. Accordingly, to enable athletes to achieve a maximal performance at a desired time, it is necessary to strictly control their training loads through structuring and planning in periods or stages, also known as periodization (Bompa, 1984). Furthermore, thorough knowledge of the organic adaptive processes triggered in athletes by training is important (Moreira, 2010). Therefore, we investigated the effects of the application of selective loads periodization (SLP) on physical stress markers and heart rate variability (HRV) in basketball players (N=16) before and after a competition period. Methods: The experimental protocol consisted of evaluating the autonomic modulation of HRV by a spectral analysis of the time series composed of R-R intervals (RRI) obtained in the supine position and during a tilt test. The evaluation of stress markers consisted of measuring plasma catecholamines, cortisol and free testosterone. Results: The results showed no significant changes in HRV, plasma concentrations of catecholamines and free testosterone when pre-competition and post-competition values were compared. However, reduced levels of plasma cortisol were observed. Discussion: Our results suggest that the organisation of training by SLP during the competition period produced beneficial adaptations in basketball players. This conclusion is supported by the absence of change in the autonomic modulation of HRV, plasma concentrations of catecholamines, free testosterone and the testosterone/cortisol ratio. In addition, the observed reduction of cortisol levels indicates an attenuated response of musculoskeletal catabolic processes between training sessions. References: Bompa T. Theory and methodology of training: the key to athletic performance. Boca Raton (FL): Kendall/Hunt, 1984. Moreira A. #### **CYCLING ENDURANCE PERFORMANCE IS DESCRIBED BY THE POWER-LAW NOT CRITICAL POWER**

Passfield, L., Coakley, S.L., Jobson, S.A.

*University of Kent*

Introduction The critical power (CP) model of Monod & Scherrer (1965) proposes an exercise intensity - time relationship that describes maximum work capacity. The determination of CP is typically restricted to intensities that result in exhaustion in >2-min and <15-min, as the model's validity has been questioned when determined from data outside of this range. An alternative explanation however, may be that CP is not the most appropriate model for describing the exercise intensity - time relationship, and that this becomes apparent when a wider range of intensities are examined. A simple alternative to CP is to describe performance with the ubiquitous power-law (i.e. as a fatigue curve). To test this hypothesis, we compared CP and the power-law model over a wider range of intensities than typically used to determine CP. Methods Our participants were fifteen active males (mean ± SD; age 28 ± 9yr, body mass 82.9 ± 9kg, maximum aerobic

power  $283 \pm 28W$ ,  $VO_{2max}$   $49.5 \pm 7$  ml/kg/min). Participants completed an initial maximal incremental test and two familiarisation trials to exhaustion. Then in a random order they completed nine cycle ergometer trials to exhaustion, each separated by at least 48-h. Five of these trials were within the typical range of intensities for CP determination (80%, 90%, 100%, and 110% maximum aerobic power output). Four trials were outside the typical range for CP determination (60%, 70%, 150%, 200% maximum aerobic power output). Data from the five trials within the typical range were used to generate two models (CP and power-law). The two models were then used to predict the actual performance in the four trials performed outside of the typical range for CP determination. A two way (model, power output) repeated measures ANOVA and estimated marginal means were used to compare the actual power output for the trials with those predicted by CP and power-law models. Significance was accepted at  $P < 0.05$ . Results There was no difference between models in their fit to data within the typical range of intensities used to determine CP (80%, 90%, 100% and 110%,  $P > 0.05$ ). Outside this typical range the power-law predicted actual performance better than CP at all intensities. Parameter estimates were similar for actual performance and the power-law model in trials at 60%, 70% and 150%. In contrast, the CP model was only similar to the actual performance in the 70% trial. Neither model predicted actual performance in the 200% trial. Conclusion This study demonstrates that the power-law, not critical power, predicts cycling endurance performance from 60% to 150% of maximum aerobic power output. ## ANTHROPOMETRIC DETERMINANTS AND PHYSICAL CONDITION IN RHYTHMIC GYMNASTS

Mendez Rial, B.1, Timmons, W.2, Verheul, M.2

1: University of Vigo (Vigo, Spain), 2: Institute for Sport, Physical Education and Health Sciences University of Edinburgh (Edinburgh, UK)

**Introduction** Anthropometric characteristics and physical condition are believed to be important predictors of the level of performance in elite rhythmic gymnasts (e.g., Avila-Carvalho et al., 2012). We aim to investigate to identify and determine the relationship between both. **Methods** We measured the anthropometric characteristics and physical condition of 12 competitive (national-level), female rhythmic gymnasts (aged 12.17 (+1.59) years). On average, the gymnasts had 6.04 (+3.60) years of training experience and trained 11.42 (+3.26) hours per week. We used standardised laboratory-based tests: Anthropometric and body composition determinants (height, body mass, body composition, Beighton 9-point joint laxity), flexibility (sit and reach, trunk hyperextension and passive and active high hip extension), static strength (Kendal, Wedge and Plank) and agility (hexagon test). Results The height of the gymnasts was 150.10 (+9.79) cm, the BMI was 16.95 (+1.59) kg/m<sup>2</sup> and body fat percentage was 13.75 % (+2.18). The mean level of joint laxity was 5.33 (+2.15), with 66.67% of the gymnasts scoring over 4 points on the Beighton scale. Sit and reach flexibility was 30.49 cm (+4.38) with both legs, 32.62 cm (+3.52) the left leg and 32.60 cm (+4.44) right leg. Maximal trunk extension was 162.70 degrees (+10.74) from the horizontal. The maximal hip extension ROM was 30.58 degrees (+6.71) for the left leg and 25.50 (+5.37) for the right leg, the difference between the passive and active ROM was 30.33 degrees, left leg (+14.84), and 25.75 degrees right leg (+12.57). The gymnasts maintained the required position for 27.62 seconds (+12.96) in the Plank test, 25.05 seconds (+12.12) in the Wedge test. In the Kendal test, the loss of control of the neutral pelvis occurred at 38.67 (+5.77) degrees from the vertical axis. Agility was measured as 12.28 (+1.65) seconds in the hexagon test clockwise and 12.50 (+2.19) seconds anticlockwise. **Discussion** In conclusion, the results are in accordance with the findings reported in previous studies (Avila-Carvalho et al., 2012; Douda et al., 2008; Rutkausakaita and Skarbalius, 2009). Further data analysis will provide correlations between, a) strength and flexibility indicators and anthropometric measures and b) balance and coordination. **References** Avila-Carvalho LA, Klentrou P, da Luz Palomero M, Lebre E. ## THE DEVELOPMENT OF ANTHROPOMETRIC AND PHYSIOLOGICAL CHARACTERISTICS IN RETAINED AND RELEASED ELITE YOUTH FOOTBALL PLAYERS AGED 8-19 YEARS

Saward, C.1, Sunderland, C.1, Goto, H.2, Morris, J.G.2, Nevill, M.E.2

1: Nottingham Trent University (Notts, UK), 2: Loughborough University (Leics, UK)

**Introduction** A major aim of the professional football Academy is to guide young players towards becoming senior professionals. Anthropometric and physiological characteristics may influence this process. Indeed, characteristics including height, mass, aerobic capacity, power, speed, and agility have differentiated between senior players of varying playing standards (Stølen et al., 2005). The aim of this study was to examine the development of anthropometric and physiological characteristics of retained and released elite youth footballers aged 8-19 years. **Methods** A fitness testing battery was used to assess the anthropometric and physiological characteristics of 350 elite youth footballers aged 8-19 years, belonging to a professional Academy. Players were repeatedly assessed, up to 22 times, across six football seasons from 2007-2013. The assessments conducted included three vertical jump tests (rocket jump; countermovement jump; countermovement jump with arm swing), a 30 m sprint test (splits at 5, 15m), a slalom agility test and the Yo-yo Intermittent Recovery Test 1. Height and mass were also assessed. At the end of the study players were categorised as retained or released by the Academy. Multilevel analysis was used to model the development of each anthropometric and physiological variable for released and retained players. Relevant parameters were systematically added to a null model and were accepted on the basis of significant improvements in model fit as indicated by the likelihood ratio test statistic ( $p < 0.05$ ). Results All anthropometric and physiological characteristics improved with age. Development of slalom agility was best described with a quadratic age term and all other variables with cubic age terms. There was random variance in the intercepts and slopes for all models. Compared to released players, retained players were significantly quicker on the 5, 15 and 30 m sprints and slalom agility tests. **Discussion** Anthropometric and physiological characteristics develop in a non-linear manner and there is variance in the timing, tempo, and magnitude of changes. This variability highlights the need for flexibility from coaches when considering anthropometric and physiological factors in the talent identification process (Philippaerts et al., 2006). Retained players had superior acceleration, speed and agility suggesting that assessing these physiological characteristics throughout adolescence can provide useful information in predicting progression through an Academy. **References** Philippaerts R, Vaeyens R, Janssens M, Van Renterghem B, et al (2006). *J Sports Sci*, 24, 221-230. ## STUDY OF CONTROLLING IMPACTS IN CHILDREN AND ADOLESCENTS ON HEMODIALYSIS

Thys, S., Potreck, H., Schaar, B.

*German Sport University Cologne*

**Introduction:** The incidence of end stage renal disease (ESRD) is in childhood and adolescence significantly lower than in adults. For hemodialysis adults there are validated activity guidelines according to American College of Sports Medicine with respect to intensity, frequency, duration and type of physical load. For children and adolescents with equal diseases, there are less specific informations. Especially in training sessions, that take place during dialysis, there are very limited findings. Aim of this pilot study is to review controlling impacts of a subjective measured aerobic endurance training in children and adolescents during hemodialysis. **Methods:** The study involved 5 children with ESRD. The trial is a single-group experiment with pre-/ posttest design. The intervention consisted of a 12-week subjective controlled training with two to three sessions per week. The training took place during dialysis on a spinning bike. The following parameters were recorded: heart rate (in beats/min.), blood pressure (in mmHg), subjective perceived exertion by Borg, duration (in min.). Also the pedaling frequency is set in a range between 60-70 revolutions/min.. Based on a cardiopulmonary exercise testing before dialysis (spirometry, protocol of Godfrey), the examination of exercise capacity was reviewed. **Results:** Subjective controlled aerobic endurance training is feasible and well tolerated. The consideration of the heart rates during the course of training phases indicates that two subject has trained during the main phase in the range of its individual ventilatory threshold (VT1). The other subjects were  $11,6 \pm 8,82$  beats/min. below the ventilatory. The analysis of the blood pressure shows a drop down of  $21,4 \pm 17,87$  mmHg in systolic blood pressure in the process of training in all subjects. The diastolic blood pressure declines by two subjects continuously with increasing duration ( $13 \pm 5,66$  mmHg). **Discussion:** In the present study, due to the low examination of exercise capacity in dialysis children, a subjectively controlled training was performed. Regarding to the individual assessment of the subjects can be seen, that various competitive levels are shown. Three volunteers trained below their ventilatory threshold. One possible reason for not reaching the ventilatory threshold could be the blood pressure development. Especially the systolic value falls in the course of training in all subjects. **References:** Berlin, J.A.&Colditz, G. A.(1990). *Am.J.Epidemiol.*, 132(4),612-628. ## THE PROFICIENCY OF SERVE AND RECEPTION OF ADOLESCENT MALE VOLLEYBALLERS' IN ESTONIAN CHAMPIONSHIPS IN 2005 AND 2008.

Stamm, M., Stamm, R.

*Tallinn University*

**Introduction** The study analyses volleyballers' performance at Estonian championships for U16 (boys up to 16 year-olds) in two tournaments – Tartu 2005 and Rakvere 2008. The participants were members of eight best teams of Estonia at the moment. **Methods** To record the games an original computer program Game was used, which was first introduced in the *International Journal of Volleyball Researches* (Stamm et.al 2000). For simultaneous recording of the performance of two opposing teams, two computers equipped with the program Game were used. Parallel recordings were made by volleyball experts. Twenty – eight indicators of proficiency in the game were registered, but in this study we focus only on the elements of serve and reception. All together 56 games were analyzed. **Results** From our data we can conclude that the quality of serve was improved. In 2005 there were 278 serves which earned a point at once (aces) (SD = 4,26) and 309 serves (SD = 4,18) in 2008. These data were statistically significant. When we look at the mistakes during the serve we can see that there were also less mistakes in 2008 Championship tournament. In 2005 – 308 mistakes and in 2008 – 246 mistakes where the opposite team got a point. The same thing appears when we look at the average of the proficiency index. It has been statistically significantly increased from 0,38 (SD = 0,10) to 0,45 (SD = 0,07). Now when we look at the reception values then we can see that the amount of mistakes during the reception is statistically significantly increased, in 2005 – 272 (SD = 3,65) and in 2008 – 292 (SD = 4,24). Also every player in each game has made reception mistakes in average 0,65 (SD = 0,58) in 2005 championship and in 2008 - 0,75 (SD = 0,62). But when we look at the index of proficiency we can see that it is still increased a little - 0,52 in 2005 and 0,54 in 2008, although the last date were not statistically significant. **Discussion** The quality of serve is playing more important role in the game from year to year. It is not any more simply the element to begin the ball rally in volleyball, but it has become a real attacking element. In concordance are increased the amount of mistakes during the reception, but the proficiency index of reception is still better in 2008 than in 2005. We can explain the phenomena so that the amount of mistakes was higher during the reception in 2008 than in 2005, but those balls which the players could catch, they played them more correctly and directly in 2008 than in 2005. **References** Stamm R.,Stamm M., Oja A. (2000). *Int. J Volleyball Res*, 2 (1), 18 – 22.

## COMPARISON OF ANTHROPOMETRIC PROFILES BETWEEN DIFFERENT SENIOR MALE VOLLEYBALL COMPETITION LEVELS: NATIONAL TEAM, FIRST AND SECOND PORTUGUESE DIVISIONS.

Carvalho, A.1,2,3, Mourão, P.1, Resende, R.1,2,3, Abade, E.3, Carvalho, C.1,2,3

*1:ISMAI (Maia, Portugal), 2: CIDAF (Maia, Portugal), 3: CIDESD (Portugal)*

**Introduction** Identifying and describing the players' anthropometric profiles may contribute to better understand the differences among different level athletes. In fact, the morphological characteristics are considered essential to achieve top level performances in volleyball (Malousaris et al., 2008). The aim of this study was to compare the anthropometric profile of elite male volleyball players of the national team, first and second portuguese divisions. **Methods** 73 players participated in the study and were divided into 3 groups: GA (n=17, national team), GB (n=28, first division) and GC (n=28, second division). The data collected included the weight, height, arm span, 7 skinfolds (triceps, biceps, subscapular, suprailiac, abdominal, thigh and calf), 4 body perimeters (relaxed brachial, contracted brachial, thigh and calf) and 2 body diameters (humerus and femur). **Results** Differences were found between groups with players from the GA presenting the highest weight ( $87.95 \pm 5.30$ kg,  $p < 0.05$ ) height ( $194.08 \pm 5.24$ cm,  $p < 0.05$ ), arm span ( $199.59 \pm 6.80$ cm) and lean mass values ( $77.88 \pm 5.17$ kg,  $p < 0.05$ ). The fat mass percentage of the GA players was the lowest ( $11.56 \pm 2.03$  %). **Discussion** The anthropometric profile of volleyball players may vary according to competitive levels. The results of the present study show that are differences in morphological profiles between playing levels. The highest values of weight, height, arm span and lean mass presented by the GA players show that this variables are important in top level competitions. Thus, coaches should consider these profiles in talent selection

programms to identify players with potential to achieve elite performances. References Malousaris, G. G., Bergeles, N. K., Barzouka, K. G., Bayios, I. A., Nassis, G. P., & Koskolou, M. D. (2008). Somatotype, size and body composition of competitive female volleyball players. *Journal of Science and Medicine in Sport*, 11(3), 337-344. doi: DOI.10.1016/j.jsams.2006.11.008

### VALIDITY OF LACTATE TURN POINTS OF TRAINED AND UNTRAINED SUBJECTS WHILE TREADMILL RUNNING

Wallner, D.1, Simi, H.1, Burgsteiner, H.1, Hofmann, P.2

1: FH JOANNEUM Univ. Appl. Sci. Syria, Austria; 2: Karl-Franz.-Univ. Graz, Austria

**Introduction:** According to the lactate shuttle theory (Brooks, 2002), two turn points (LTPs) and three distinct phases of lactate metabolism may be detected during incremental exercise tests (Hofmann & Tschakert, 2011) and from several constant load exercise bouts on cycle ergometer. The aim of this study was to validate LTPs detected during incremental running tests on a treadmill by means of constant load running (CE) slightly below and above the pre-determined LTPs in a heterogenous group of subjects. **Method:** 16 healthy male and female subjects (age: 38.9±17.6 yrs; BMI: 23.6±5.5 kg; VO<sub>2</sub>max: 46.3±9.1 ml/kg/min) performed a maximal incremental exercise (IE) test on a treadmill (start: 1.5 m/s (female), 2.0 m/s (male); increments: 0.2 m/s every minute). The first (LTP1) and the second (LTP2) lactate turn point were determined by means of linear regression break point analysis. CE tests (30 min) were performed at 5% Pmax below and above LTP1 and LTP2 in all subjects. Heart rate (HR) and gas exchange variables were determined continuously and blood lactate concentration (La) was determined at rest, at the end of every workload step (IE) and every 5 min after reaching target running speed (CE). **Results:** Power output in IE was 3.6±0.6 m/s at Pmax, 2.9±0.6 m/s LTP2 (77.8±3.5% of Pmax) and 2.4±0.4 m/s of LTP1 (60.7±5.4% of Pmax). Blood lactate concentration (La) was 8.21±1.61 mmol/l (Pmax), 3.33±0.83 mmol/l (LTP2) and 1.93±0.58 mmol/l (LTP1), respectively. Mean running speed of CE was 2.14±0.37 m/s (LTP1-), 2.49±0.40 m/s (LTP1+), 2.73±0.45 m/s (LTP2-) and 3.02±0.52 m/s (LTP2+) which were 55.8±4.6 %Pmax (LTP1-), 63.4±6.0 %Pmax (LTP1+), 73.9±3.0 %Pmax (LTP2-) and 81.0±3.2 %Pmax (LTP2+) and resulted in La of 1.24±0.71 mmol.l<sup>-1</sup>(LTP1-), 2.26±0.86 mmol.l<sup>-1</sup> (LTP1+), 4.86±1.90 mmol.l<sup>-1</sup> (LTP2-), and 7.29±2.19 mmol.l<sup>-1</sup> (LTP2+), respectively. Subjects completed all 30 min of CE up to LTP2- and stopped after 11.6±5.6 min at LTP2+. 13 of 16 subjects presented a lactate steady state at LTP2-. At LTP1- baseline La was given. **Conclusion:** In support of the lactate shuttle theory, two distinct turn points and three phases of lactate metabolism were detected and validated during both IE and CE in treadmill running. LTPs distinguished the lactate curve into different metabolic domains, were significantly related to the CE lactate response and define and discriminate the main metabolic trainings zones "low", "moderate" and "vigorous" for constant load exercise training in running. **References:** Brooks G.A. ### FATIGUE DURING INTERCHANGE-SPECIFIC SIMULATED RUGBY LEAGUE MATCH PLAY

Highton, J.1, Icke, R.1, MacNay, S.1, Waldron, M.2, Twist, C.1

1. University of Chester (Chester, UK). 2. University of New England (Armidale, Australia)

**Introduction:** Declines in work rate associated with neuromuscular fatigue have previously been observed during competitive rugby league match play (Duffield et al., 2011; Waldron et al., 2012). The nature of this change in distance covered and high-intensity running is dependent on the nature of the playing bout performed. Whole-match (~ 80 min) players demonstrate a subtle and steady decline in work rate, whereas interchanged players (approximately 21 min) exhibit a rapid decline in the first exercise bout, followed by a lower-intensity u-shaped profile in their second bout (Waldron et al., 2012). The aim of this study was to determine the extent of changes in player work rate, physiological and perceptual markers of fatigue and muscle function during a simulated interchange-specific rugby league movement protocol (RLMSP-i). **Methods:** Twenty-two elite level academy players from two different clubs in the English Super League (age = 19.8 ± 0.6 years; body mass = 89 ± 6.7 kg; stature = 179.9 ± 3 cm) completed the RLMSP-i involving 2 x 23 min bouts of exercise interspersed with 20 min passive recovery. During the protocol participants wore a 5 Hz GPS device to determine distance covered (m/min), high-intensity distance covered (> 14 km/h; m/min), average speed (m/s), peak speed (m/s), sprint speed (m/s) and heart rate (b/min). Blood lactate, glucose, vertical jump height and isometric handgrip force were also measured throughout the protocol in a subset of the sample (n = 8; age = 18.9 ± 1.4 years; body mass = 92.2 ± 8.9; stature = 182.8 ± 4.2 cm). **Results:** Distance covered (m/min) declined from quartile 1 to 4 in bout 1 (106 ± 2.9 to 104.3 ± 104.3) and bout 2 (104.1 ± 3.5 to 102.7 ± 3.6). High intensity running was lower in bout 2 (23 ± 3.2 m/min) than bout 1 (25.3 ± 3 m/min), and declined across quartiles of play (26.1 ± 2.7 to 22.2 ± 3.4 m/min), as did peak sprint speed (22.6 ± 1.4 to 20.6 ± 1.6 km/h). Heart rate, countermovement jump height, blood lactate and glucose concentration did not change over the course of the protocol. **Discussion:** The RLMSP-i elicits changes in distance covered in high-intensity running which are similar to, albeit less marked than, those reported during competitive rugby league match play. Thus, the RLMSP-i offers a potentially useful method to assess fatigue in interchanged rugby league players. The causes of this decline are unclear, as muscle function and physiological markers of fatigue remained unchanged throughout the protocol. **References:** Duffield R, Murphy A, Snape A, Minett GM, Skein M. (2011). *J Sci Med Sport*, 15(3), 238-43. Waldron M, Highton J, Twist C. (2012). *Int J Sports Physiol Perform*, Epub ahead of print.

### BASKETBALL: LONG LIVE TIME DURATION REQUIRE HIGHER LOADS ON HEART RATE, BUT THEY ARE LESS FREQUENTLY

Daniel, J.1,3, Bonganha, V.1, Mercadante, L.A.2, Cavaglieri, C.R.1, Montagner, P.C.1, Borin, J.P.1

UNICAMP Campinas, UNICAMP Limeira, PUC-Campinas

**Introduction:** Basketball is an intermittent modality, consisting of actions in moments of live time (LT) in different intensities and durations (d), separated by moments of stoppage time (ST), of different d. Some authors analyzed several aspects related to the actions and demands imposed but not analyzed the d of LT and ST moments and their physiological responses. The aims of this study were to analyze the d and frequency (f) of LT and ST, as well as the %HR in their moments. **Methods:** Ten Brazilians elite basketball players (27.6±5.54years; 91.61±11.51kg; 1.93±0.08m) were observed in one basketball game of the National Basketball Championship. LT refers the time during which the game clock was running and the ball was in play. ST refers the time during which the game clock was stopped. The f and d of LT and ST moments were obtained by video analysis. The maximum HR was obtained by the Maximal Multistage 20m Shuttle Run Test. The HR values during the test and the match were obtained by a HR monitor. At the same instant was activated a digital timer, to later synchronize the data of the monitors with the LT and ST. The data were kept in computational bank and produced information in descriptive way. **Results:** The f of the moments were: LT ≤10s = 14, >10s ≤20s = 10, >20s ≤30s = 4, >30s ≤40s = 8, >40s ≤50s = 6, >50s ≤60s = 3, >60s ≤70s = 5, >70s ≤80s = 6 and from that 1 or 2; ST ≤10s = 12, >10s ≤20s = 17, >20s ≤30s = 6, >30s ≤40s = 4, >40s ≤50s = 7, >50s ≤60s = 4 and from that 1 or 2. The %HR were: LT ≤30s e 110s between 80-84.9%HR, 40-60s and 80s between 85-

89.9%HR, 70s, 90s, 100s, 140s and 210s between 90-94.9%HR; ST  $\leq$ 40s between 85-89.9%HR, 50-80s and 120s between 80-84.9%HR, 100s between 75-79.9%HR and 90s, 110s and 180s  $<$ 75%HR. The ST  $\geq$ 90s were due to time-outs, combined with more free throw. Discussion The higher f ( $\geq$ 10) of LT and ST occurred in up to 20s, but can still be considered for LT to 80s and 60s up to ST. The longer d of LT, the higher %HR and most times above 30s showed average between 85-94.9%HR. McInnes et al (1995) found an average of 89.2%HRpeak for LT in the whole game. The longer d of ST, the lower %HR and over 40s are needed for reductions below 85%HR. As found by McInnes et al (1995), the greatest reductions were HR during time-outs (70-75% and 60%HRpeak). This information is very important for the organization of the training in relation to the choice of d of exercise game without interruption and pause duration for recovery, with respective f. ## SPRINT PERFORMANCE OF FEMALE SOCCER PLAYERS OF THE GERMAN FIRST AND THIRD LEAGUES

Araújo, M.C.1, Baumgart, C.1, Freiwald, J.1

1: *Research Center for Performance Diagnostics and Training Advice - FLT (University of Wuppertal, Germany)*

Introduction Evaluation of sprint performance is a common test in soccer. While there are many data in reference to male players, information about female players is still limited [1]. So, the aim of this study was to compare linear sprint performance of female players of the first (elite) and third (sub-elite) leagues in Germany. Methods Twenty-four elite (Women-Bundesliga, n = 12, 22.3  $\pm$  4.8 years, 61.7  $\pm$  8.1 kg, 168.1  $\pm$  0.1 cm) and sub-elite (Women-Regional-Liga West n = 12, 17.7  $\pm$  2.6 years, 60.0  $\pm$  5.3 kg, 163.2  $\pm$  0.1 cm) outfield female players performed a 20 m linear sprint test including 5 m and 10 m split-times. Sprint times were measured with double light barriers (TDS 2002, Austria). Players accomplished three trials interspersed with a 3 min rest and the mean of the two fastest were used for analysis. Differences between groups were determined through Student t-Test for independent samples. Statistical significance was set at p  $\leq$  0.05. Results Elite female players of the German first league are older (p = 0.007) and run at least 7% faster (p < 0.001) over all sprint distances (20 m: 3.46  $\pm$  0.09; 10 m: 2.02  $\pm$  0.06; 5 m: 1.20  $\pm$  0.04 s) than sub-elite players of the German third league (20 m: 3.71  $\pm$  0.11; 10 m: 2.18  $\pm$  0.07; 5 m: 1.31  $\pm$  0.05 s). Discussion Linear sprint performance has been reported as able to differentiate female soccer players of different levels in Australian and Sweden [2,3] as well as sprint speed to distinguish between drafted and non-drafted high-level players in an American professional selection process [4]. Similar results could be found in the present study with female players of the German first and third leagues. However, the influence of age in the sprint performance must be further investigated. Even better results have been already observed for players of the Germany Women's National Squad (1.05 s over 5 m) [5]. Linear sprint test over 5 m, 10 m and 20 m seems to be a good parameter to differentiate competitive level in women's soccer. References [1] Vescovi JD, Rupf R, Brown TD, Marques MC. (2011). ## COMPARISON OF ANTHROPOMETRIC PROFILES BETWEEN DIFFERENT SENIOR MALE BASKETBALL COMPETITION LEVELS: FIRST, SECOND AND THIRD PORTUGUESE DIVISIONS

Carvalho, C.1,2,3, Mourão, P.1, Sá, P.1,2,3, Abade, E.3, Carvalho, A.1,2,3

1: *ISMAI (Maia, Portugal)*, 2: *CIDAF (Maia, Portugal)*, 3: *CIDESD (Portugal)*

Introduction Elite basketball requires for optimal morphological characteristics and a high level of physical, technical and tactical capacities. Previous investigations have been focused on the ideal anthropometric profiles of elite players, however there is a lack of data concerning to the European players (Ostojic, Mazic, & Dikic, 2006). This study aimed to compare the body composition and somatotype characteristics of elite basketball senior players participating in the Portuguese first, second and third division. Methods 89 male senior players participated were divided into 3 groups: GA (n=29, first division), GB (n=31, second division) and GC (n=29, third division). The data collected included the weight, height, arm span, 7 skinfolds (triceps, biceps, subscapular, suprailiac, abdominal, thigh and calf), 4 body perimeters (relaxed brachial, contracted brachial, thigh and calf) and 2 body diameters (humerus and femur). Results Differences were found between groups with players from the first division presenting the highest weight (97.64  $\pm$  12.55kg, p < 0.05) height (195.59  $\pm$  7.93m, p < 0.05), arm span (198.83  $\pm$  10.64cm) and lean mass values (79.37  $\pm$  8.67kg, p < 0.05). The fat mass percentage of the first division group was the lowest (18.44  $\pm$  3.46%). Discussion The anthropometric profile of basketball players may be heterogeneous and vary according to competitive levels. The results of the present study show that are differences in physical profiles between playing levels. Apparently, elite players present the highest values in weight, height, arm span and lean mass. These variables may be considered as important for success in top-level basketball. Our results are in accordance with this idea, since the first division players' physical profiles presented the highest values in such variables. The unique demands of each division require for specific training and recruiting processes. Coaches should be aware of these differences to design accurate training programs and maximize the players' fitness level. References Ostojic, S. M., Mazic, S., & Dikic, N. (2006). Profiling in basketball: Physical and physiological characteristics of elite players. *Journal of Strength and Conditioning Research*, 20(4), 740-744. doi: Doi 10.1519/00124278-200611000-00003

**NO DIFFERENCES BETWEEN 24H, 3H AND 30MIN RECOVERY IN THE ESTIMATIONS OF CRITICAL POWER AND W' IN CYCLING**

Karsten, B., Jobson, S.A., Hopker, J.G., Petigna, L., Beedie, C.

*University of Greenwich*

Introduction Measurements of Critical Power (CP) and W', total work that can be performed above CP, requires a set number of time-to-exhaustion (TTE) trials. Recovery periods of 24h between trials are common, making this protocol impractical. The aim of this study was to compare estimates of CP and W' derived from protocols using 24h, 3h and 30min recovery times. Methods Six male cyclists (mean  $\pm$  SD: age  $33 \pm 9.4$  yr, body mass  $73.45 \pm 6.28$  kg, Maximal Aerobic Power (MAP)  $350 \pm 40$  W,  $VO_{2max}$   $49.97 \pm 3.51$  ml  $\cdot$  kg  $\cdot$  min $^{-1}$ ) completed three testing methods for the estimation of CP and W'. Method 1 required tests separated by a recovery of 24h (CP24, W'24), method 2 by 3h (CP3, W'3) and method 3 by 30 min (CP30, W'30). Cyclists were blinded to all performance feedback. The 3h and 30min testing method were performed in the order from lower to higher TTE intensities, whilst the 24h testing was performed in a randomised order. Lactate was sampled at rest before each trial and immediately after exhaustion. CP and W' were estimated using the work-time model ( $IP = W' + (CP \cdot t)$ ). Results Repeated measure ANOVA identified no significant differences between CP and W' estimates derived through the three protocols (CP: F (1.8, 9.2) = 1.40, p = 0.29; W': F (1.5, 7.5) = 3.67, p = 0.09). Mean Standard Error (SE) values for CP24 were  $3 \pm 2.96$  W, for CP3 they were  $4 \pm 1$  W and for CP30 they were  $1 \pm 0.93$  W. Table 1: Mean Difference (W), 95% Confidence Intervals and Limits of Agreement between CP estimates. CP24 vs. CP3 CP24 vs. CP30 CP3 vs. CP30 Mean Diff. (W)  $4.79 \pm 6.87$   $0.78 \pm 8.21$   $-4.01 \pm 6.34$  95% CI -3.53 - 32.53 8.88 - 34.29 -10.58 - 21.04 LoA (W) -10.21 to 18.54 - 16.87 to 17.54 -16.44 to 8.8 Table 2: Mean Difference (W), 95% Confidence Intervals and Limits of Agreement between estimates of W'. W'24 vs. W'3 W'24 vs. W'30 W'3 vs. W'30 Mean Diff. (kJ)  $-0.80 \pm 3.94$   $3.45 \pm 5.00$   $4.25 \pm 2.97$  95% CI -4.9 - 14.49 -1.83 - 22.86 1.13 - 15.59 LoA (kJ) -8.5 to 6.96 -6.4 - 13.28 -1.55 to 9.98 Discussion Results suggest that recovery periods as low as 30min between trials provides a valid estimate of CP and W' in cycling. Despite our subjects starting trials following 3h and 30min recovery with elevated lactate, no impact on performance was observed. Results support those of Jenkins and Quigley (1992), and Housh et al. (1990) who utilised 3 h recovery periods, and Nebelsick-Gullett et al. (1988) who used a 30 min protocol. References Housh D, Housh T, Bauge S. (1990). Res Q Exerc Sport. 61(4), 406-409. Jenkins D. (1992). Endurance training enhances critical power. **EFFECTS OF COORDINATION EXERCISES ON MOTION CAPACITY OF PRESCHOOL CHILDREN—QUANTITATIVE AND QUALITATIVE CHANGES IN THROWING AND CATCHING ABILITY—**

Umezaki, S.1, Nakatani, T.1, Yamamoto, D.1, Hashimoto, M.2, Nakasuga, T.3

1: *Tenri University (Nara, Japan)*, 2: *Osaka Kyoiku University (Osaka, Japan)*, 3: *Kyushu University (Fukuoka, Japan)*

Introduction The purpose of this study was to investigate the effects of a coordination exercise program focused on basic ball handling techniques on quantitative and qualitative changes of throwing and catching abilities among preschool children. Methods The subjects were 30 preschool children (14 boys, 16 girls), each five years of age. A four week control period and a four week exercise period were separately established. According to the instruction guidelines, the exercise program was conducted for 40 min for a total of eight sessions over a four week period. The subjects performed motion capacity tests (standing broad jump and side jump) and ball handling tests (control, catching and tennis ball handling) during each exercise session. Their throwing and catching motions were video recorded and then evaluated using five typical developmental stages of motion patterns (Nakamura et al., 2011). Results The mean scores showed a statistically significant increase in the side jump, catching, tennis ball handling and score evaluation for throwing and catching motions in the exercise period compared to the control period. There were no gender related differences in scores. Discussion Recently, Nakamura et al. (2011) reported that the developmental stage of the fundamental motions of preschool children in 2007 was significantly lower than preschool children in 1985. In our research, the evaluation scores for throwing and catching motions in the exercise period were consistent with the 1985 scores; however, the control period scores were approximate to the 2007 scores. Our results suggest that the coordination exercise program focused on basic ball handling technique enhances the ball handling capacity and agility among five-year-old preschool boys and girls, who require adequate exercise instruction to improve their throwing and catching abilities. **PHYSIOLOGICAL PREPARATIONS OF A SEMI-ELITE VETERAN KAYAK PADDLER – A CASE STUDY.**

Sheldrick, R.1, Hardman, S.1, Ingham, S.2

1: *English Institute of Sport (Bisham, UK)*, 2: *English Institute of Sport (Loughborough, UK)*

Introduction This case-study outlines the training approach of a sub-elite veteran athlete in preparation for an individual (K1) 125 mile kayak marathon over 4 days of racing that included 77 portages. The athlete's personal aim was to complete the race in <20 h. Typical novice and world class race times are <24 h and <18 h respectively. Methods The subject was a female ex-Olympic cross-country skier (51 yrs; 1.70 m;  $64.8 \pm 1.7$  kg; sum of 8  $54.3 \pm 4.3$  mm) with a consistent 33 yrs aerobic training history. The subject's training history was a high volume, low intensity (HVLI) approach before the programme. A linear training periodisation was used focusing on 1-2 performance variables per training phase. Training phases were 1) 8 wks pre-season: high intensity interval training (HIIT), 2) 12 wks aerobic endurance: HVLI, 3) 6 wks portaging (P), 4) 6 wks on-water race pacing (OWP), 5) 1 wk taper (TP). Training duration (h.week $^{-1}$ ) was HIIT  $10.8 \pm 2.1$ ; HVLI  $13.3 \pm 1.6$ ; P  $10.2 \pm 0.6$ ; OWP  $11.2 \pm 0.8$ ; and TP 2.8. Weekly training intensity < lactate threshold (LT), LT to anaerobic threshold (AT) and >AT was HIIT 65%, 17%, 18%; HVLI 70%, 25%, 5%; P 56%, 34%, 10%; OWP 60%, 31%, 9%; and TP 35%, 47%, 18%, respectively. Training responses in HIIT and HVLI were assessed using laboratory ramp tests to max using a cycle ergometer to determine  $VO_2$  (CV: 4.0%) and

LT. Time per repetition for a standardised on-water session (4 x 10 min) was monitored in P. Results VO<sub>2</sub>MAX increased from 43.7 to 49.3 mL.kg<sup>-1</sup>.min (+12.8%) after HIIT and to 52.6 mL.kg<sup>-1</sup>.min (+6.7%) after HVLI. LT increased by 25 W (+20%) after HVLI. Time per repetition of monitored on-water session decreased by 12 s (-2%) after P. Calculations of smallest worthwhile change showed this decrease to be meaningful. Total race time was 20:43:30 (hh:mm:ss), setting a new >50 female course record and winning the senior single ladies, >50 female and veteran female classes. Average river flow rate was +34.3 m<sup>3</sup>.s<sup>-1</sup>, 11.6% slower than when the former >50 female course record was set. Discussion Improvements in VO<sub>2</sub>MAX after HIIT and HVLI training supports previous research suggesting both training methods improve aerobic capacity (Laursen, 2010). The results also demonstrate a veteran athlete's ability to adapt to endurance training, contradicting the view that veteran athletes only attenuate the age-related decline in performance with training (Maharam et al., 1999). Improvements in VO<sub>2</sub>MAX and LT were reflected in on-water improvements. This case study highlights the trainability of a sub-elite veteran athlete using a linear training periodisation. ### SPEED TESTING DURING SPECIFIC ATTACKS IN FENCING

Weichenberger, M.1, Liu, Y.1, Steegmüller, W.2, Steinacker, J.M.1

1: University of Ulm, Ulm, Germany; 2: German Fencing Federation (DFB), Bonn, Germany

Introduction Fencing bouts are characterized by various attacks with the aim of hitting the opponent with the weapon. The speed during fencing attacks is considered to be important for competition success, but there is a lack of data on speed testing in fencing because no suitable methods have been established. The aim of the study was therefore to develop a method for speed testing in fencing and to determine speed at specific fencing attacks. Methods 8 male epee fencers of the German Olympic Team (27.5 ± 4.7 yrs, 90.8 ± 10.7 kg, 189.6 ± 4.9 cm) took part in the study. The measurements were focused on speed of the weapon hand during the fencing attacks touch (TOU), lunge (LUN), step forward lunge (SFL) and fleche (FLE). An optical motion capture system (2000 Hz, Lukotronic, Austria) with 16 active infrared markers was used to determine speed. A fencing dummy with target areas was developed and integrated into the system for detecting reaction time (RTIME) of fencers. The study participants performed 5 trials for every fencing attack. During attacks, distance of the tip of the epee to target (DIST), mean speed (MEANSPD), maximum speed (MAXSPD), speed in the moment of hit (HITSPD) and time to reach maximum speed (TMAXSPD) were measured. Parameters of attacks were compared by one-way analysis of variance (ANOVA). Results MEANSPD at SFL (3.21 ± 0.49 m/s) was higher compared to FLE (2.62 ± 0.60 m/s, p < .01), LUN (2.13 ± 0.30 m/s, p < .01) and TOU (1.76 ± 0.57 m/s, p < .01). MAXSPD at SFL (4.05 ± 0.92 m/s) was higher than during LUN (3.44 ± 0.62 m/s, p < .01) and TOU (2.60 ± 0.55 m/s, p < .01), but no significant differences between SFL and FLE (3.85 ± 0.66 m/s) were found. HITSPD at SFL (2.75 ± 0.75 m/s) was higher than during LUN (2.34 ± 0.46 m/s, p < .05) and TOU (1.69 ± 0.66 m/s, p < .01). Differences in HITSPD between SFL and FLE (2.54 ± 0.57 m/s) and LUN and FLE were not significant. DIST at SFL (1.55 ± 0.16 m) was greater than at LUN (0.99 ± 0.11 m), FLE (1.00 ± 0.21 m) and TOU (0.25 ± 0.09 m). TMAXSPD for FLE (0.36 ± 0.11 s) was better than for LUN (0.44 ± 0.12 s, p < .01) and SFL (0.96 ± 0.11 s, p < .01). No significant differences were found for RTIME at TOU (0.20 ± 0.03 s), LUN (0.19 ± 0.04 s), SFL (0.20 ± 0.05 s) and FLE (0.20 ± 0.05 s). Discussion The developed method and the described speed parameters are suitable to analyze reaction time and movement speed during fencing attacks. We report here data derived from a newly developed, complex motion analysis method and found significant differences between speed parameters of different fencing attacks. The motion analysis method will be further evaluated and developed to provide a tool for performance testing in fencing.

### ELITE FEMALE SOCCER PLAYER'S BODY COMPOSITION AND POSTURAL STABILITY

Vaidova, E., Zahalka, F., Maly, T., Gryc, T.

Charles University in Prague, Faculty of Physical Education and Sport

Introduction The sport training should lead to symmetric development of the body. However player's lower limbs are unequally loaded during soccer trainings and matches. It may cause asymmetric development of the muscular apparatus or difference in balance of lower limbs. Therefore, the aim of this study was to evaluate bilateral symmetry in fluid distribution of lower limbs and postural stability in elite female soccer players. Methods Twenty elite female soccer players of Czech representation (n = 20; aged 23.3 ± 4.3 years; height 167.2 ± 6.4 cm; weight 60.9 ± 5.3kg) participated in the study. Body composition was measured by multifrequency bioelectrical impedance analyzer InBody 3.0 with segmental distribution of body fluids in lower limbs. Postural stability was measured by pressure measurement system FootScan (RScan, Belgium) by one lower limb stand test (Flamingo). The test lasted for 60 s. Evaluation was based on movement of Centre of pressure (COP) and evaluated parameters were front-back deviation (Y), right-left (X) deviation and Total Travel Way (TTW). Results The average values of movements of COP in right-left direction in stance on right and left lower limb Xavg = 18.6 ± 6.6 mm, resp. Yavg = 17.8 ± 3.3 mm. The average values of front-back direction in stance on right and left lower limb Yavg = 32.5 ± 14.2, resp. Xavg = 30.2 ± 7.7 mm. The average values of Total Travel Way parameter in stance on right and left lower limb TTWavg = 831.9 ± 319.8 mm, resp. TTWavg = 888.9 ± 451.3 mm. The average value of fluid distribution symmetry between right and left lower limb 0.0655 ± 0.0049 liter. Analysis of correlation between morphological dysbalances and differences in stability didn't demonstrate significant correlation r = 0.01; p > 0.05. Conversely, the relation appears to be orthogonal. Mean value of fluid distribution in the right, resp. left lower extremity was 5.98 ± 0.61 l, resp. 6.03 ± 0.62 l (p < 0.01). This difference was significant. Difference during comparison of means stability in test called flamingo – right lower extremity (889.0 ± 463 mm) and left extremity (831.9 ± 328 mm) wasn't significant (p > 0.01). Discussion Based on measured values was research sample homogenous in both postural stability and fluid distribution between lower limbs. Significant correlation between morphological dysbalances and differences in stability wasn't found. However difference in fluid distribution between lower limbs was significant. One of the main requirements for soccer players is ability to perform specific movement activities in appropriate manner by both lower limbs. ### FORCE AND TESTOSTERONE RESPONSES AND RECOVERY TO A SINGLE SESSION OF COMBINED ENDURANCE AND STRENGTH LOADINGS BEFORE AND AFTER TRAINING: "ORDER EFFECT"

Schumann, M.1, Kraemer, W.J.2, Walker, S.1, Izquierdo, M.3, Häkkinen, K.1

University of Jyväskylä1, University of Connecticut2, Public University of Navarra3

INTRODUCTION Endurance (E) loading performed immediately before strength (S) loading may compromise the gains in maximal S (e.g. Cadore et al. 2012) when compared to the opposite training order (E+S vs. S+E). While this is attributed to neuromuscular fatigue pro-

duced by the E loading, differences in recovery between E+S and S+E have not been studied. This study investigated acute responses and recovery in maximal S and serum testosterone (T) to a combined loading of E+S vs. S+E before and after combined training as well as 1RM strength development. METHODS 29 untrained men (30±5 years, 179±6 cm, 77±9 kg) were matched to an E+S (n=12) or S+E (n=17) group and conducted E and S training combined in a single session (2-3x [1E+1S or 1S+1E]/wk) for 24 wks. Before (0) and after the training (24) subjects performed a 1RM test in leg press and one standardized E+S or S+E loading. This loading consisted of explosive, hypertrophic and maximal leg press exercises (S) conducted either before or after an E loading of 30min cycling. Maximal isometric leg press (MVC) and serum T were measured before (PRE) and after the loading (POST) and after 24h and 48h. RESULTS At 0 MVC decreased in both loadings at POST (E+S, 24%, p<0.001; S+E, 22%, p<0.001), while no responses in T were observed. At 24h and 48h of recovery T decreased in E+S (24h, 23%, p<0.01; 48h, 21%, p<0.001) but not in S+E (between group difference p<0.05), while MVC returned to PRE values in both groups. At 24 MVC decreased at POST (E+S, 25%, p<0.001; S+E, 27%, p<0.001) but no significant responses in T were observed. At 24h and 48h MVC returned to PRE values in E+S and S+E, while T was only slightly lowered in E+S and not significantly different from S+E. Both groups increased 1RM at 24 (E+S, 13%, p<0.001; S+E, 17%, p<0.001). DISCUSSION This study did not show differences in acute loading responses in MVC and T between the E+S and S+E loadings either before or after the training. Although the recovery in MVC was mainly completed after 24h both before and after the training, at 0 T was reduced in E+S at 24h and 48h of recovery showing an order effect (E+S vs. S+E). After 24 weeks of training, however, this decrease of T in E+S became smaller and the difference between E+S and S+E was reduced. Whether this reduced between group difference may be associated with 1RM strength gains during higher frequency and/or longer periods of training needs further investigation together with thorough examination of training-induced neuromuscular adaptations. ### CENTRALLY ACTING PERFORMANCE MODIFIERS IN OPEN-ENDED VERSUS CLOSED-ENDED EXERCISE TESTS

Oomen, J., Gosens, W.

*Fontys Sporthogeschool*

Introduction Exercise performance is regulated by a series of complex mechanisms to insure that humans always exercise with reserve and terminate the exercise bout before there is a catastrophic failure of homeostasis<sup>1</sup>. Testing methodologies have traditionally included open-ended submaximal cycle performance tests at a fixed percentage (constant work rate test) maximal power output (W<sub>max</sub>). The reproducibility of these Time to Exhaustion (TTE) protocols show poor reproducibility compared with closed-ended test protocols such as the time trial (TT)<sup>2</sup>. The poor reproducibility of TTE protocols has been attributed to the fact that TTE protocols do not have a clearly defined ending point and psychological factors (i.e. motivation, monotony, and boredom), that might influence performance are more pronounced in these tests than in closed-ended test in which the ending point of the test is known<sup>2</sup>. Therefore, the purpose of the study was to evaluate the contribution of centrally acting performance modifiers to exercise performance in open-ended and closed-ended test protocols Methods Subjects performed an incremental exercise test to determine their maximal workload (W<sub>max</sub>). In the first exercise test subjects had to perform a TT on an electromagnetically braked ergometer (Lode Excalibur Sport) in linear mode (RPM dependent) at approximately 70%W<sub>max</sub> for 30 min. During this test subjects only received feedback about the progress of their performance in kJ and received no time cue. In the second test, subjects were asked to cycle to exhaustion during a constant work rate (CWR) test at the mean workload of the TT test. In the CWR test (initially without time cue), the cycle ergometer was set in the hyperbolic mode (RPM independent). If exercise endurance time of the CWR test was shorter than in the TT test, subjects received a time cue and got informed about their TT time to completion performance. Heart rate was monitored during both tests. Results Preliminary results. One male subject performed all tests. The time trial time to completion was 31 minutes and 33 second at a mean workload of 287 W (66% W<sub>max</sub>). In the CWR test the subject cycled to exhaustion in 17 minutes at 287W. Subject was not able to extend the performance after showing the TT time to completion. Heart rate showed the same pattern although TRIMP score was lower in the second test (71 vs 116). Discussion One subject is not enough to draw firm conclusions, but it's very interesting that the second test was about 14 minutes shorter (with the same physiological response in heart rate). Centrally acting performance modifiers do influence exercise performance, especially in open-ended exercise test protocols. 1. Noakes, T. The Central Governor Model in 2012: eight new papers deepen our understanding of the regulation of human exercise performance. *British journal of sports medicine* (2012). 2. ### CORRELATION BETWEEN HANDGRIP STRENGTH AND PERFORMANCE IN NON-PROFESSIONAL BOXERS

Invernizzi, P., Scurati, R., Longo, S., Michielon, G.

*Università degli studi di Milano*

Introduction Handgrip is a popular test used to predict performance in different sports (Garrido et al., 2012), like boxing. In fact, it has been shown that among the main determinants of boxing performance in elite middleweight boxers, handgrip strength is well correlated with ranking in boxing competition (Guidetti et al., 2002). Based on this study, we sought to investigate whether other parameters, such as maximal strength of non-dominant hand and endurance strength could be also related to boxing performance, measured as percentage of total victories (%TV) and knock-out victories (%KO). Methods Twelve non-professional boxers (age 27±4 years, height 173.2±8.9 cm, body mass 68.3±6.6 kg, years of practice 7±4) were recruited for this study. After submaximal contractions as warm-up, each participant performed 3 maximal isometric voluntary contraction of both dominant (dMIVC) and non-dominant (ndMIVC) hands on a hydraulic handgrip dynamometer. Each contraction was sustained for 5 s and separated by 5 min rest. Subsequently, 3 trials of dMIVC and ndMIVC were performed until exhaustion. Time to reach 50% of MIVC (dT50 and ndT50) was measured to assess endurance strength. 15 min rest was given between trials. In both tests the best performance of the 3 trials was considered. Differences between dominant and non-dominant hands were evaluated as well as correlations between MIVCs and T50s with %TV and %KO. RESULTS There was a significant 9% difference between dMIVC and ndMIVC (58.1±10.1 vs 52.9±4.5 kg, respectively, p<0.01). dMIVC was significantly correlated with %TV and %KO (r=0.58 and 0.61, respectively, p<0.05). No differences between dT50 and ndT50 nor other correlations were found (p>0.05). Discussion In accordance with the literature, handgrip strength was significantly related with boxing performance (Guidetti et al., 2002). Additionally, we showed that the correlation concerned the dominant hand which was stronger than the non-dominant one, and it was related to %TV and %KO in our sample of. In conclusion, dominant handgrip strength could be used as an acceptable parameter to predict non-professional boxers level of preparation. References 1. **KIMARTOP: NEW TECHNOLOGY TO OPTIMIZE THE TRAINING OF THE "BASE" IN ACROBATICS.**

León, K., Bortoleto, M.

*Universidad de Extremadura*

**Introduction** The acrobatics disciplines, has experienced a significant growth in Sports as well in Arts. Particularly in group acrobatics practices we highlight the role of the Base, responsible to support/raise/throw, and the Top responsible to balance, figures or aerial acrobatics (BROZAS; NOWOTYNSKI, 2002). These protagonists assume different roles in acrobatics, performing part of their training in group and also individually, trying to develop specific abilities and skills (FEDEC, 2006). The present investigation brings the first advances of the new technology KIMARTOP (LEÓN; BORTOLETO, 2012) which main function is to simulate the Top on static position allowing the planning and systematization of the Base training. **Methods** The methodology can be described in four moments: a) problem identification; b) concept development and device design; c) prototype confection; d) tests performance. It has been developed tests with 3 experienced Bases (2 men and 1 woman – all adults), in different days. They performed 4 different basic exercises with 10 repetitions each with no load, followed by 10 and 25% of the Top weight. **Results** - from the four exercises proposed, 3 has permitted a very close technical simulation; - it was suggested to modify the inferior support to allow the exercise execution from the floor with the Base in dorsal recumbent position; - a better loads control and also other practice variables; - the possibility to practice with lower loads in relation to the Top weight; - more safety and autonomy to the Base, once the device allow the use of lunge system. **Discussion** It has been used two different supports for this research: hand and foot. The experts indicated the need of other kinds of support, trying to adapt the grab to the variance of each acrobatic technique and ergonomics. The experts suggest the need of development of others structures as well as flexible devices to support the loads trying to perform a closer simulation the Top real body. It was also observed the possibility to apply the device to the practice of the Bases (or Catchers) of Banquine, as well as "head to head", "foot to head", "hand to head" exercises. The KIMARTOP presents itself as an important resource to clubs where the training of the group acrobatics exists, specially the Hand to Hand modality. **References** BROZAS, M. P.; NOWOTYNSKI, W. **PHYSIOLOGICAL AND PHYSICAL DEMANDS OF A WOMEN'S FOOTBALL MATCH**

Martínez-Lagunas, V., Niessen, M., Hartmann, U.

*University of Leipzig*

**Introduction** Despite the increased popularity of women's football worldwide, scientific research regarding its physiological and physical requirements is still scarce. For this reason, the purpose of the present study was to investigate for the first time the physiological and physical demands of a women's football match by means of simultaneous portable spirometry and GPS (Global Positioning System) measurements. **Methods** After proper familiarisation, a full 90 min competitive friendly match (11 vs. 11) was organised for continuous assessment of physiological and physical variables among 10 outfield German female football players (21.3±2.9 yrs, 163.1±7.2 cm, 60.0±4.6 kg). The physiological variables that were evaluated consisted in oxygen uptake (VO<sub>2</sub>), heart rate (HR) and blood lactate concentration (La, measured every 15 min). The physical variables measured through the GPS devices included total distance (D<sub>total</sub>), distance covered at >16 km/h (D>16km/h), and speed. Players' maximal VO<sub>2</sub> and HR values were determined under laboratory conditions. Dependent t-tests were used to assess differences between the game halves. **Results** The average VO<sub>2</sub>, HR, La, D<sub>total</sub>, and D>16km/h during the full match were 28.3±4.6 ml/min/kg (52% VO<sub>2</sub>max), 152±10 bpm (79% HRmax), 2.17±0.81 mmol/l, 7230±1474 m and 631±358 m (9% D<sub>total</sub>), respectively. There was a large individual variability among these variables ranging from 7-57% (mainly due to the positional role). All mean values, except for La and D>16km/h, decreased significantly in the 2nd compared to the 1st half (6-11% reduction, p<0.01). The mean peak VO<sub>2</sub> and HR values achieved during the match were 53.0±3.8 ml/min/kg (98% VO<sub>2</sub>max) and 182±8 bpm (94% HRmax). The average and peak speed attained throughout the game corresponded to 4.9±0.9 km/h and 24.3±2.4 km/h. **Discussion** Similar to other authors [2-4], we also found a large individual variability and a significant reduction in match demands in the 2nd compared to the 1st half. However, our results are lower than published data on VO<sub>2</sub> values of male football players collected through portable spirometry during friendly games [2] and on HR [3, 4], La [1] and GPS physical data [4] of female football players during competitive matches. Possible reasons for these differences may include player characteristics, game conditions, methodological differences, and movement impairment due to the measuring equipment. Further studies using a larger sample size (players and games) should be conducted in order to verify these results. **References** 1. Davis, JA, et al. (1993). *Sports Med*, 16(3), 180-189. 2. **THE VALIDITY OF THE MULTISTAGE FITNESS TEST IN ACTIVE 8-12 YEAR OLDS**

Metcalf, A.J., Castle, P.C., Brewer, J.

*University of Bedfordshire, Polhill campus (Bedfordshire, UK)*

**Introduction** The multistage fitness test (MSFT) (Ramsbottom et al, 1988) provides participants with an estimated maximal oxygen uptake (VO<sub>2</sub>max) and is regarded as a valid field-based test to estimate cardiorespiratory fitness (Castro-Pinero et al, 2010). The MSFT has become very popular in schools because of its low cost and its limited need for equipment. The aim of this investigation was to assess the predicative validity of the MSFT using several speed and strength variables in active young people. **Methods** Sixty active young people between the ages of 8-12 year olds (Boys, n = 25; Girls, n = 35) were recruited from a local athletics club. Anthropometric data was collected including height, weight, BMI, body mass, free fat mass and total body water using tanita scales (BC41MA Segmental, Cranlea). Isokinetic strength was measured using a back and leg digital dynamometer (Takei A5402) and a hand grip dynamometer (Takei A5401). Sprint speed was recorded using electronic light gates (Brower test centre systems, Cranlea). Aerobic fitness was assessed using the MSFT (Ramsbottom et al, 1988). **Results** Significant relationships were observed in all young people between the MSFT scores and both 10m (r = -0.42, P < 0.05) and 40m (r = -0.47, P < 0.05) sprint times. Significant relationships were also observed in gender specific groups for 40m sprint in both boys (r = -0.57, P < 0.05) and girls (r = -0.40, P < 0.05) however, only girls had a significant relationship in 10m sprint performance (r = 0.48, P < 0.05) whereas boys did not (r = -0.35, P > 0.05). A relationship between MSFT scores and maximal hand grip strength was significant in all subjects (r = 0.40; P < 0.05) and girls (r = 0.49; P < 0.05) however, not significant in boys (r = 0.29; P > 0.05). **Discussion** The results of this study show that MSFT scores are related to speed and strength performance measurements in young people. This suggests that in young people aged 8-12 years old, a single 10m and 40m sprint can be a good predictor of aerobic fitness as demonstrated by their performance on the MSFT. While the MSFT scores may therefore, be a relevant indicator of aerobic fitness in

young people, the results also suggest that those who are active in more anaerobically demanding exercise such as team sports may develop both aerobic and anaerobic fitness compare to those young people who are less active. ### CHANGES OF SPEED IN PUBERTAL SOCCER PLAYERS

Radziemiński, Ł., Jastrzębski, Z., Jaskulska, E., Konieczna, A., Ignatiuk, W., Bichowska, M.

*Gdansk University of Physical Education and Sport*

**Introduction** Many authors (Williams and Reilly, 2000; Reilly et al., 2000) claims that speed is one of the strongest predictors of talent in soccer. Therefore, systematic verification of sprinting ability is one of the most important elements of training process at all levels of competition. The aim of the present study was to compare sprint test performances of pubertal soccer players in five different time points. **Methods** Twelve young soccer players (age:  $12.04 \pm 0.36$  yrs, height:  $152.58 \pm 5.16$  kg, weight:  $39.71 \pm 5.99$ ) from Arka Gdynia football club performed five sprint tests during a 20-month period. Each attempt took place in the indoor facility with synthetic running surface during competitive season. Times were recorded by photocells positioned at the start line and at the finish lines of each run. All sprints were performed from the standing position on a distance of 5 m, 10 m, 15m and 30 m from the start line (S) and 5 m and 10 m from the line situated 2 meters behind the start line (2 meters run-up - R). ANOVA for repeated measures and post-hoc Tukey test were used to find any significant differences. **Results** During analyzed 20 month period, significant ( $p < 0.05$ ) improvements in sprint times were noted in all distances. Interestingly the regression of speed level was observed between trials 3 and in distances of 5 m (S), 10 m (S), 10 m (R) and 15 m. **Discussion** Due to logistic and methodical difficulties there are not many publications presenting results of cyclical researches of speed development. Papaiaikovou et al. (2009) observed that significant improvements of speed level occurred after every 2-3 years, what is in line with our results. However, cited study was conducted on different subjects. At the age of 12-14 during puberty when boys are growing very fast, disharmony of maturation is often observed what has a negative influence on the neuro-muscular coordination. At this age speed development might be disturbed and individualization of physical loads seems to be very important part of the training process. The greatest dimension of disharmony in speed development of this study subjects was observed in Test 4 what might explain adverse comparisons with other authors' findings (Wong et al., 2010). ### ANTHROPOMETRIC, TECHNICAL AND CONDITIONAL MEASURES ON VOLLEYBALL WOMEN PLAYERS SCHOOL SPORTS

João, P.V.1,2, Mota, M.P.1,2, Cotiuga, I.1

*1) University of Trás-os-Montes and Alto Douro*

**Introduction** The present study was carried out in order to identify and analyze the anthropometric, conditional and technical indicators of athletes during the training process. **Methods** The sample is composed of  $n=17$  female athletes with an average age of ( $13.88 \pm 0.33$  years), participants in the 14-under category of the Girls National Volleyball Championship within School Sports. The anthropometric indicators, conditional components and the technical service indicator were evaluated. To verify the existence of statistically significant differences between athletes of different ages and specific positions, we used the One-way ANOVA, followed by the Tukey's Post Hoc Test from multiple comparisons. The Pearson's  $r$  Correlation Coefficient was also used in this study. In order to analyze the technical service indicator three games were observed, corresponding to a total of 199 actions. Descriptive statistics were used through frequencies and percentages and inferential statistics using the  $\chi^2$  Chi-square to determine the degree of dependence. **Results** The obtained results indicate significant differences, exclusively, in the variable body mass between the different specific positions. Although there are no significant differences in height and wingspan, these factors are still pointed out to be important to the Volleyball sport. A strong relationship of dependence between the anthropometric variables and several conditional components has also been denoted. **Discussion** Regarding the evaluation of the service it was noticed that the service zone most used by the athletes was zone 6 and the service direction with the highest percentage was the parallel, being the middle player and outside player, the female players that most contributed to the predominance of the same. The study on the relationship between the variables zone and service direction and their effectiveness has shown that the majority of services have allowed the construction of any type of attack, which is carried out from zone 6 and with parallel trajectory. Finally, we can emphasize that the service zone and the service direction showed significant association with the specific position. However, none of the analyzed variables (service zone, service direction and specialized player) interfered in a determinant way with the service efficiency. ### MATURITY-ASSOCIATED DEVELOPMENTAL CHANGES IN CHANGE OF DIRECTION AND DRIBBLING SPEED IN YOUNG SOCCER PLAYERS

Duarte, J.1, Valente-dos-Santos, J.1, Pereira, J.1, Simões, F.1, Rebelo-Gonçalves, R.1, Severino, V.1, Vaz, V.1, Figueiredo, A.1, Elferink-Gemser, M.1, Malina, R.M.2, Coelho-e-Silva, M.1

*University of Coimbra, Portugal*

**INTRODUCTION:** The purpose of the current study was to assess the developmental changes in change of direction and dribbling speed in youth soccer players taking into account skeletal age (SA), maturity status, body size, estimated fat mass, aerobic endurance, lower limb explosive strength and annual volume of training. **METHODS:** Eighty-three male soccer players aged 10-15 years (SA) at baseline were annually followed over 5 years, resulting in an average 4.4 observations per player. After testing for multicollinearity, multi-level regression modeling was used to examine the longitudinal developmental changes on change of direction and dribbling speed. **RESULTS:** Maturity-associated variability was significant in change of direction and also dribbling speed among young soccer players aged 12-14 years with better scores being performed by late maturers. Moreover, the predicted longitudinal scores for change of direction and dribbling speed improved with SA ( $P < 0.01$ ), SA2 ( $P < 0.01$ ) and skeletal maturity status entered as an additional developmental predictor ( $P < 0.05$ ). Estimated fat-free mass ( $P < 0.01$ ), aerobic endurance ( $P < 0.01$ ) and lower limb strength ( $P < 0.01$ ) were additional predictors in both models. The soccer-specific skill, dribbling speed, was also explained by annual volume of training ( $P < 0.05$ ). **CONCLUSION:** Skeletal ma-

turity status explains inter-individual variability on maximal short-term run performances with and without the ball possession at early ages of participation in competitive soccer. The effects tend to persist across ages combined with longitudinal changes in body composition and functional fitness. In the particular case of the ball test, annual volume of training was also a longitudinal performance predictor.

### PSYCHOSOCIAL STRESS AND RECOVERY ARE RELATED TO PERFORMANCE IN ELITE RUNNERS

Otter, R., Brink, M.S., Lemmink, K.A.P.M.

*Hanze University of Applied Sciences Groningen*

**Introduction** Elite runners enhance performance by means of a physical training program leading to alternately physical stress and recovery. However, it is suggested that psychosocial stress and recovery can also influence performance (Kentta & Hassmen, 1998). The purpose of this study was to analyze the relationship between changes in psychosocial stress and recovery and changes in performance in elite runners. **Methods** Thirteen elite runners (9 male/4 female; age:  $24 \pm 6$  years; height:  $176 \pm 11$ cm; weight:  $64.1 \pm 10.1$ kg) completed two HR based sub-maximal tests with 7 weeks in between. Based on the LSCT protocol for cyclists, runners performed 6 minutes at 70% of maximal heart rate (HRmax) followed by 6 minutes at 80%HRmax and 3 minutes at 90%HRmax (Lamberts et al., 2011). Heart rate recovery (HRR) was determined over the first minute of passive rest as performance indicator. Both tests were performed under standardized environmental conditions (temperature:  $19 \pm 1^\circ\text{C}$ , humidity:  $39 \pm 8\%$ ). Psychosocial stress and recovery were measured before each submaximal test using the RESTQ-sport (Nederhof et al., 2008). **Results** On average HRR decreased with  $2.3 \pm 12$  bpm. Changes in general stress, general recovery, sport specific stress and sport specific recovery were  $-0.6 \pm 2.5$ ,  $0.3 \pm 1.1$ ,  $0.5 \pm 2.0$  and  $0.5 \pm 2.7$ , respectively. Higher general stress and lower general recovery were significantly related to a change in HRR ( $r = -0.581$ ,  $p = 0.037$ ;  $r = 0.582$ ,  $p = 0.037$ , respectively). **Discussion** Non-sports related psychosocial stress and recovery play an important role when optimizing performance of elite runners. When psychosocial factors are carefully monitored, it can provide insights that can lead to appropriate interventions to optimize performance of elite runners. Examples of interventions are adapting training load or implementing recovery enhancing strategies. **References** Lamberts, R. P., Swart, J., Noakes, T. D., & Lambert, M. I. ### PREDICTION OF RACE TIME DECREASE, DUE TO THE PERFORMANCE -OFF, IN RUNNING 3000M TO MARATHON

Pavei, G., Minetti, A.E.

*Università degli Studi di Milano*

**INTRODUCTION:** It is crucial for runners to set, as a training goal, the finish time for a given race compatibly with the available fraction of their metabolic power for that distance. But, is the decay in the available power the same for best results of a runner (PB) competing in all distances (3000, 5000, 10000, 21097 and 42195 m) as in world records (WR) often set by different, specifically trained, athletes? In case, a mathematical model of that decay could suggest, on the basis of a known performance, the racing time at which to train for the other distances. The literature reported different power decay models, linearly (Saltin 1973) or curvilinearly (Peronnet & Thibault 1989) related to the racing time. Since the running cost is reported as constant in this range of distances (Minetti 2004), the speed decay is supposed to reflect the decrease of the available aerobic power fraction. Here we: 1) check the speed decay model, 2) test whether the decay 'slope' is similar in WR and PB and, 3) construct a prediction equation for finish times. **METHODS and RESULTS:** The PB from 3000m to marathon of 16 top-class marathon runners and the WR in the same distances were examined. After realizing that the speed decay with distance was not linear, the equation by Peronnet & Thibault (1989) was adapted as:  $(v/v_{map}-1)*100=E*\ln(td/t_{map})$ , where  $v$  is the running speed at the distance  $d$  (m) and at 3000m (at which we suppose that 100% of the maximum aerobic power ( $v_{map}$ ) is available),  $t$  is the PB (s) and  $E$  is the 'endurance capability index' (%) proposed by the authors. The analysis of actual WR with that equation brought to  $E=-5.692\%$ , while for the more reliable athletes (9 out of 16, when  $R^2>0.97$ ) we obtained  $E=-5.194\pm 0.702\%$ . **DISCUSSION:** Metabolic power decrease at increasing distance better follows a non-linear (logarithmic) path and is substantially the same for PB and WR. To predict the finish time we need to rearrange the above equation according to  $v=d/t$  and  $v_{map}=map/t_{map}$ . We obtain:  $d=map*(td/t_{map})*(1+E/100*\ln(td/t_{map}))$  where  $E=-5.692$ ,  $map=3000m$  and  $t_{map}$  is the 3000m PB (s). The use of a graphic program allows to read the predicted finish time for whichever distance in the range 3000m to the marathon. When WR for 3000m is used ( $t_{3000}=440s$ ) we obtain  $t_{5000}=759s$  (WR=757.4s),  $t_{10000}=1589s$  (WR=1577.5s),  $t_{21097}=3531s$  (WR= 3503s) and  $t_{42195}=7444s$  (WR=7418s). A (wrong) linear interpolation should have brought to 795, 1686, 3661 and 7417s, respectively. The file with the complete model will be downloadable at the website [albertminetti.it](http://albertminetti.it). **REFERENCES** Saltin B (1973). Limiting factors of physical performance, 235-52. ### THE RESEARCH OF PREFERENCE FACTORS IN FOOTBALL PENALTY SHOOTOUT

Biyik, K., Satici, A., Imamoglu, O., Con, M.

*UNIVERSITY OF ONDOKUZ MAYIS*

The aim of the training was examining the choice factors in penalty shootout which is effective. The students, who studies in Yasar Dogu Physical Education and Sports High School, and the student athlete, who plays licensed football in Regional Amateur League in Super Amateur teams in Samsun city, were exercised. While video cameras and speedometer are used in shootouts, some surveys were applied in the cause of psychological factors. Furthermore a survey was applied to get the knowledge of which footed are the athlete. Statistically one way variance, chi-square and Scheffe tests are examined on evaluation of penalty shootouts and descriptive statistics was used for the research about psychological factors. Obtained informations were named via frequency and percent. A statistical evaluation was done among the players as to their positions whether they are effected by the goalkeeper or not. As a result of this evaluation, it is

determined that nothing but the's physical appearance and experience made difference on players' performance ( $P < 0.05$ ). There is no meaningful difference between players as to their position about when a player is coming to shoot the ball, if he changes his decision or not according to the statistical evaluations ( $P > 0.05$ ). However when importance level ( $P = 0.067$ ) is taken, it is determined that attacking players' possibility of changing decision are more likely than others like % 23-34. There were some players who is not in favour of shooting penalty and feeling uncomfortable. Even there is no statistically difference, it was defined that defending players are more nervous about shooting critical penalties. It was observed that in between players having l stress, right handeds are having less stres that left handeds or both handeds during shootout ( $p < 0.01$ ). Among 330 shoots, %68,2 of them scored and %31.8 of them failed. %54.6 of penalties were taken by the inside of right foot. It was noticed that success or failure of the penalty depends on shooting technique, speed ( $p < 0.05$ ) and does not depend on the color of the keeper's sportsgear ( $p > 0.05$ ). Last of all, coaches should prepare his players fully on psychological and tactical areas, should apply special training schedule in order to help players on improving these skills.

## QUANTIFICATION OF ANAEROBIC CAPACITY OF YOUNG ATHLETES OF FUTSAL THROUGH TEST RAST

Rezende, T.1,2, Silva, A.J.1, Gonçalves, L.1, Sotério, A.A.1, Marche, A.L.2

UNICAMP (1), UNIFEG (2)

**INTRODUCTION** The indoor football or futsal is an intermittent sport, with acceleration, deceleration and re-acceleration in very short distances. In these actions, the player is required to change directions or make maneuvers over the opponent. Then, the capacity of production of power in high levels during a prolonged time is important for players performance improvement. The running anaerobic sprint test (RAST) is a very simple method that can be used to evaluate performance of futsal players, due to the possibility of estimating neuromuscular and energy determinants of maximal anaerobic performance (ZAGATTO et al., 2009). It could also be used to establish parameters for prescribing training and for getting full potential of the players or preserving them from fatigue during an official match. The aim of this study was to quantify the anaerobic parameters in young futsal athletes with the RAST method, not commonly used in this modality of sport. **METHODS** The volunteers used in this study were all male ( $N=07$ ), with an average age of  $16,4 \pm 0,8$  years old, weighing  $65,8 \text{ kg} (\pm 9\text{kg})$  and mean height of  $172,4 \text{ cm} (\pm 0,06 \text{ cm})$ . They were students of a futsal school organized by the Sports Department of the city hall of Guaxupé (MG, Brazil), practicing the modality three times per week in sessions of 1.5 hour. The volunteers were accompanied along four consecutive weeks, and then their anaerobic capacity was compared with the influence of practice time of futsal. **RESULTS** Comparing the initial values with values obtained after four weeks of training, statistic significant difference was not found in peak power (watts) ( $509,6 \pm 111$  vs  $562,5 \pm 138,6$ ) or mean power (watts) ( $421,6 \pm 81,2$  vs  $400,7 \pm 84,4$ ). The relation between peak power and weight was also not different, however, statistic difference was found in mean power per weight after the four weeks of training ( $6,4 \pm 0,85$  vs  $7,17 \pm 0,95^*$ ). **DISCUSSION** The dynamic of the futsal game, with alternations of rhythm, direction and distance of each race performed, demands high levels of aerobic and anaerobic capacity. Expanding and diversifying the number of methods used in futsal players evaluation can help coaches and trainers in the formation of a better team (ARINS et al., 2007). The anaerobic capacity is a very simple test with a low cost that is not commonly applied. This study characterized anaerobic capacity in young athletes, showing that difference can be found in a short period of time. More tests should be done in other groups of ages and levels of training in order to implant this test more widely. **REFERENCES** Arins FB, Silva RCR. (2007). Rev. Bras. Cineantropom Desempenho Humana, 9(3) 291-6. Zagatto AM, Beck WR, Gobatto CA. (2009). J Strength Cond Res, 23(6), 1820-7.

## POTENTIAL PERFORMANCE ENHANCEMENT IN ELITE FLATWATER KAYAKING WITH NEW TECHNIQUE FOR BIOMECHANICAL ANALYSIS

Rosdahl, H., Nilsson, J.

Swedish School of Sport and Health Sciences

**Introduction** With a greater understanding of the kinetics and kinematic factors involved in the modern paddling technique, performance enhancement may be reached. For this purpose force-measuring systems are needed in kayaking. No studies have examined the specific forces developed within the kayak on the foot-bar and seat (Michael et al. 2009). Accordingly, the aim of the present project was to develop the necessary technique. **Methods** Equipment setup was designed to make it possible to store the force data from the foot-bar, seat and paddle together with data from a GPS, a 3-D accelerometer and electrogoniometers in a portable data-acquisition system (DaqCube). The whole force recording system can be fitted into a racing kayak. Furthermore, a jig and procedures for calibration of the paddle force transducers was developed, devices for measuring forces on the kayak foot-bar and on the seat during on-water kayak paddling were constructed and evaluated thoroughly and software for analysis of the recordings developed. **Results and Discussion** The current preliminary results indicate that the data-acquisition system is functional in a practical setting. The new foot-bar and seat force devices allow recording of forces within functional limits with high validity and reliability. Reliability of both devices was tested in a laboratory setting in a test-retest design and the coefficient of variation (CV) for foot-bar push and pull forces ranged from 0.1 to 0.8% while the CV for the seat forces varied between 0.6 - 2.2%. Validity was supported by a strong linearity found between the transducer output signal and load force in the push and pull directions for both foot-bar transducers and the seat-force measuring device. Overall, the present study opens up for new applied research of the forces generated during on water paddling and within the kayak and thus new ways to optimize kayak paddling performance can be obtained. **References** Michael JS, Smith R, Rooney KB (2009) Sports Biomech, International Society of Biomechanics in Sports, 8: 167-179 Nilsson J and Rosdahl H (2013) New devices for measuring forces on the kayak foot-bar and on the seat during flat-water kayak paddling. Manuscript under revision.

## A NEW APPROACH TO MONITOR STRESS AND FATIGUE DURING ALTITUDE TRAINING IN ELITE ATHLETES

García-Ramos, A.1, Feriche, B.1, Iglesias, X.2, Calderón, C.3, Chaverri, D.2, Barrero, A.2, Nebot, V.4, Schuller, T.5, Štrumbelj, B.6, Qiu, J.7, Rodríguez, F.A.2

FCAFD, University of Granada (Granada, Spain)

**INTRODUCTION** The total score of fatigue, a self-reported 8-items questionnaire (TSF-8), is a valid indicator of training stress and fatigue in swimmers (Aitlaoui et al., 2007). However, it does not include relevant issues such as arms tiredness or appetite. We aimed to contrast the validity of a derived 10-items questionnaire (TSF-10) by comparing both methods with session RPE and altitude-related clinical symptoms in elite athletes during altitude training (AT). **METHODS** 34 elite swimmers participating on an AT camp (CAR Sierra Nevada, 2.320 m) during three weeks (W1 to W3, 6 days/wk, 3 sessions/d). Subjects answered three self-reported questionnaires: 1) session RPE (Foster et al. 2001), within 30 min after each workout, with scores weighted for the day (s-RPEw); 2) TSF-10, based on TSF-8 with two added items

(arms tiredness and appetite); and 3) Lake Louise (LL) for acute mountain sickness symptoms. RESULTS Data were obtained from 673 questionnaires corresponding to 1,350 training sessions. Mean ( $\pm$ sd) s-RPEw was higher at W2 (5.30 $\pm$ 1.77) compared to W1 (4.57 $\pm$ 1.90) and W3 (4.80 $\pm$ 1.99) ( $p < 0.05$ ). LL scores reported in W1 (2.02 $\pm$ 1.6) were higher than in W2 (1.83 $\pm$ 1.6) and W3 (1.61 $\pm$ 1.6) ( $P < 0.05$ ). TSF-8 (18.0 $\pm$ 5.9) and TSF-10 (23.2 $\pm$ 7.0) scores in W1 were higher than in W2 and W3 (TSF-8: 16.9 $\pm$ 5.3 and 16.6 $\pm$ 6.6; TSF-10: 22.3 $\pm$ 6.4 and 21.7 $\pm$ 8.0, respectively) ( $p = 0.025$ ). LL scores showed good association with both TSF-8 ( $r = 0.46$ ) and TSF-10 ( $r = 0.49$ ) ( $p < 0.001$ ) values, peaking at W3. Items added to TSF-10 showed a moderate association with LL scores ( $r = 0.34$  and  $0.22$  for arms tiredness and appetite, respectively) ( $p < 0.001$ ). DISCUSSION Both TSF-8 and TSF-10 are equally valid tools for assessing training stress and fatigue during AT. Likewise, LL is useful to ascertain dis-acclimatization health disturbances (Calderon et al., 2011). The observed link between appetite scores in LL and TSF-10 justifies the inclusion of this item. We conclude that the extended version of the fatigue questionnaire (TSF-10) adds further information and, combined with the LL questionnaire for hypoxia-related health disturbances, can be considered a useful approach to assess well being and fatigue during AT in elite swimming athletes. ### AGREEMENT BETWEEN MATURITY STATUS DERIVED FROM INVASIVE AND NON-INVASIVE INDICATORS OF BIOLOGICAL MATURATION IN ADOLESCENT MALE SOCCER PLAYERS

Coelho-e-Silva, M.J.1, Duarte, J.1, Pereira, J.1, Simões, F.1, Rebelo-Gonçalves, R.1, Severino, V.1, Valente-dos-Santos, J.1, Ribeiro, L.1, Figueiredo, A.J.1, Malina, R.M.1

1: FCDEF-UC (Coimbra, Portugal), 2: University of Texas (Austin, USA)

INTRODUCTION: Grouping players by maturity status has long been a focus of research in youth sports and more recently has been included as central to long term athlete development model. The second objective addresses the issue of concordance between classifications based on the non-invasive methods and skeletal maturity METHODS: The sample included 181 players aged 11-14 years. The Fels method (Roche et al. 1988) was used to determine skeletal age (SA). Players were classified into three categories based on the difference between SA and chronological age (CA). On time maturity status was an SA within  $\pm 1.0$  year of CA, late maturing was an SA behind CA by more than 1.0 year, and early maturing was an SA in advance of CA by more than 1.0 year. Predicted ages at PHV were obtained using the algorithm labeled maturity offset (Mirwald et al., 2002) were classified relative to the three samples upon which the protocol was developed. On time was defined as a predicted age at PHV within 1 SD of the overall mean age at PHV (12.9 to 14.7 yrs), late as an age at PHV  $> 14.7$  years and early as an age at PHV  $< 12.9$  yrs. Cross-tabulations of maturity status classifications were calculated. Cohen kappa coefficients were calculated to evaluate the concordance of maturity classifications with pairs of maturity indicators. RESULTS: Concordance between SA-CA classifications and the non-invasive classification was 55% among players 11-12 years and 57% (predicted age at PHV) among players 13-14 years. Expected chance agreements between classifications were 51% in players 11-12 years, and 52% in players 13-14 years. Kappa coefficients were low in the two age groups, respectively, 0.11 and 0.13. The coefficients indicate relatively poor agreement between maturity classifications. Spearman rank-order correlations between maturity classifications, though significant ( $p < 0.01$ ) are low to moderate, 0.43 among players 11-12 years and 0.29 among players 13-14 years. CONCLUSIONS: Although the indicators were related, concordance of maturity classifications between SA and predicted APHV was poor. Talent development programs call for the classification of youth as early, average, and late maturing for the purpose of designing training and competition programs. Non-invasive indicators of maturity status have limitations for this purpose. REFERENCES: Malina et al. (2004). *Growth, Maturation, and Physical Activity*. Human Kinetics Champaign, Illinois. ### BASIC MOTOR ABILITIES VS. BASKETBALL SPECIFIC SKILLS

Antic, T., Dikic, N., Baralic, I., Vukasinovic-Vesic, M., Anjdelkovic, M.

*Sports Medicine Association of Serbia*

Introduction Basketball is a complex motor activity consisting of a combination of basic motor skills and specific basketball movements that are performed at high speed in a short time. The purpose of the study was to determine to what extent there is a correlation between basic motor abilities and specific basketball skills. Methods Twenty-seven female basketball players (age: 13.84 $\pm$ 0.92) performed motor and specific basketball tests. Three basic motor abilities were assessed: anaerobic endurance (300 yard test), speed (T test of agility) and explosive strength (vertical jump). Control dribble (CD), shooting (SH) and defensive movement (DM) tests were conducted to evaluate specific basketball skills. Measurements were performed three times over a period of 18 months (every six months) in order to ensure validity of results. Correlation statistics was used for result analysis. Results For the evaluation of parameters we used the measurement (of possible three) with the best results. Achieved values for 300 yard test, agility (AG) and vertical jump were 76.78 $\pm$ 4.44 s, 12.44 $\pm$ 0.68 s and 30.96 $\pm$ 4.13 cm, respectively. Performance in CD (20.57 $\pm$ 1.92 s), SH (6.28 $\pm$ 0.54 scores for 30 s) and DM (27.79 $\pm$ 2.06 times for total time of 2x30 s) was correlated with anaerobic endurance (AE), agility and explosive strength (ES). The correlations between CD and AE, AG and ES were:  $r = 0.28$ ,  $r = 0.68$  and  $r = -0.11$ , respectively. Considering SH skills following correlations with AE, AG and ES were obtained:  $r = -0.33$ ,  $r = -0.64$  and  $r = 0.11$ , respectively. In the end, DM was correlated with AE ( $r = -0.40$ ), AG ( $r = -0.60$ ) and ES ( $r = 0.32$ ). Discussion The obtained results showed strong correlation between agility and all three specific basketball skills, which points the importance of this motor ability for on-court basketball performance. Regarding AE there was medium correlation of this motor ability with specific skills. Considering the short duration and high intensity of performed basketball tests, this result is logical since the energy for this work is provided by creatine phosphate energy system rather than lactate one. Small correlation between vertical jump and specific basketball skills specifies that this motor ability does not affect mentioned basketball skills in a highly manner. Of course there is an unquestionable importance of vertical jump in other aspects of basketball. Conclusion Success in basketball certainly depends on genetic potential of an individual to develop both motor and specific basketball skills. Whether the genetic potential is going to be fully realized largely depends on adequate training. Working on basic motor skills, especially in younger age, with the emphasize on agility, greatly contributes to the improvement of specific basketball skills which is a prerequisite for becoming a top basketball player.

**INTRAMUSCULAR DIFFERENCES IN FASCICLE LENGTH, SARCOMERE LENGTH AND SERIES SARCOMERE NUMBER OF THE HUMAN QUADRICEPS FEMORIS: A CADAVERIC STUDY**

Hirata, K., Komatsu, T., Yamada, K., Wakahara, T., Kawakami, Y.

*Waseda university*

Introduction Skeletal muscles are characterized for its force-velocity-power potentials by the number and length of muscle fibers. Cadaveric studies have provided information on muscle fiber or fascicle length (LF) and the number of sarcomeres in series in a fiber (NS) of various muscles, from which the average sarcomere length (LS) has been estimated (e.g., Wickiewicz et al., 1983). Few studies however have clarified intra-muscular differences in LF or NS, although it has been shown that regional differences in architectural parameters within a muscle could influence its length-force-velocity relationship (Blazevich et al., 2006). We aimed to examine in a cadaver study intramuscular differences in LF, LS and NS of the four muscles of the human quadriceps femoris (rectus femoris: RF, vastus lateralis: VL, vastus intermedius: VI, and vastus medialis: VM). Methods The quadriceps femoris was dissected from the left leg of a cadaver (sex: male, body height: 153 cm, body mass: 59.6 kg, hip and knee joint angle: anatomical position). The lengths of fascicles removed from five sites of RF (proximal, medial, central, lateral and distal sites), four sites of VL (medial side of proximal, lateral side of proximal, central and distal sites), three sites of VI (proximal, central and distal sites), two sites of VM (proximal and distal sites) were determined with a caliper. Several muscle fibers were isolated from each fascicle at each site, and in the microscopic image of each fiber, sarcomere lengths were measured at five positions (0%, 25%, 50%, 75% and 100% fiber length). The LS was determined as the average of the sarcomere lengths at five positions. The NS was determined by dividing LF by LS. Results & Discussion The LF, LS and NS of each muscle ranged from 60.5 - 74.6 mm, 1.86 - 2.30  $\mu$ m and 30692 - 36124 in RF, 59.7 - 80.5 mm, 1.72 - 2.00  $\mu$ m and 33512 - 43593 in VL, 37.4 - 62.2 mm, 1.75 - 2.34  $\mu$ m and 17614 - 34397 in VI, and 61.7 - 87.1 mm, 1.81 - 2.02  $\mu$ m and 32435 - 47270 in VM, respectively. The LF showed significant regional differences in all muscles of quadriceps femoris. On the other hand, there was no significant variation in LS among the sites of each muscle. The intramuscular differences in NS corresponded well to those in LF, suggesting that intramuscular differences in LF are matched with NS while LS is kept constant throughout a muscle. We conclude that LS change can be estimated from the measurement of LF change that has been carried out in vivo. References Wickiewicz TL, Roy RR, Powell PL and Edgerton VR (1983). **BILATERAL STRENGTH ASYMMETRY DURING VERTICAL JUMP IN VOLLEYBALL PLAYERS**

Borras, X., Balias, X., Drobnic, F.

*Universitat de Vic*

BILATERAL STRENGTH ASYMMETRY DURING VERTICAL JUMP IN VOLLEYBALL PLAYERS Borràs, X.1, 2, Balias, X.2, Drobnic, F.2 1: Uvic (Spain), 2: GIRSANE. CAR (Spain) Introduction Bilateral imbalances may affect performance. Asymmetry between limbs is considered predisposing factor for injury when differences are greater than 15% (Knapiak, 1991). Double leg vertical jump has been observed as a reliable functional task to assess limb functional limitations (Impellizzeri et al., 2007). The purpose of this study was to evaluate the bilateral strength symmetry in volleyball players applying a vertical jump test protocol. Methods Sixteen male of the Spanish National volleyball team performed a squat jump (SJ), a countermovement jump (CMJ), and a CMJ with arms (CMJa). Jumps were recorded simultaneously in a two force platforms (Kistler), one under each leg. Symmetry index was calculated using the formula (stronger-weaker)/stronger x 100. Parameters used for comparison were maximum peak force and total impulse. Results Peak force symmetry index values for each type of jump were: SJ 4.0%, CMJ 5.5%, CMJa 4.2%. Symmetry index for total impulse values were SJ 8.1%, CMJ 8.8%, CMJa 11.9%. All differences between strong and weak limb are statistically different ( $p < 0.05$ ). Discussion With respect the peak force values, the symmetry index oscillates among 4.0% and 5.5% and is statistically different. This agrees with the results found by Newton et al (2006) in softball players and is discordant with Lawson et al (2006). Nevertheless, Lawson et al (2006) compare right - left leg, and this comparison may hide asymmetry due to leg compensations (Newton et al 2006). Total impulse symmetry index are slightly higher, oscillating among 8.1% and 11.9% and are also statistically different. In conclusion, volleyball players present strength asymmetry between limbs although it can not be considered as a risk factor for injury. **THE EFFECT OF A 6-WEEK PNF STRETCHING TRAINING ON VARIOUS MUSCLE-TENDON PARAMETERS**

Konrad, A., Gad, M., Tilp, M.

*Karl-Franzens- University Graz*

Introduction There is only one study (Mahieu et al., 2009) that analyzed the effect of long-term PNF stretching on muscle-tendon properties. They reported an increase in range of motion (ROM) but no changes in passive resistive torque and Achilles tendon stiffness. Thus, ROM increase was explained with increased stretch tolerance. However, muscle and tendon stiffness during passive movements was not measured and results are in contrast to findings by Kato (2009) who reported a change in passive tendon stiffness following a static stretching program. Therefore, we performed a PNF stretching training and included the missing muscle and tendon parameters in our analysis. Methods 49 subjects agreed to participate in the study. The group was divided into 25 subjects who performed a PNF stretching training of the calf muscles 5x/week and controls that did not perform any stretching training. Before and following a six-week stretching intervention, we determined maximum dorsiflexion with a goniometer and muscle fascicle length and pennation angle at neutral ankle position (90°) and maximum dorsiflexion with ultrasound. Furthermore, ankle joints were passively moved with a dynamometer and the displacement of the muscle-tendon junction was simultaneously observed with ultrasound. This allowed determining length changes in

tendon and muscle and hence calculating stiffness by dividing force change by length change. Furthermore, joint stiffness was calculated by dividing change in passive torque by change in ankle angle. Mean values before and following the six weeks were compared with paired t-test. Results Due to minor quality of ultrasound videos five subjects from the ROM measurement and seven subjects from the dynamometer measurement had to be excluded. In the intervention group mean ROM (n=20) increased from 31.45+/-7.3° to 33.50+/-7.3° (p=0.02). Pennation angle increased from 18.5+/-1.8 to 19.5+/-2.1° (p=0.01) in neutral but not in the maximum dorsiflexion position. Fascicle length did not change in either position. Although joint and muscle stiffness did not change, mean tendon stiffness (n=18) decreased significantly from 10.58+/-3.42 to 9.10+/-2.89 N/mm (p=0.03). No parameter changes were observed in the control group. Discussion We conclude that PNF stretching for 6 weeks increases ROM and affects the stiffness of the Achilles tendon during passive movements. Furthermore, muscle fascicle angle is increased in resting position (90°). Since Mahieu et al. (2009) did not observe changes of tendon stiffness during MVC measurements it seems that tendon properties and muscle geometry are rather altered when muscles are not voluntarily activated. ## EFFECTS OF ANKLE BRACES ON GROUND REACTION FORCE AND ELECTROMYOGRAMS DURING LANDING MOVEMENT

Tsuchida, Y.1, Miyakawa, T.2

1:Graduate school, Kawasaki University of Medical Welfare 2:Kawasaki University of Medical Welfare

Introduction Percentage of ankle injuries in total sports injuries are about 15%. Percentage of ankle sprains in total ankle injuries are about 85%. Furthermore, it was reported that most of people who have had ankle sprains have them again within a year. Ankle braces are used for prevention of sprains and prevention of recurrence of injury. Recently, various types of braces are developed and sold. The new featured brace developed by company D is 15g. This brace is mounted so as to wind around the ankle, consists of a movable pad made from foam material and has a stretching belt. The brace works by adding pressure to the tibia and fibula, and on the muscles relating to plantar flexion and dorsiflexion. Therefore, the aim of this study was to verify the effect of ankle braces on ground reaction force (GRF) and electromyograms (EMG) during landing movement. Methods Ten young healthy males subjects (Height:171.8±3.7cm, Weight:62.2±6.2kg, Age:21.4±1.9yr) were chosen. All subjects gave informed consent. Two conditions were set, one with a brace on the right ankle and one without. And physical tasks measured were landing movement from a box of 30cm and 50cm in both conditions. All subjects performed each task three times in all conditions. Ground reaction force and electromyograms during landing movement were measured. Muscles to be examined were the long fibular muscle, lateral head of gastrocnemius muscle, interior head of gastrocnemius muscle, soleus and anterior tibia muscle. Results On GRF during landing movement, comparing the condition of wearing a brace and without, showed no significant differences. When subjects were measured without a brace, GRF condition of 30cm was significantly lower than at 50cm(p<0.05). On EMG of all examined muscles during landing movement from 30cm, comparing the condition of wearing a brace and without showed no significant differences. On EMG of interior head of gastrocnemius muscle during landing movement from 50cm, the condition of wearing a brace was significantly lower than without(p<0.05). Discussion On 30cm, GRF when subjects wore a brace was higher than without. Subjects landed from the same place but the GRF was different. When people land on the floor, ankles pronate and supinate. Maeda reported that the angle of ankles pronate and supinate landing on one foot were larger than on both. From these, this brace possibly makes the angle of the ankles pronate and supinate limitary. On 50cm, EMG of interior head of gastrocnemius muscle when subjects wore a brace was lower than without. Kameda reported that muscle activity at lateral head of gastrocnemius muscle, and interior head decrease with greater angle of the knee. From these, this brace supported buffer action during landing movement.

## THE EFFECTS OF GRADED SLOPES AND THE USE OF HIKING POLES ON LOWER EXTREMITY MUSCLE ACTIVITY

Gierlinger, G., Christian, J., Schwameder, H.

University of Salzburg

Introduction Walking on graded slopes requires exertion of greater forces across lower extremity joints. In the course of walking downwards, the knee joint absorbs up to 70 percent of the total negative work. The use of hiking poles as a tool to reduce lower extremity joint load as well as muscle activity is widely accepted. Especially when the hiking poles are used technically right, the load on the ankle and knee joint can be reduced by up to 56 and 25 percent, respectively (Schwameder, 1999). Despite increased attention to effects of inclination on human gait during the last years, many questions remain unresolved. Therefore, the goal of the present study was to identify the muscular response to walking with hiking poles. Methods Twenty-six healthy male students of the University of Salzburg with average age, height and weight of 25.4 (±2.5) years, 178.9 (±6.5) cm and 75.4 (±9.2) kg respectively, volunteered to complete this study. All participants were instructed to walk up and downhill on a treadmill at four, eight and twelve degrees. Furthermore, the double poling technique was performed as participants walked downwards with the hiking poles. Muscle activity was recorded of tibialis anterior (TA), soleus (SO), medial gastrocnemius (GA) and vastus (VA), medial (SM) and lateral hamstring (BF), rectus femoris (RF) as well as gluteus maximus (GL). Gait characteristics were obtained with Novel® Pedar insoles. Data was processed with a custom written Matlab® code and statistically analysed applying one-way ANOVA with repeated measures (Bonferroni,  $\alpha=0.05$ ). Results Regarding both mean activity and burst duration, no significant differences were observed between walking with and without hiking poles. Nonetheless, tendential differences are apparent. When walking downwards, the mean muscle activity of TA, GA, SM, BF, RF and GL increased while the activity of SO and VA decreased. In terms of the burst duration, tendential increases were found regarding TA and SM. Decreases were observed concerning GA, BF, VA, RF and GL. Discussion The present study revealed that using hiking poles is not beneficial to unload the lower extremity joints and muscles. In fact, hiking poles expose inexperienced or recreational hikers to increased muscle fatigue and consequently increased injury risk. ## INNOVATIVE TECHNOLOGIES FOR KNEE REHABILITATION IN SUBJECTS WITH ANTERIOR CRUCIATE LIGAMENT INJURIES

Benvenuti, P.1, Biscarini, A.2, Carnevali, V.2, Mastrandrea, F.2, Zanuso, S.3

1: University of Verona (Italy), 2: University of Perugia (Italy) 3: University of Greenwich (UK)

Introduction Recent theoretical studies indicate that during leg extension exercises the tibiofemoral shear forces and the ACL strain-forces can be externally modulated. These modulations can be obtained by a controlled displacement of the application point of the resistance

force along the lower-leg during the knee flexion/extension (Biscarini, 2008), or through an external compressive force applied on the knee joint (Fleming et al., 2007). Methods We have designed and developed two innovative leg extension prototypes which integrate these functions. In the first prototype, the resistance lever of a standard leg-extension equipment was replaced by a linear guide along with the resistance pad can slide. The pad movement along the guide is generated by an electric motor controlled by an angular encoder placed on the rotation axis of the equipment, and a linear encoder installed along the linear guide. A feedback control algorithm was developed to provide an accurate and fast dynamic control of the pad positioning. In the second prototype, a foot platform was inserted at the distal side of the resistance lever to exert a controlled axial compression on the lower limb during the exercise. Two protocols for surface EMG and imaging techniques measurement were designed to assess and compare the levels of hamstring co-contraction (which is known to represent a protective factor for the ACL) and the anterior tibial translation (which is proportional to the ACL strain-force), during the exercise with these two new prototypes and the standard equipment, at different levels of external resistances. Each trial was also repeated encouraging the subjects to intentionally enhance hamstring co-activation during the exercise. Results EMG data collected on seventeen healthy subjects indicate that hamstring co-activation is not influenced by pad movement and axial compression. However, the hamstring co-activation was increased from two to four times when the subjects were encouraged to intentionally co-contraction the knee flexor muscles during the leg extension exercise. Discussion Intentional hamstring co-contraction in leg extension exercises can be an effective strategy for ACL protection and tibiofemoral joint stability in ACL deficient patients, and in rehabilitation programs after cruciate ligament reconstruction. Further investigations with imaging techniques will definitely assess the effectiveness of the two prototypes. References Biscarini (2008). ### CONTRIBUTION OF THE PLANTAR FLEXION TO MAXIMUM FOOT GRIP FORCE

Koyama, K.1, Miura, T.2, Horiuchi, K.3, Maruyama, T.3, Kobayashi, K.3, Kurihara, T.4, Yamauchi, J.3,5

1:Tain University of Yokohama, 2:ALCARE, 3:Tokyo Metropolitan University, 4:Ritsumeikan University, 5:Future Institute for Sport Sciences

[Introduction] An understanding of force generating mechanism of foot was important key to understand human bipedal locomotion. Foot muscles are divided into two muscle groups: plantar intrinsic foot muscles (PIFM) and the extrinsic foot muscles (EFM). These muscle complex supports the foot arches and generate force during the bipedal movement (Fiolkowski et al., 2003); however, it is still unclear how PIFM and EFM separately contribute to the total force generating capacity of foot. It is well known that, in order to prevent a re-injuring, using arthrodesis materials such as taping and cast can limit the range of motion (ROM) of joint (Rovere et al., 1998). While, this technique may be useful to isolate each muscle generation force in the complex muscle movement. From this point of view, ankle cast induced reduction of ROM in ankle may reduce EFM availability and this may be able to determine the contribution of PIFM and EFM separately to foot muscle function. [Purpose] This study was to investigate how plantar flexion contributes to the foot muscle strength by using ankle cast arthrodesis technique. [Methods] Seven healthy subjects (age, 24.2±3.1year; height, 1.70±0.09 m; body weight, 67.7±24.3 kg; mean±SD) participated and were measured active ROM in ankle, maximum foot grip force (FGF) and plantar flexion force (PFF) on the goniometer (NIHONKOHDEN, Japan), the foot grip dynamometer (Takei Scientific Instruments, Japan) and the manual dynamometer (NIHON MEDIX, Japan), respectively, in two conditions; barefoot (BAR) and reduced ROM of ankle by cast (CAS; CASTLIGHT-α, ALCARE, Japan). ROM was determined from maximum range of dorsiflexion to plantarflexion. For the measurement of PFF, subjects sat with 90, 180 and 90 degrees of ankle, knee and hip joint, respectively, and placed their arm in front of the chest and pressed their fore-foot on the dynamometer maximally. For the measurement of FGF, subjects optimally graded the grip-handle bar of the dynamometer by toe and finger of foot in a sitting position and exerted maximum force. Both PFF and FGF measurements were performed three trials and used best trial for a further analysis. [Results] FGF and PFF were significantly ( $p<0.05$ ) decreased in CAS as comparable with BAR (FGF; CAS: 10.4±3.1 kg vs. BAR: 13.6±4.5 kg, PFF; CAS: 458.7±81.2 N vs. BAR: 514.5±93.6 N). ROM was significantly decreased in CAS (CAS: 23.0±5.3 deg vs. BAR: 52.0±11.8 deg,  $p<0.01$ ). [Discussion] These results of the present study suggest that muscle force from plantar flexion contributes to foot grip force generation to some extent. Extrinsic foot muscles embedded in foot and ankle joint may have some functional role to generate foot muscles. [References] Rovere GD, Clarke TJ, Yates CS, Burley K. (1988). ### TIMING OF MUSCLE CONTRACTION INFLUENCES FUNCTION OF MUSCLE FIBERS

Hirose, K., Tarodachi, N., Tsutsumi, M., Ogiso, K.

Kogakkan University

Introduction When a physical activity is performed quite timely, a quick and accurate response is produced. However, it is hard for us to get high performance if the timing is upset. The present study was designed to examine how a gap of timing to perform maximal voluntary knee extension affects functions of the vastus lateralis muscle fibers (VL). Methods Eighteen male subjects performed a 10-consecutive isokinetic knee extension (90 deg/s) that comprised 7 passive and 3 maximal voluntary contractions (MVC). It was repeated 8 sets with intervals of 2 minutes. They were asked to relax their muscles and exert MVC as quickly as possible only when a light turned on at 60 deg of the knee joint angle (0deg = full extension) in the 3rd, 6th and 9th extensions (C60). Only in the 4th and 8th sets, the timing of light stimulus was changed from 60deg to 50deg (C50) or 70deg (C70). The subjects did not inform of it. VL-EMG activity was monitored to check relaxation before the light stimulus. Pre-motor time (PMT), electromechanical delay (EMD), total reaction time (TRT) and movement time to the peak torque (MTPT) were calculated. A point (P) where a fascicle arose from the deep aponeurosis and pennation angle (PA) were measured on VL ultrasonic images. The subjects classified their MVC performance into 5 grades after each set. Results PMT and TRT were significantly longer in C70 than in C60. EMD was significantly longer in C50 than in C60. There were no significant differences in MTPT. The time delay was the largest at the first MVC that the timing of light stimulus was changed, and gradually decreased with the repetitions. Changes in PA near the deep aponeurosis from the light stimulus to the peak torque tended to be larger in C50 or C70 than in C60. The subject's self-evaluation on MVC performance remained unchanged. Discussion When the timing of muscle contraction was unexpectedly changed, the reaction time lengthened. This is similar to results obtained when the visual information was interrupted (Takase et al., 2009). The delay would be mainly caused by the central nervous system if the timing is hastened. On the other hand, it might be related to the knee joint movement if the timing was delayed. VL contracted so that the fascicle might bite at the deep aponeurosis tightly. It looked as if VL tried to make up for the delay in response. However, the muscular movement like snapping may cause irregular strain of the deep aponeurosis and result in muscle strain injuries at myotendinous junction (Garrett, 1990). The subjects could not recognize differences in the timing of muscle contraction. This suggests that the subject's kinesthesia does not always agree with the actual movement. ## IN VIVO MUSCLE FIBER BEHAVIOR DURING A 100-CONSECUTIVE JUMP

Tsutsumi, M., Mori, Y., Hirose, K., Ogiso, K.

*Kogakkan University*

**Introduction** An exhausting SSC exercise decreases EMG activity and joint stiffness (Horita et al., 1999a, b) during the 1st half of the ground contact phase, which results in the decrease in positive work during the following concentric phase. The present study was designed to examine how an exhausted SSC jump affects functions of the gastrocnemius lateralis muscle (GL). **Methods** Fourteen healthy males were volunteered in this study. They performed a maximal 100-consecutive both-legs jump without information of number of the repetitions. They were instructed to put both hands on the waist and to make the contact time as short as possible. Longitudinal sectional images of GL were obtained. A point (P) where a fascicle arose from the deep aponeurosis and the other 4 points on the fascicle and deep aponeurosis 1cm and 2cm away from the point P were digitized. From the coordinates, pennation angle (PA) and movement of point P was measured for the ground contact phase. Electromyographic activity was measured from 8 leg muscles. The EMG was full-wave rectified and averaged (aEMG) for the ground contact phase. Jumping movement was filmed at 300Hz to calculate the leg joint angles. Blood samples were collected to measure the blood lactate (BLa) concentration before and after the jump. **Results** Jumping height was significantly lower in 91-100th jump ( $17.1 \pm 4.8$ cm) than in 1-10th jump ( $25.5 \pm 5.7$ cm), whereas ground contact time tended to increase from  $204.7 \pm 31.2$ ms to  $238.9 \pm 49.1$ ms. Movement of point P tended to decrease from  $0.28 \pm 0.18$ cm to  $0.18 \pm 0.14$ cm. PA remained unchanged at land-on and take-off, but changes in PA tended to decrease from  $3.4 \pm 1.9$ deg to  $2.6 \pm 1.1$ deg. aEMG tended to decrease in every muscle. Changes in the ankle joint angle significantly decreased for the ground contact phase. In the 2nd half, it tended to decrease, whereas changes in the hip joint angle tended to increase. BLa was significantly increased after jumping ( $1.8 \pm 0.5$  mmol/L to  $5.9 \pm 2.3$  mmol/L). **Discussion** The present study demonstrated that GL had not been able to contract smoothly by an exhausted SSC jump. This is in agreement with results obtained by the other repeated exercise (Sakuma et al., 2009). Fatigue caused by a 100-consecutive jump hindered shortening of the muscle and change in PA, which lengthened the ground contact time and finally decreased the jumping height. It is probable that the hip extension was emphasized in the 2nd half of ground contact phase to compensate the decrease in GL function in the latter half of the jump. **References** Horita T, Komi PV, Nicol C, Kyröläinen H. ## EFFECT OF RELAXATION RESPONSE TIME BASED ON DIFFERENT TONIC LEVELS

Yotani, K.1, Tamaki, H.2, Nakamoto, H.1, Yuki, A.3, Kirimoto, H.2, Takahashi, H.2, Kitada, K.4, Ogita, F.1

*1:National Institute of Fitness and Sports, 2:Niigata University of Health and Welfare, 3:National Center for Geriatrics and Gerontology, 4:Ishikawa National College of Technology*

**Introduction:** Response time of relaxation reflects an important role in the execution of movement in humans (Buccolieri et al., 2003; 2004). However, effects of different tonic levels on response time are not well understood. We examined relaxation response time in the triceps surae muscle and assessed the effects of different tonic levels. **Method:** Eight healthy male athletes (mean age,  $23 \pm 2$  yrs) were studied using simple visual reaction tasks. The tasks, an isometric contraction or relaxation of the right triceps surae muscle, were performed as quickly as possible in response to a visual signal. Contraction response time (C-RT) was measured from the visual signal to electromyogram (EMG) activity onset of the triceps surae muscle. The relaxation tasks used three tonic levels, that is, 25%, 50%, or 75% of the maximum voluntary contraction (MVC). Relaxation response time (R-RT) was measured from the visual signal to the termination of EMG activity. EMG was recorded from the right-lateral gastrocnemius (LG), medial gastrocnemius (MG), and soleus (SOL) muscle simultaneously with production of the light signal. **Results:** R-RT in LG, MG, and SOL muscle showed a tendency to become longer in order of 75%MVC to 25%MVC as the tonic level increased. R-RT of 25%MVC was significantly longer than C-RT in the MG and SOL muscles ( $P < 0.05$ ). Moreover, the R-RT of 50%MVC or 75%MVC was significantly longer than C-RT in all three muscles ( $P < 0.05$ ). The relative increase in R-RT of 75%MVC to C-RT (100%) did not differ significantly between muscles. However, the relative increase in R-RT of 25%MVC was significantly lower in the LG muscle than in the MG or SOL muscles ( $P < 0.05$ ). **Conclusion:** These results suggest that R-RT in the triceps surae muscle increases as the tonic level increases. In addition, compared with C-RT, the R-RT has different effects in different muscles depending on the tonic level. **References:** Buccolieri A., Avanzino L., Trompetto C., Abbruzzese G. ## INFLUENCE OF QUADRICEPS FORCE EXERTION ON TRICEPS SURAE ACTIVITY DURING PLANTAR FLEXION

Suzuki, T., Kinugasa, R.

*Kanagawa University*

**Introduction** Leg lengthening is fundamental for various activities of daily living, such as sit-to-stand and walking. Leg lengthening is composed of hip extension, knee extension and plantar flexion. Some recent studies have reported that activation of knee extensors and flexors provoked changes in activities of the plantar and dorsiflexors, and vice versa (Aruin, 2001; Hwang et al., 2001). We therefore investigated changes in triceps surae activity with quadriceps activation during isometric voluntary plantar flexion. **Methods** Nine healthy male subjects produced 10 - 100% of the maximum voluntary plantar flexion torque (% MVC) every 10% MVC. For each plantar flexion, the subjects were asked to perform the force exertion of the quadriceps at 0%, 50%, and 100% of the maximum voluntary knee extension (% KEMVC). Electromyographic activity was recorded from the triceps surae during all the tasks. **Results** The integrated electromyographic activity (IEMG) significantly altered ( $p < 0.05$ ) for the Sol with quadriceps activation, but not for the medial ( $p = 0.79$ ) and lateral gastrocnemius ( $p = 0.29$ ). The significant increases in the IEMG of the Sol were observed between 0% and 50%, 50% and 100%, 0% and 100% KEMVC. **Discussion** The novel finding was that Sol activity increased under quadriceps activation during isometric plantar flexion. In physiological point of view, the central drive may provoke an increase in Sol activity and a decrease in the activities of the other plantar flexors to maintain a given plantar flexion torque. Because there are a facilitatory heteronymous projection from the quadriceps to the Sol and inhibitory pathways from the quadriceps to the other plantar flexors such as the peroneus brevis (Meunier et al., 1993), it is possible that these peripheral neural inputs are related to observed modulation of the activities of the plantar flexors. **References** Aruin AS. 2001. *Percept Mot Skills*, 92(2), 563-8. **IMPORTANCE OF TENDINOUS TISSUE LENGTHENING DURING THE INITIAL PHASE OF EXPLOSIVE POWER EXERTION**

Edamatsu, C., Kusumoto, K., Yamaguchi, H., Iida, T., Yamano, C., Kawakami, M.

*Kurashiki University of science and the arts*

**Introduction:** Explosive power is required during dynamic movement in sports. Studies on the mechanism underlying explosive power have clarified the importance of tendinous tissue (TT) during movement with the help of ultrasonography. This study aimed to examine the mechanism underlying explosive power by observing the behavior of the muscle-tendinous complex during the drop jump (DJ) in athletes and non-athletes. **Methods:** Five male athletes who were long or triple jumpers (age,  $24.4 \pm 4.1$  y; height,  $169.5 \pm 6.5$  cm; weight,  $61.4 \pm 5.3$  kg; personal best record,  $7.35 \pm 0.52$  m or  $14.93 \pm 0.78$  m) and 5 male non-athletes (age,  $20.0 \pm 1.0$  y; height,  $168.6 \pm 3.3$  cm; weight,  $54.6 \pm 4.6$  kg) volunteered to participate in this study. Change in the TT length of the gastrocnemius medialis (GM; the distance from the muscle tendon junction to the calcaneus along the line of action of the tendon) during DJ from a height of 0.3 m was measured using a high-speed camera and ultrasonography equipment. Electromyographic parameters and ground reaction force were measured in synchrony with the camera and ultrasonography equipment. **Results and Discussion:** The reactive strength index (RSI) was greater in athletes ( $2.95 \pm 0.22$ ) than in non-athletes ( $1.18 \pm 0.24$ ). Athletes pre-activated the GM muscle and increased the TT length during the subsequent braking phase of DJ. In contrast, non-athletes hypoactivated the GM during the contact phase. Therefore, non-athletes could not sufficiently increase the TT length during the subsequent braking phase. A significant difference was noted in TT lengthening during the braking phase between athletes and non-athletes, but there was no significant difference in maximum lengthening of the TT during the push-off phase. However, individual differences in the TT stiffness were noted. Therefore, we compared the correlation between the RSI and TT-lengthening of individuals. The RSI correlated significantly with TT lengthening during the braking phase ( $r = 0.758$ ,  $p < 0.05$ ), but no correlation was found between RSI and maximum TT lengthening during the push-off phase. **Conclusion:** These results suggest that lengthening of the TT is extremely important during the initial phase of exertion of explosive power.

**EFFECTS OF DIFFERENT LOADS IN A SLED TOWING SPRINT ON STIFFNESS. A PILOT STUDY**

Cánovas, J.I, Márquez, G.I, Marfínez-Valencia, M.2, Marín-Pagán, C.1, Alcaraz, P.1

*1: UCAM (Murcia, Spain), 2: UCLM (Toledo, Spain)*

**INTRODUCTION** Sled towing training has become a popular method for speed training. However, its effects on running kinetics remain unclear. Few studies have been performed on how resisted training can affect vertical and leg stiffness (Brughelli et al., 2008; Alcaraz et al., 2012). The purpose of this study was to investigate how stiffness is affected by different sled towing loads during sprint. **METHODS** Twelve healthy active volunteered men ( $24.9 \pm 2.6$  years;  $81.0 \pm 8.1$  kg;  $1.79 \pm 0.06$  m) participated in this study. After a specific warm-up, subjects performed 10 x 10m sprints in different conditions: unresisted, and by towing 10, 15, 20 and 30% of their body mass (Bm) added on the sled. Two trials were performed under each condition. The order for the trials was randomized and a 3-min rest period was allocated to remove the effects of fatigue. Vertical (Kvert) and leg (Kleg) stiffness in the 8-10 m interval were estimated based on the modelling proposed by Morin et al., (2005), from mechanical parameters: body mass, forward velocity, leg length, flight time and contact time. Flight and contact times were obtained from a 4-m contact platform, and forward velocity was calculated by a photocells system. **RESULTS** Repeated-measures ANOVA revealed significant differences in vertical stiffness between unresisted sprints and all loaded sprints ( $p \leq 0.05$  for all trials). Similarly, there were differences between lower (10, 15% Bm) and higher (30%) loads ( $p = 0.05$  and  $0.02$ , respectively). However, no statistical differences were found in leg stiffness ( $p > 0.05$ ). **DISCUSSION** These data showed that load on sled causes a decrease in Kvert compared with an unresisted sprint. Furthermore, differences between lower and higher loads were found, which may indicate that magnitude of load will provoke different effects on stiffness. That may be explained due to an increase of contact time in stance phase, and a greater CM vertical displacement when load increases (Morin et al., 2005). However, Kleg is not affected by external load added on the sled. Non significant changes in displacement of the leg spring (from the initial leg length) may explain these results (Morin et al., 2005). Nowadays, only one study (Alcaraz et al., 2012) has focused on effects of weighted sled training on stiffness, but no significant differences were found after applying the training protocol. Future studies are needed to determine whether these acute effects will produce stiffness adaptations when sled towing training protocols were applied. **REFERENCES** Alcaraz PE, Elvira JL, Palao JM. **14:00 - 15:00****Mini-Orals****PP-BN14 Motor Learning [ML] 3****EXAMINE THE PROCESS OF TRANSITION ON LEARNING THE WHOLE BODY MOVEMENT COORDINATION**

Chen, H.H.1, Fang, Y.Y.2, Hsu, Y.F.2

*1: Taitung University 2: Laboratory Elementary School of Taitung University*

**Introduction** The sudden change of progress from unable to able to perform a motor task is one of the most interesting topics in motor learning. It has been found that the learning condition affects the dynamics of learning system. To investigate the process of transition and the effect of learning condition on the whole body movement coordination, the present study manipulated the task difficulty in learning the novel task of riding the bicycle on a roller training plate and analyzed the coordination of whole body movement during the process of acquisition of this skill. **Methods** Sixteen male college students and four elite cyclers participated as the learners and experts respectively. The learners will be grouped into two (8 per group) in terms of learning condition of difficult and easy when they practice to ride. The goal frequency for rotation of wheel was modified as the learner can ride continually. The transfer tests of easy/difficult condition were implemented immediately after practice. The successful riding time, the difference of speed between the goals and riding (error of goal speed, EGS) and the kinematics of markers attached on whole body segments were record for analyses. **Results & discussion** Compared to the experts, no significant difference of EGS was found for the learners indicated the skill of task in this study was obtained by most of the learners. Three types of progress (typical, fast and slow) at the beginning of practice in terms of successful time at the begin-

ning of learning were found. There were 7 learners in the typical s shape learning curve in which an abrupt change from 0 second of riding time to more than 10s riding time was shown. The slower learners (4) also show s shape learning curve but with more trails between unable and able riding. The fast learners (5) could ride more than 10s in about two trials. Subsequently, the learners rode under goal of speed in the exponential curve implicated the stable movement coordination has been formed. PCA on the kinematics data reveals that 6 components could explain 86% of variance in whole body movement. The indicator of components showed that the coordination of up and down motion of legs and the balance of whole body changed during transition related to the progress curves for the representative learners. No difference of EGS was found between easy and difficult learning condition was found in transfer tests. The transition of whole body movement coordination in the present study seems to correspond to what was found in literatures and could be explained by the saddle node transition. The influence of learning condition on the application of skill instruction will be discussed.

### ROBOT-GUIDED IMPLICIT SENSORIMOTOR LEARNING CAN SHAPE THE MOVEMENT PATTERN

Kümmel, J., Kramer, A., Pfeiffer, L., Gruber, M.

*University of Konstanz*

Background: Facilitating and accelerating motor (re-)learning is the goal of coaches, teachers and therapists. In neurorehabilitation, end-effector robot-aided rehabilitation devices have been successfully tested, e.g. to improve gait in stroke patients (Merholz 2009). However, it is not clear whether robotic devices guiding the learner through the trajectory of a movement (such as a tennis stroke or a golf swing) can facilitate motor learning in healthy subjects. In addition, it is not known if robot-guided learning requires the learner to be aware of the intended movement trajectory (explicit learning) or not (implicit learning). The aim of this study was to investigate if robotic guidance can be used to implicitly shape the movement pattern of a golf swing. Methods: 34 healthy participants were assigned to one of the following 3 groups: the first and second group (EA, n=12; LA, n=11) practised golf swings, whereas the control group (CON, n=11) did not practice. The difference between the two intervention groups was that in the EA group, the wrist was bent early during the upswing phase of the robot-guided swings, whereas in the LA group, it was bent late in the upswing phase. The participants were unaware of the existence of these different interventions. The two-week training period comprised 5 sessions. Each session consisted of 5x10 robot-guided golf swings with 5x2 non-guided golf swings in between. To divert the participants' focus of attention from the wrist angle, they were instructed to focus on the correct start position, the velocity of the golf swing and the correct position at the end of the upswing. Before (PRE) and one day after the end of the training period (POST), 6 non-guided golf swings were recorded with a motion analysis system. Results: The analysis of variance (3x2, group x time) revealed a significant group x time interaction effect for the wrist angle during the upswing phase. In the early upswing phase, the wrist angle decreased in EA only (PRE 163±9° to POST 153±18°,  $p < 0.05$ ), whereas no significant differences emerged in LA (PRE 157±13°; Post 158±14°) or CON (PRE 160±6°; Post 162±9°). Discussion: The robot-guided training intervention was successful in implicitly shaping the intended movement pattern, here the time-course of the wrist angle. This might have implications for the motor skill learning of complex motor tasks in general: as beginners do not have an internal model of the correct movement yet, the actual movement cannot be compared to the internal model of the correct movement (Sanger 2004). Robotic guidance might provide the beginner with such a model, potentially accelerating the learning process.

### IMITATION OF BIOLOGICAL AND NON-BIOLOGICAL MOTION DISPLAYED IN A NON-HUMAN AGENT IS MODULATED BY SELECTIVE ATTENTION

Dutoy, C., Bennett, S.J., Elliott, D., Gowen, E., Hayes, S.J.

*1: LJMU (Liverpool, UK), 2: McMaster University (Canada), 3: University of Manchester (Manchester, UK)*

Introduction The acquisition of new motor behaviours requires a person to copy a movement that is not already represented in their own repertoire. This process is known as voluntary imitation and depending on environmental context and nature of the observed stimulus, lower-level (sensorimotor) and top-down (attention) processes are engaged. Here, we examined whether selective attention (attention directed to a specific aspect of a movement) and end-state goals modulate lower-level processes that code biological (unnatural or natural velocity generated by a human) and non-biological (constant velocity generated by a computer) motion. Methods Thirty-six participants were assigned to a general-attention or specific-attention group. The general-attention group was instructed to reproduce the agent, whereas the specific-attention group was instructed to imitate the exact motion trajectory profile of the agent. During 84 trials each group imitated a non-human agent (white dot) in a goal-directed (moved to a target) or goal-less (moved to no-target) context. The motion trajectory profile of the agent was manipulated across trials to display natural, unnatural or constant velocity. The dependent variables were analysed using repeated measures ANOVAs. Results The performance data revealed a main effect of attention:  $F(1,34) = 4.734$ ,  $P = 0.036$ . Post-hoc testing showed the general-attention group, irrespective of motion trajectory and target presence, was more accurate ( $p < 0.05$ ) at replicating movement time than the specific-attention group. The kinematic data showed that both groups replicated the different motion trajectory profiles,  $F(2,68) = 115.345$ ,  $P < 0.01$ . Importantly, a Group x Motion interaction  $F(2,68) = 4.673$ ,  $P = 0.013$  indicated the specific-attention group was more accurate at replicating the natural and constant velocity motion trajectory profiles than the general-attention group. Discussion The findings show that biological (unnatural velocity) and non-biological (constant velocity) motion are coded during voluntary imitation. Moreover, the ability to imitate movement time and movement kinematics was modulated differentially as a function of attention. Top-down factors (attention) were shown to affect lower-level visuo-motor processes in automatic imitation (Heyes, 2011), but the current data set are the first to show this interaction during complex imitation. References Heyes, C. (2011). Psychological Bulletin, 137(3), 463-483.

### EFFECTS OF PLAYING BEHAVIOUR ON MENTAL REPRESENTATIONS AND BALANCING SKILLS IN PRESCHOOL CHILDREN

Augste, C.I., Tulis, M.2

*University of Augsburg*

Introduction For preschoolers associations between coordination and cognitive abilities have been demonstrated, especially in the sector of visual and spatial perception and spatial thinking (Payr, 2011). In the context of decreasing movement occasions for nowadays children, the present study aims to investigate the influence of playing behaviour on mental body representations and coordination skills. Methods As part of the School Entry Health Examination 1,489 children (726 female, 763 male, Mage = 5.8 years, SD = 0.3) completed a balancing test (backwards on a 6 cm wide beam) and a man drawing test (MZT) (Brosat & Töttemeyer, 2007). Children's outdoor playing behaviour and playing time with electronic devices were recorded by a parental questionnaire. Using a path model, the influence of these two variables on cognitive representations of the human body (MZT) and to the balancing skills was tested. Results All paths in the

model were significant ( $p < .004$ ,  $\chi^2 = 52.4$ ,  $df = 9$ ,  $CFI = .97$ ,  $RMSEA = .057$ ). Increased playing time with electronic devices was significantly associated with a reduced outdoors playing time ( $\beta = -.17$ ) and had a negative impact on the performance in the MZT ( $\beta = -.08$ ). Both a high level of outdoors playing time ( $\beta = .07$ ) as well as a good score in the MZT ( $\beta = .11$ ) were associated with better performance in balancing. Discussion A well-developed coordination and mental representation of the body are important enrolment requirements. The findings underline that in kindergarten long term use of electronic media have a negative effect on it. By contrast, pre-schoolers, who frequently have motion-based interactions in the direct environment, generate skills that are supportive for the cognitive and motor development. ### SENSORIMOTOR ADAPTATION AND TRANSFER AFTER ONE-SIDED AND ALTERNATING PRACTICE: EXTENSION OF THE STANDARD STATE-SPACE MODEL AND INSIGHT INTO CORTICAL PROCESSES

Griepernau, B., Mierau, A., Werner, S., Strüder, H.K.

*Institute of Movement and Neurosciences*

Introduction: Sport-specific studies addressing bilateral training practices have shown that a training of the non-dominant extremity can enhance the performance of the dominant extremity not only for beginners, but also for experienced athletes (e. g. Haaland and Hoff 2003). This effect is typically attributed to a contralateral transfer of motor learning. The aim of the present study was to investigate the mechanisms underlying sensorimotor adaptation and transfer after one-sided and alternating practice. Methods: Sensorimotor adaptation experiments have been performed to quantify the rates of adaptation and transfer after one-sided and alternating practice. In parallel, the electrocortical activity of the subjects was measured by electroencephalography (EEG). A mathematical model for the adaptation process in the brain was set up and evaluated by fitting to the experimental data. Results: It was found that intermanual transfer occurs for both unilateral as well as alternating practice. The adaptation process did not differ significantly for one-sided training with the dominant or the non-dominant hand, but for alternating training. Extending the standard state-space model for sensorimotor adaptation (Thoroughman and Shadmehr 2000, Taylor and Ivry 2011) to the alternating practice, the mental representation of the adaptation could be addressed. The data suggests that for alternating practice different learning rates for the two hands apply, that are furthermore different from the unilateral learning rates of the respective hand. The EEG data revealed within and between group differences in the alpha band over contralateral and ipsilateral sensorimotor areas during adaptation. Discussion and Outlook: Our results contribute to the understanding of the general underlying principles effective during contralateral motor transfer. This can help to optimize bilateral training practices in sports and might also be used in the rehabilitation of patients with hemiplegia. Thus, the use of the non-dominant hand can be used as a specific impulse in movement acquisition. References: E. Haaland, J. Hoff (2003). *Scand. J. Med. Sci. Sports*, 13:179–184, 2003 K. A. ### BENEFITS OF THE QUIET EYE: IT IS THE SEEING, AND NOT THE LOOKING

Klostermann, A., Hossner, E.J.

*Institut of Sport Science*

Introduction Although the performance-enhancing effect of the quiet eye (QE) is well documented (e.g. Vickers, 2011), until now, underpinning mechanisms have been studied only rudimentarily. Therefore, an inhibition hypothesis is proposed, postulating that the QE period is crucial for the inhibition of movement variants so that the most appropriate variant can be optimally parameterized (Klostermann, 2012). The aim of this study was to test a central prediction of this hypothesis by examining whether QE effects depend on the availability of relevant visual information over the QE period. Methods In a within-subject design both, QE onset and information availability were manipulated using an experimental paradigm in which 20 participants had to throw balls as accurate as possible at a virtual target disk (Klostermann et al., in press). The manipulation consisted of a peripheral flicker cue to evoke a final fixation earlier or later at one of four possible target positions at which correspondingly the target disk was presented earlier or later. QE onset and offset – i.e. beginning and end of the last fixation on the target position before movement initiation – as well as the radial error (RE) were calculated as dependent variables and analyzed by 2 (QE onset) x 2 (target onset) ANOVAs with repeated measures and planned t-tests. Results The QE manipulation was successful as, independent of target onset, earlier QE onsets were found in the early compared to the late QE onset conditions,  $F(1, 19) = 34.7$ ,  $p < .001$ ,  $\eta^2 = .65$ . No differences in QE offset were revealed. Beyond that, RE was significantly lower in the early compared to the late target onset condition,  $F(1, 19) = 4.6$ ,  $p < .05$ ,  $\eta^2 = .19$ . Finally, a significant QE onset x target onset interaction was found,  $F(1, 19) = 5.4$ ,  $p < .05$ ,  $\eta^2 = .22$ , revealing performance differences only between the early QE / target onset condition and the remaining three conditions (all  $ps < .05$ ). Discussion The results support the inhibition hypothesis in so far as throwing performance did not depend on the QE duration per se but on the duration in which information about the actual target position was displayed over the QE period. This finding indicates that QE benefits are based on the effective use of task relevant visual information, further emphasizing the functionality of the QE for offline parameterization processes (e.g. Klostermann et al., in press) as being proposed in the inhibition hypothesis. ### ADEQUACY LEVEL IN CHILDREN FOR VARIABLES OF STATIC AND DYNAMIC BALANCE IN RELATION TO THE NUTRITIONAL STATUS

Dorst, D.G.B.1, Barbeta, C.J.1, Dorst, L.M.2, Roman, E.P.1, Barbeta, V.J.1, Alves, A.C.3, Barros Filho, A.A.4

1: FAG(Cascavel, Brasil) e UNICAMP (Campinas, Brasil), 2: FAG (Cascavel, Brasil) e Secretaria de Estado do Esporte (Curitiba, Brasil), 3: FAG(Cascavel, Brasil), 4: UNICAMP (Campinas, Brasil).

Introduction Current children are impaired, because they have a few daily tasks, due the high demand of technological advances, computers, games, TVs, finally, any task that demands a low physical effort is considered sedentary. These aspects have been causing problems of growth and motor development of children. The aim of this study was to associate static and dynamic balance with nutritional status of children in preschool age. Methods The sample consisted of 201 preschool age children (mean age of 3.95 months) enrolled at the Childhood Education Center and public schools of the city of Cascavel – Paraná. For BMI assess, was used the formula: height divided by squared weight. The Age Classification of Center for Disease Control and Prevention was used as reference for data comparison (CDC-NCHS, 2000). To verify neurofunctional development, the Neurological Exam of Lefèvre (1972) was performed, specifi-

cally for static and dynamic balance. The study was accepted by the Ethics Committee of Assis Gurgacz Faculty, nº 112/2011. The statistical analyses were processed by SPSS, version 15.0 for descriptive statistic with percentage calculation and qui-squared test, with a level of significance of 5%. Results No significant difference was found between the balance proportions when compared with BMI groups. The best index of adequacy was verified at tests of static and dynamic balance for children with a proper classification of BMI, and the worst results were found for those who were with percentile above 85, which already requires care. 34% presented inadequacy at tests of static balance (18% female, 16% male), 43% inadequacy at tests of dynamic balance (16% female, 27% male). 16% of children are obese (5.5% female, 11% male). Discussion High levels of body mass are observed, which harms a good motor development, also of balance, although not significant statistically, but should be an expressive factor to settle in long-term. ### **NUTRITIONAL STATUS OF CHILDREN FROM CHILDHOOD EDUCATION CENTER OF THE CITY OF CASCAVEL-PARANÁ**

Dorst, D.G.B.1, Barbeta, C.J.1, Dorst, L.M.2, Roman, E.P.1, Barbeta, V.J.1, Barros Filho, A.A.3

1: FAG(Cascavel, Brasil) e UNICAMP (Campinas, Brasil), 2: FAG (Cascavel, Brasil) e Secretaria de Estado do Esporte (Curitiba, Brasil), 3: UNICAMP (Campinas, Brasil).

Introduction The rhythm of nutritional transition at developing countries is a much debated issue, which many study shows very rapid changes from innutrition to obesity between children and adolescents, while others studies shows an evident coexistence of innutrition and obesity (Clemente, 2011). The aim of this study was to verify the nutritional status of children enrolled at Childhood Education Center of the city of Cascavel-Paraná. Methods The sample consisted of 209 children (102 females and 107 males) from 24 Educational Centers, with age from 3 to 5 years. The age classification from the Center for Disease Control and Prevention CDC-NCHS, 2000) established the proper BMI for children between ages of 2 to 20 years. Results 90% of children presented ideal weight, 6% requires care and 3% weighting a little less than ideal. 75% optimum height, 11% requires care, 6% demands attention and 7% above the height. Weight was appropriate for both sexes (68%), 18% with overweight risk, 11% with underweight risk and 3% with underweight. According to the BMI percentile classification, from females, 1% of underweight, 4% of underweight risk, 67% normal, 17% overweight and 11% obese. For males, 6% underweight, 11% underweight risk, 55% normal, 7% overweight and 21% obese. Discussion The majority sample was within the normal range. Significant Index was of 17% of children that presented overweight risk to height and 11% with obesity, for female, and for male 7% with overweight and 21% with obesity. Reinforcing data found at Foschini study, Campos (2010) with 38.37% of overweight. The obesity prevalence was 15.78%. These data shows a trend to obesity in Brazilian children, requiring an urgent attitude from the public health. References Campos JADB, Foschini ALR. ### **EFFECTS OF A PRE-PERFORMANCE ROUTINE ON BASKETBALL FREE-THROW TRAINING IN A COLLEGE PHYSICAL EDUCATION CLASS**

Nagata, N.

*Keio University*

Introduction Pre-performance routine (PPR) is a cognitive and behavioral strategy used to obtain the optimal state relative to the performance of successful tasks. Previous research reveals that, for non-experts attending college golf classes for 8 weeks (3 times a week; 24 sessions in total), skills training with a PPR improved the objective assessment (Crews & Boutcher, 1996). The purpose of this study was to examine whether the PPR on basketball free-throw training in a college physical education class can improve performance in a shorter period than that arrived at in Crews and Boutcher's research. Method The participants in this study were 19 undergraduate students enrolling in two college basketball classes (class A = 12, class B = 7). The classes comprised 14weeks (held once a week; 14 sessions in total). In the first session, 20 foul shots were performed as a pretest after obtaining the participants' informed consent. In the second session, the participants enrolled in class A were given an explanation about the PPR, and each participant established a consistency behavior as a PPR executed prior to each shot. Next, they performed 20 free throws as an instruction test. The participants enrolled in class A performed the instruction test along with the PPR. In contrast, the participants enrolled in class B performed the instruction test with no PPR. From the third to twelfth sessions, each participant was given a free-throw training for 5 minutes. In the thirteenth and fourteenth sessions, the participants performed 20 shots each as a post-training test; the higher result from the two post-training sessions was taken as the posttest score. The results of the pretest, instruction test, and posttest in each class were compared using a Friedman test. Result The mean and standard deviation of successful shots in class A in each test were pretest:  $7.75 \pm 3.52$ , instruction test:  $7.67 \pm 3.87$ , and posttest:  $10.33 \pm 2.84$ . On the other hand, the corresponding results in class B were pretest :  $6.29 \pm 3.68$ , instruction test:  $6.43 \pm 5.06$ , and posttest:  $9.00 \pm 4.51$ . The Friedman test revealed that there was a significant difference in the performance of class A ( $p < .05$ ). A post-hoc analysis indicated that the result of the posttest was higher than that in the instruction test ( $p < .05$ ). Discussion The results of this study show that including PPR in skill training increases the number of successful shots performed in spite of fewer sessions. Cohn (1990) suggests that PPR is utilized for establishing and selecting motor parameters on the basis of the schema theory; this suggestion was also included in the participant interviews in this study. Therefore, it is assumed that including PPR in skill training would be useful in the efficient learning of skills. References Cohn, P. J. ### **A NEW APPROACH TO DECISION-MAKING ABILITY INTRODUCING A NEW CONCEPT "KAN" AS THE DECISION-MAKING ABILITY**

Sato, M.

*Numazu College of Technology*

In ball games, it is important that the player always grasps the constantly changing game situations and copes with each situation by optimal actions. Such ability is called the decision-making ability. Although a large number of studies have been made on the decision-making ability in a field of sports psychology, the results of those researches do not function effectively in practice (Akira, N., 1985; Hiroshi,

A., 2012). Therefore the aims of this study are to critically examine the previous researches on decision-making, clarify the problem of such researches, and show the validity of a new concept "KAN" for the decision-making ability. Through a comparative examination, the central issue in the previous researches was made clear. This issue was to break up the decision-making ability into the tactical thinking ability (to analyze a game situation and to select a play) and the execution ability in a play. In this case (to consider a play selection to the exclusion of a play execution), the best play in each game situation becomes the standard for the selection. For that reason, if a player does not select the best play, it is a wrong selection. However, the optimal play selection in each game situation should be different depending on the player's skill (the execution ability in a play). In short, the optimal play in a game situation must be considered based on the player's execution ability. As opposed to the above-mentioned approach, the term "Kan" can be defined as the unified ability to select the optimal play (action) in a game situation and execute this play (action) (Akitomo, K., 2005). "Kan" is the concept which is considered from a player's standpoint. In this concept "Kan", the relationship between the tactical thinking ability and the execution ability in a play is considered to be like the two sides of the same coin. For that reason, the player can select only the action (play) in accord with his execution ability. This idea has an important meaning from a decision-making training point of view, because it should be possible to set a criterion for the decision-making ability by way of the execution ability, and to train the decision-making ability along with the training of the execution ability. It follows from what has been said that introducing a new concept "Kan" will produce a new course of action on decision-making studies in the future. References Akira, N. ##### IMPORTANCE AND USE OF NEW TECHNOLOGIES BY GENDER AND AGE FOR TEACHERS THAT WORK IN EXTRACURRICULAR SPORTS ACTIVITIES

Villalba-Pérez, A.1, González-Rivera, M.D.1, Campos-Izquierdo, A.2

1: *University of Alcalá (Alcalá de Henares, Spain)*, 2: *Polytechnic University of Madrid (Madrid, España)*.

**Introduction** Today, the new technologies take a very important role in the field of physical activity and sport in general and more specifically in the educational system. (Cabero et al, 2000). The aim of this study is to analyze the importance of extracurricular sports activities teachers attributed to the new technologies, and to know they use the new technologies by gender and age. **Methods** The quantitative methodology consisted of a cross-sectional survey. Cluster sampling was used. The final sample size was 188 teachers that work in extracurricular sports activities in schools in Spain. Data was collected through structured questionnaires with face-to-face interview. All the statistical analyses were done using the SPSS/Windows 19.0 statistical software. The inferential analysis with Cronbach's was .802. Signification levels were set at  $p < 0.05$ . **Results** The 53.28% of men considered very important to apply new technologies recognizing 45.2% use new technologies frequently. With respect to women, a 52.94% considered very important to apply and 37.25% use them frequently. By age 30, 45.24% considered very important to apply new technologies, between 30 and 44 years, 89.58% and from 45, 64.28%. Finally, comparing the old with the frequency of use, 38.89% use technology resources and internet very often up to 30 years, 56.25% between 30 and 44 years and 42.86% of those older than 45 years recognizes to use rarely or never. **Discussion** Men considered more important to apply new technologies than women and recognize use them more often. Between 30 and 44 years when greater importance attributed to new technologies coincide also when they use more. Recent studies have examined gender differences in a variety of contexts, including the internet use and these studies have revealed interesting differences in how men and women perceive the new technologies (Ilie, Van Slyke, Green & Lou, 2005). **References** Cabero, J., Salinas, J., Duarte, A.M., Domingo, J. ##### A PROGRAM FOR RESOLVING STUDENT DILEMMAS IN UNIVERSITY PHYSICAL EDUCATION CLASSES

Yuko, T.

*Keio University*

**Introduction** This study develops and verifies new life skill acquisition programs for high-level life skill students (high-skill group) in university physical education (P.E.) classes. Unlike middle- and low-skill groups, the high-skill group can apply pre-acquired life skills to P.E. class activities, thereby not acquiring new life skills in classes (Tokairin, 2012). Prior to beginning this study we assigned high-skill group students sport leadership roles within classes and gave them roles in leading others outside classes using online notes. The high-skill group's leadership facilitated communication throughout the class, and we found that high-skill group students acquired new life skills. **Methods** This study utilized 192 first-years in eight P.E. classes (104 male, 88 female) at private universities in Kanagawa prefecture. To monitor life skill level transition through classes we conducted surveys before and after the program. The interposition program involved group or class leadership through active communication with others using online notes. We used thirty items in the five subscales from 5 Life Skills Inventory. **Results** Using K-means clustering we categorized three groups: the high-skill group (intervention n31 / control n24), the low-skill group (intervention n20 / control n14), and the middle-skill group (intervention n50 / control n53). We reviewed the life skill level transition through P.E. classes by variance analysis using three factors: program (online notes intervention group / control group) x skill levels (high / middle / low) x timing (before / after). We confirmed secondary interactions at timing x program x skill level ( $F(1,181)=7.661$ ,  $p < .01$ ) in "choosing." In the "choosing" acquisition level before and after physical activities we confirmed a significant difference in the average of the high-skill group's intervention sub-group (25.16 → 27.26,  $p < .001$ ). **Discussion** In P.E. classes students have different skill levels and dilemmas occur between the high-skill group who are good at sports and the low-skill group who are not. For low-level students, it is rational to choose uncooperative behavior as a consequence of their strong feelings of inadequacy toward physical activity and interaction with others, and they cannot share the same goals with others at the beginning of the class. Additionally,

a dilemma can arise for the high-skill group when over-consideration of the low-skill group prevents them from fully performing. There is a class program for the low-skill group who are not good at physical activity to resolve these dilemmas, but there is no effective program for the high-skill group. In this study we discuss an effective program for the high-skill group based on the above issues. References Tokairin Yuko, 2012. "Influence of University Physical Education Classes on Students' Acquisition of Life Skills - Focusing on Students' Original Skill Level at The Beginning of the Course ". Keio SFC Journal 89-108.

### OPEN UNIVERSITY OF BRAZIL, DOES NECESSITY OVERCOME QUALITY?

Ribeiro da Silva, A., Alves, E.D., Barros, J.F.

*Universidade de Brasília e Universidade Federal do Rio Grande do Norte*

In Brazil, there are teachers working with Physical Education and other subjects without having a college degree. In 2005, the Open University of Brazil (Universidade Aberta do Brasil, UAB) was established, with many distance degree courses, in order to supply needs in cities where there are not qualified professionals, colleges or universities in their vicinity. The Physical Education College in the University of Brasília (FEF/UnB) has joined his experience and, in July 2007, it released a selection process for the distance physical education degree course, through the Pro-College Degree (only public system teachers who do not have graduation degree) and UAB (open to the general public). In the end of 2011, the course already had more than 500 frequent students in the North, Northeast, Midwest and Southeast areas of Brazil; and in January 2013, 200 new vacancies were opened for the referred course, beyond 1385 places for 6 other degree courses and 1 specialization course. Most students in the Physical Education course are teachers already, and they comply with a hard working journey, which – consequently – may cause doctent evasion and low performance during the course by students. EAD (Distance Education) researchers and workers are continuously trying to reduce these issues, however – and beyond – it is necessary for the workers' study and qualification, who deal with this category of teaching, to be better prized by public managers, making official the profession and the remuneration for the EAD professionals. Unquestionably, it will promote a good and significant reflection for the quality of basic and superior teaching of Physical Education in Brazil. References Fernandes, M. L. ### THE EDUCATIONAL PHILOSOPHIES OF PRE-SERVICE AND IN-SERVICE PHYSICAL EDUCATION TEACHERS

Baisch, B.1, Cai, S.2, Kornspan, A.3

*1.Westpark Community Middle School, 2.3. University of Akron, OH USA*

Introduction The development of a philosophy can aid a physical education teacher in dealing with various professional issues encountered. Employers often request that a teacher candidate present their professional philosophy of teaching. Therefore, physical education pedagogy professionals suggest that a philosophy be developed during one's educational preparation and modified based on knowledge and experience (Wuest & Bucher, 2009). The purpose of the present study was to analyze the educational philosophies of pre-service and in-service physical educators. Methods Current beliefs of physical educators toward five modern, educational philosophies as they were applied to physical education were investigated. A survey was constructed to identify educational philosophies of physical educators. The Inventory of Physical Education Philosophies Survey consisted of 30 close-ended statements, which required the participant to respond on a five-point Likert scale, ranging from Strongly Agree (5) to Strongly Disagree (1). Scores were added in order to have a final score of agreement toward each philosophy. A 6 was the lowest score possible and 30 was the highest score possible. A total scores of 23 or more showed strong agreement with a particular philosophy and total scores of 15 or less demonstrated strong disagreement with a particular philosophy. Seventy participants (35 pre-service and 35 in-service) completed the survey. Results Measures were evaluated on the total mean scores of each philosophical category between groups. Progressivism was found to be the category with the highest mean scores of agreement for both groups followed by social reconstructivism, existentialism, essentialism, and perennialism. Significant differences were found between the in-service and pre-service groups for the philosophies of perennialism, social reconstructivism, and existentialism ( $p < .05$ ). Discussion Findings of the study indicated that pre-service teachers' tend to move toward more progressive philosophical positions that support the findings by Ryan (2007). A high prevalence of student-centered philosophies implies that physical educators place a great deal of responsibility for learning on the students. Such findings may be a result of the promotion of democratic classrooms. Results further suggest that pre-service physical educators support student-centered philosophies to higher levels of agreement compared to in-service physical educators. References Ryan, T. G. (2007). The identification of pre-service teachers' philosophical orientation. *New Zealand Journal of Teachers' Work*, 4(1), 39-47. Wuest, D. A. & Bucher, C. A. (2009). *Foundations of Physical Education, Exercise Science, and Sport Studies* (16th. ed.). New York, NY: The McGraw-Hill Companies, Inc.

### PRE-SERVICE TEACHERS' PERCEPTIONS OF TEACHER EDUCATION PROGRAMS AND CONTRIBUTIONS FOR THEIR PROFESSIONAL LIFE

Sousa, T., Cunha, M., Batista, P.

*Faculty of Sport*

Introduction Teaching education should give practical and theoretical tools to assist students making the transition from academic education to professional training (Azevedo, Pereira & Sá, 2011). Usually, the practicum, in the context of initial training, seems to be a process that implies a conflict between what the pre-service teachers have and what they need to face the reality of the school context. In this way, a better understanding of this process can contribute to improve and renew the initial training programs. This study is the first step (an exploratory one) of a questionnaire validation to Portuguese language about student teachers' perceptions concerning teacher education and its contribution for their professional life. Methods Seventy two pre-service teachers participated in the study (39 women's) with a range age between 22 to 38 years old ( $24,18 \pm 0,37$ ). A preliminary Portuguese version of the questionnaire developed by Ezer, Gilat, and Sagee (2010) was used to collect data. The instrument contains five components: i) agents of training; ii) components of teacher training; iii) roles of teachers; iv) motivation for teaching; and v) conceptions of the teaching and learning process. A rank system of 1 to 7 was used in two leading components and a six point Lickert scale in the following sections. In data analysis descriptive statistics (mean and standard deviation) and Independent-Samples T-Test were used. Results and discussion The student-teachers ( $n=66$ ) mostly valued the cooperative teacher ( $2,80 \pm 2,23$ ) and the specific didactic teachers ( $3,50 \pm 1,89$ ). They also rate the teaching experience ( $2,39 \pm 1,96$ ) and the didactic classes ( $2,85 \pm 1,53$ ) as the most significant components of training. Concerning to teacher role they consider that is more relevant to develop the students' unique personal abilities ( $3,00 \pm 1,93$ ). Results also showed that the students-teachers are more extrinsi-

cally motivated for teaching ( $3,95\pm 0,79$ ) and to traditional conceptions ( $4,52\pm 0,68$ ) about the teaching-learning process contrasting, therefore with Ezer, Gilat and Sage's (2010) findings which highlighted more intrinsically motivations and constructivist conceptions about teaching and learning. On the other hand, the same ranking was found concerning to the components of teacher training. In this case the elements more valued for both in teaching experience were the cooperating teacher and the teachers from didactics. Acknowledgements This study is part of a project funded by University of Porto, multidisciplinary projects with the following reference: PP\_UJUP2011 69

### **VALIDATION OF A QUESTIONNAIRE TO ASSESS TEACHER SUPPORT OF POSITIVE BEHAVIORS IN PHYSICAL EDUCATION**

Sánchez-Oliva, D., Leo, F.M., Amado, D., Chamorro, J.M., García-Calvo, T.

*UNIVERSITY OF EXTREMADURA*

**Introduction** Education has been one of the main center of attention for public administrations, trying to reach the integration of the new generations in the society as the principal aim. Thus, there are numerous authors who emphasize physical education context as an ideal frame to personal and social development in adolescents, where physical education teacher is considered as a fundamental key in the positive development of adolescents (Armour et al., 2012). **Methods** Participants included 357 Spanish teachers (231 males and 126 females) aged 28 to 61 years (Mage = 39.41 years; SD = 8.61), and an average experience of 15.3 years. To carry out the aim of the study, an adapted version of the Questionnaire of Positive Behaviors in Physical Education (CCPEF: Sánchez-Oliva et al., in press) was used, adapting either the introduction sentence and the items included in that questionnaire. **Confirmatory factor analyses (CFA)** were also conducted on the study to test the psychometric properties with maximum likelihood estimation, including 18 questionnaire items as indicators and 5 factors as latent variables. Results Results analysis emphasized a structure formed by 18 items, grouped in five factors: Respect for rules and materials Support, Respect to others Support, Self-Control Support, Assessment of effort Support and Cooperation Support. The model fit indexes from the CFA were:  $\chi^2/df = 6.81$ ; CFI = .95; TLI = .94; SRMR = .05 and RMSEA = .06. The regression weights between items and latent variables ranged from .63 to .78. Moreover, self-report measures showed acceptable levels of reliability ( $\alpha > .70$ ). **Discussion** The current study provides an instrument that let examine teacher support about the development of positive behaviors in physical education pupils. Results are consistent with those found by Sánchez-Oliva et al. (in press), emphasizing a questionnaire with a structure formed by 18 items and 5 first order factors, which let assess to what extent teacher promotes personal (Self-Control and Assessment of effort) or social (Respect for rules and materials, Respect to others and Cooperation) adaptive behaviors. **References** Armour, K., Sandford, R., & Duncombe, R. ### **TO BE A TEACHER: THE ANTICIPATORY SOCIALIZATION IN PROFESSIONAL DECISION**

Queirós, P., Batista, P., Gomes, P.

*University of Porto / Faculty of Sport*

**Introduction** The practice is a central element in the process of teacher's socialization, but the way of life of each individual is also plays an important role in how they achieve his profession (Flores & Day, 2006). Regarding this evidences it is important to examine how the anticipatory socialization influences student's decision to come to an undergraduate program of Teacher Education. **Methods** For data collection, semi-structured biographic interviews were conducted with 10 student teachers that are in the first year of Teacher Education program, at the Faculty of Sport, University of Porto. The statements were audio recorded and transcribed verbatim. The transcriptions were submitted to a content analysis using the Nvivo10. This paper only focused the content about their motivations for coming to an undergraduate program of Teacher Education, in particular the socialization agents. **Results and discussion** Through the speeches of the participants were identified several socializing factors. These include experiences in PE classes and in sport practices out of the school (Curtner-Smith, 1999), success in sport (Evans et al. 1995) and interactions with PE teachers (Mawer, 1996). Specifically we can state that: i) Physical Education (PE) teachers emerged as the main socialization agent. Their exigency, motivation, knowledge, proximity, companionship and confidence are characteristics identified by the participants, awakening them the desire to be, in the future, PE teachers; ii) family seems to adversely affect this choice, feeding a duality between satisfactory professional achievement and the largest number of professional outlets; iii) PE classes and sports practice left significant marks in participants, and they usually tend to identify themselves with the main stakeholders (teachers and coaches). The feeling of satisfaction and skilful in the practice where they obtained recognition; iv) individual reflection, provided by some specific situations, revealed a crucial element in the decision process (worked like a booster). The history of the subject emerged as the stronger factor that influence how each student becomes a teacher. **Acknowledgements** This study is part of a funded project-Foundation for Science and Technology (FCT) with the following reference: PTDC/DES/115922/2009. **References** Curtner-Smith, M. ### **INCIDENCE OF THE EXPERIENCE AND ECONOMIC REMUNERATION ABOUT THE TYPE OF MOTIVATION IN COACHES IN SCHOLAR SPORT**

Pulido, J., Sanchez-Oliva, D., Leo, F.M., Gonzalez-Ponce, I., Sanchez-Miguel, P.A.

*UNIVERSIDAD DE EXTREMADURA*

**Introduction** In the sport context, there are numerous significant that spend their time on make the physical activity practice possible in scholar age. The coach, who is considered an important key in the integral teaching of children and adolescents who practice any affiliate sport (Jowett and Cokerill, 2003). Thus, this significant become a direct agent of socializing influences. Therefore, the main aim of the study is focused on the analysis of motivations which deals with a sport coach, as well as examines the influence of the experience and

economic remuneration of themselves. Methods Participated, a total amount of 154 voluntary coaches, 124 male and 30 female trainers (M = 32,4 years; SD = 6,51). To select the motives that coaches indicate to carry out their function, the adaptation into sport of the Work Motivation Inventory (WMI: Blais et al., 1993) was used. This instrument is composed by six types of motivational regulations: intrinsic, integrated, identified, introjected, external and amotivated. Moreover, an open question was used to measure the experience: "How many years are you working as a coach?". After analyzed the median of every sample, two different groups of coaches were selected regarding experience: coaches with experience (six years or more than six years of experience; n = 82) and coaches without experience (less than six years of experience; n = 72). The economic remuneration was assessed by a dichotomy question: Do you receive any economy incentive to train?" with two possible answers, "YES" (n = 46) or "NO" (n = 108). Results Coaches who received any economy incentive to train had significant higher scores in every reason to train (intrinsic, integrated, identified, introjected and external) than those coaches who did not receive any incentive, with the exception of amotivation. Furthermore, taking into account the experience as independent variable, there was not found any significant differences in the motivational regulations. Discussion Respecting the obtained results and taking into account the main aim of the study, motivational regulations showed significant differences with regard to a remunerated coach or a non remunerated coach, not only in those motivations referring to something external to the activity, such as introjected or external, but also those more self-determined regulations, such as intrinsic, integrated and identified. Therefore, coaches' motives to train will be influenced by the economy incentive, being crucial to show high self-determination levels. On the other side, there were not significant differences with respect to motivations because coaches' level of experience was considered. A coach with or without experience will not be difference in his/her impetus to develop the trainings. References Blais, R. et al., (1993). L'inventaire des motivations au travail. *Reveu québécoise de psychologic*, 14(3), 21-23. Jowett, S. and Cockerill, I.M. (2003). ### STATUS PROFESSIONAL OF TEACHERS THAT WORK IN EXTRACURRICULAR SPORTS ACTIVITIES IN SCHOOLS IN SPAIN: PERMANENT TRAINING BY AGE

González-Rivera, M.D.1, Campos-Izquierdo, A.2

1: *University of Alcalá (Alcalá de Henares, Spain)*, 2: *Technical University of Madrid (Madrid, Spain)*

Introduction The permanent training of teachers is essential to be able to adapt to all situations and deal successfully working. Therefore, the aim of this study is to explore the permanent training according age of teachers that work in extracurricular sports activities in schools in Spain. Methods The quantitative methodology consisted of a cross-sectional survey. Cluster sampling was used. The final sample size was 188 teachers that work in extracurricular sports activities in schools in Spain. Data was collected through structured questionnaires with face-to-face interview. All the statistical analyses were done using the SPSS/Windows 19.0 statistical software. The inferential analysis with Cronbach's was .802. Signification levels were set at  $p < 0.05$ . Results The study shows very low percentages of training of teachers of extracurricular sports activities in schools in Spain in the last four years (less than 32%). The main training activity that these teachers do is attending courses (31.9%), followed by 23,9% attending seminars, 10.6% attending congresses, 4.3% doing postgraduate or master's degrees, and only 2.1% carried working groups. By age 30, 25.2% of teachers attend courses, 25.2% seminars, 2.8% congresses, 0.3% do postgraduate courses and 1% do working groups. Between 30 and 44 years, 8.1% attend courses, 14.4% seminars, 1% congresses and working groups and do no postgraduate courses. Teachers older than 45 years, 2.4% attend courses, 3.6% seminars, 0.2% congresses and do no postgraduate courses and working groups. Discussion Data obtained shows lower percentages, in all age groups, than data obtained in studies of Campos-Izquierdo (2007) and González-Rivera (2008) in different regions of Spain, Valencia and Madrid, respectively. Younger teachers do more permanent training, data that differ from the two previously mentioned studies. References Campos-Izquierdo, A. (2005). Situación profesional de las personas que trabajan en funciones de actividad física y deporte en la Comunidad Autónoma Valenciana (2004). doctoral thesis. University of Valencia. Valencia. González-Rivera, MD. (2008). El deporte escolar en la comunidad autónoma de Madrid: intervención didáctica y recursos humanos en las actividades físico-deportivas extraescolares en los centros educativos. doctoral thesis. ### STATUS LABOUR OF TEACHERS THAT WORK IN EXTRACURRICULAR SPORTS ACTIVITIES IN SCHOOLS IN SPAIN

Campos, A.1, González, M.D.2

1: *Technical University of Madrid (Madrid, Spain)*, 2: *Alcalá University (Madrid, Spain)*

Introduction The importance of professionals that develop physical activity and sport is essential for safe and effective implementation and to ensure the benefits of physical activity (Campos, 2010). The employment status of teachers that work in extracurricular sports activities is important practice healthy physical sports of young (González & Campos, 2010). The objective is study of status labour (contracts, salary and entities) of teachers of extracurricular sport activities in the Schools in Spain. Methods The quantitative methodology consisted of a cross-sectional survey. Cluster sampling was used. The final sample size was 188 teachers of extracurricular sport activities in Schools in Spain. Data was collected through structured questionnaires with face-to-face interview between January and November 2011. All the statistical analyses were done using the SPSS/Windows 19.0 statistical software. The inferential analysis with Cronbach's was .802. Results The results of the labour relations o teachers of extracurricular sport activities in Schools in Spain reveals that the 60,3% of labour relations have no contract whatsoever and 2,1% of labour relations are of self-employment type. The type of contract of teachers of extracurricular sport activities is mainly of permanent contracts (51,9%) and temporary contract are 48,1%. Most of the contracts of these teachers are part-time contracts (55,1%), while full-time contracts are 44,9%. According to hours worked, earnings are highly diversified, 54,6% the teachers earn less than 300 euros a month, 25,7% between 300 and 1000 euros, 17,6% between 100,01 and 2000 euros and 2,1% earn more than 2000 euros a month. The entities for which those teachers we obtain that these are different. Among these entities, private entities are the majority as they are 82,3% and public entities are 17,7%. Discussion Most teachers of extracurricular sport activities in Schools in Spain don't have a contract and earn less than 300 euros a month. Also the teachers with contracts have permanent contracts and are part-time. In this job there are higher situations of precarious employment (Campos, 2010). It is therefore necessary to improve the employment status of teachers of extracurricular sport activities but to ensure the benefits of physical activity and practice healthy physical sports. ## STUDENTS' PERCEPTION OF THE NEW PHYSICAL ACTIVITY AND SPORT SCIENCES DEGREE IN SPAIN

Coterón, J., Franco, E., Gil, J.

*Universidad Politécnica de Madrid*

**Introduction** The implementation of the European Higher Education Area (EHEA) in Spain has not been a controversy free process. It's required monitoring and evaluation to know its strengths and weaknesses in order to do the change process successfully. The aim of this study was to analyze how undergraduate students of Physical Activity and Sport Sciences perceive the implementation of the new system. **Methods** A validated questionnaire (Coterón & Franco, 2012) was administered to 478 Physical Activity and Sport science students in order to know their opinion about new studies' quality respect to 4 areas: general aspects (GA), academic organization (AO), teaching (T) and Bologna Process (B). A multiple linear regression was performed (backwards method) for rejecting low significance variables and determining which school organization variables (GA, AO and B) influence students' perception about B. Significant level was set at .05 **Results** Descriptive statistics were: GA (M=3.77, DT=.72), AO (M=3.34, DT=.68), T (M=3.18, DT=.61), B (M=2.22, DT=1.02). Variable T was significant ( $t = 5.62, p < 0.001$ ) in predicting the perception of B explaining 27% of the variance. Variables GA ( $t = 0.64, p > 0.05$ ) and AO ( $t = 1.23, p > 0.05$ ) were excluded from the model as not being significant. **Discussion** This study shows how methodology is considered the main strength on the Bologna process perception. According to existing literature students perceive participatory methods, one of the main basis of the new plan, as positive for their learning (Montaño & Palou, 2008; Ruiz & Oliveros, 2006; Sáez, 2000). Descriptive statistics analysis show a high satisfaction level with the new Degree, higher than found in a similar study among students of bachelor's previous plan (Coterón et al., 2012). However, there's a low overall assessment respect the Bologna process mainly due to the late start in Spain and the lack of information received (Castaño et al., 2007). The results of this study suggest, according to the findings the literature, the need to implement better information systems. **References** Castaño, E., Benito, A., Portela, A., Rodríguez, R. M. ## PHYSICAL EDUCATION TEACHER'S TRAINING: UNIFYING BACHELOR AND DEGREE

Molina Neto, V., Branco Fraga, A., Kreuzburg Molina, R.

*Universidade Federal do Rio Grande do Sul*

**Introduction** In Brazil, the training of physical education teachers (EFI) is organized in two ways: Bachelor of EFI to work in non-school and Degree in EFI to work in school settings. This model is the subject of intense academic debate, whose harshest criticism come from the students and some professors who regard the epistemological basis of initial training in EFI is the same for both types of training. This paper discusses the process of curriculum in the School of Physical Education (ESEF) Federal University of Rio Grande do Sul (UFRGS), Brazil, which includes the formation of the two modalities in a single platform professional curriculum. The question is: how to organize a curriculum that ensures a unified initial training, qualified and ensuring the right to work of graduates in teaching spaces, where the EFI/Sport Science gains visibility, while maintaining the integrity of the epistemological basis and incorporating scientific and technological innovations? **Method** From 2010 to 2012, the organization of the curriculum involved two contexts, the formulation and another of the action (Ball, 1989). We used to collect information from discussion groups: mixed groups (teachers and students), specific groups, sometimes with teachers, students and sometimes with groups of subareas of knowledge. These groups worked on two lines of action: reinterpretation of legal issues and reorganization of cores knowledge curriculum, which are: a) Fundamentals of School Education; b) Sociocultural Studies; c) Development and Learning; d) Practice Body systematized; e) Fundamentals Biodynamic; f) Training oriented Physical Education; g) Training Oriented Recreation and Health; h) Oriented Training for Sport and Leisure. **Results** In the context of formulating curriculum was debated theoretical assumptions, we analyze the situation and was recovered the socio-historical perspective in decision making. In the action's context, the project was sited again in the academic community context of, to define levels of the teaching programme and the human resources. It was in the context of the action that the resistance and criticism gained visibility and transfigured into organizational problems and vital to the curriculum being implemented. Resistances in the institutional (in conjunction with other academic units) in the field of knowledge (selection and organization of content); internal dynamics (community college). **Discussions** This curriculum, educational project unfinished by definition, has little more than one semester of 'life' and we can already anticipate some changes in your organization. However, something that became clear in the process is that it is not possible to do curriculum changes without continuing education policy of the protagonists involved, without the participation of students and teachers (SARASON, 2003), without to know their stories of life and knowledge. **References** BALL, S. (1989) *La la escuela micropolitica*. Madrid: Paidós. SARASON, S. *El predecible fracaso de las reformas educativas*. Barcelona: Octaedron, 2003.

## LEGISLATIVE COHERENCE IN COMBINING STUDIES WITH HIGH-LEVEL SPORT

Solà, J.

*Facultat de Psicologia, Ciències de l'Educació i de l'Esport Blanquerna*

**Introduction** In recent years, the regional and state governments have drawn up measures for combining studies with high-level sport. Bearing in mind the political sensitivity regarding this issue, the measures presented are not always coherent when comparing educational and sports legislation. Time management is a condition which limits two extremely demanding parallel activities. **Method** A qualitative approach with the aim of understanding the legislative coherence in combining academic training and dedication to high-level sport. **Exploratory - descriptive design** in order to examine the internal logic of current regulations regarding educational grants for athletes, and predict individual attention quota for each level of education. **Gathering information** relating to educational laws (LOE, LEC) and sports (RD 971/2007, Decree 337/2002), the data has been subjected to a double content analysis in order to compare the proposed funding and follow its coherence at different educational levels. **Results** Regulatory inconsistencies have been found such as providing better academic grants for lower-level athletes or the recognition of Physical Education always prevents them from achieving their true grade. The determining factor is time management. Documents of concurrent studies in music or dance demonstrate this. Music offers a differentiated curriculum adaptation threshold of 4h-5h and dance a threshold of 7h-15h. The list of music and dance schools that certify the hours of work are also made public, contrary to the opacity of the list of centres of attention to sport and the oversight of schools which run serious programmes that combine sport with academic life. **Discussion** It is difficult to justify the exemption of young athletes from Physical Education, regardless of average final grade. The curricular objectives of the subject are fully taken on in a voluntary commitment to the sport of 10-12 hours on average (Sola, 2010). Sports give real lessons in discipline of effort, taking care of oneself, or values

of respect when the opponent is better. At the same educational level, there is no difference between the hours spent training or geographic variables of competition (meetings, international travel ...). The lack of reference of the grants in relation to the level of time demand for different sports gives rise to ridiculous situations such as students aged just 12 and without excessive training being able to enjoy very similar grants to those offered to high school students aged 18 with double the demands of study and high amounts of training. ### **PHYSICAL EDUCATION UNDERGRADUATE COURSE IN DISTANCE MODE OFFERED BY THE BRAZILIAN OPEN UNIVERSITY SYSTEM: EVALUATION OF THE MEDIATED COMMUNICATION IN THE VIRTUAL LEARNING ENVIRONMENT FORUMS**

Feres, A., Zambeli, M., Almeida, G.

*Brasilia University*

Introduction Teacher education in Physical Education in Brazil in distance mode began in 2007 with the establishment of the Open University of Brazil in order to institutionalize a public policy in distance learning. This research examines mediation in the Moodle Virtual Learning Environment through the forum messages posted by academic advisors and students at the Physical Education undergraduate course in distance mode at Goiás Federal University. In particular it was examined the pedagogical methodology of mediation used by teachers, especially in the disciplines of the initial training courses in Physical Education, as well as how the students dialogue and appropriate mediated knowledge, and finally address comparatively the development of these disciplines in the classroom and in distance learning. Methods A bibliographical research was conducted addressing the integration of educational technologies and the influence of behavioral theory. This research is featured as a descriptive and exploratory study that uses as empirical data the course's Political-Pedagogical Project and the forums of the following disciplines: Track and Field, Volleyball, Dance, Sport's Theory, Physical Education and Health. A protocol was developed to analyze indicators of computer mediated communication in the application of content analysis, which allowed the grouping of the messages in context units both for the messages from the academic advisors as well as from the messages posted by the students. Results Preliminary results indicate that in some disciplines (Example: Anatomy) forums are not used and has little contribution in other disciplines. Interaction and collaborative learning are more related to the tutor's level of intervention. In this sense it is important to focus on appropriate pedagogical mediation that stimulates dialogue, debates and thus strengthening interaction/interactivity and therefore collaborative learning. Discussion This research indicates that both presential and distance education are important for the learning process, for the fact that each one contributes in a collaborative way to it, being that the first one is essential for issues 'on the ground', such as movement technics, feedbacks and motivation, and the second one can be really helpful to broaden and deepen the discussion on theory, allow media to contribute to illustrate the learning topics etc. Therefore, it is understood that more research is needed to explore the potentials of the combinations of these two modes, in special in Physical Education undergraduate courses.

### **INITIAL EXAMINATION OF THE PSYCHOMETRIC PROPERTIES OF THE MULTIDIMENSIONAL MOTIVATIONAL CLIMATE OBSERVATION SYSTEM**

Smith, N.1, Tzioumakis, Y.2, Tessier, D.3, Appleton, P.1, Quested, E.1, Duda, J.L.1

*1: University of Birmingham (UK), 2: University of Thessaly (Greece), 3: University of Grenoble, (France)*

Introduction Research examining the coach-created motivational environment from achievement goal (AGT) and self-determination (SDT) theory perspectives has relied almost exclusively on players' perceptions of the climate. Duda and Balaguer (2007) have suggested that developing objective rating systems to assess facets of the coach-created motivational environment may prove valuable in validating existing self-report measures and aid in the evaluation of coach education programs that attempt to modify the social environment. However, no single instrument is available that rates dimensions of the environment emphasised within AGT and SDT, and validated in sport contexts. As a result, the Multidimensional Motivational Climate Observation System (MMCOS) was developed to address this void in the literature. The MMCOS moves beyond previous behavioural coach observation systems by enabling an objective, theory-based interpretation of the motivational meaning of the multi-faceted climate created by the coach. The purpose of the present study is to examine the psychometric properties of the MMCOS. Method 57 grassroots-level football coaches from UK (17), France (18) and Greece (22) provided consent to be filmed and audio-recorded during a training session. 9 observers (3 England, 3 France, 3 Greece) completed the MMCOS coder-training programme. Recordings were split into four equal time-periods and coaching environments were rated on the prevalence of seven dimensions of the coach-created motivational environment (autonomy support, controlling, task-involving, ego-involving, relatedness supportive, relatedness thwarting and structure). Results Trained observers demonstrated a moderate degree of reliability when using the MMCOS. Exploratory factor analysis (EFA) supported a two-level hierarchical structure. The seven MMCOS dimensions loaded onto two factors accounting for 74.5% of the variance in the rated features of the environment. Autonomy Support (.66), Task-involving (.84), Relatedness Support (.82) and Structure (.81) loaded exclusively onto the first factor, whilst Controlling (.89) and Relatedness Thwarting (.78) loaded onto the second factor. The Ego-involving dimension cross-loaded onto both factors (.52/.43). Discussion Findings provide evidence for the reliability and structural validity of the MMCOS. Results of the EFA are aligned with theoretical predictions. An exception is with the cross-loading of ego-involving, which will be further examined in future studies. These findings have implications for sport-based researchers that choose to collect objective as well as subjective assessments of the motivational climate in sport via an AGT and SDT lens. Duda, J. L., Balaguer, I. (2007). *Social Psych in Sport*. Human Kinetics. Champaign, IL

## MOTIVATIONAL GOAL CLIMATE, AUTONOMY SUPPORT, AND MOTIVATIONAL RESPONSES ACROSS TRAINING AND COMPETITION IN INDIVIDUAL- AND TEAM SPORTS.

Van de Pol, P., Kavussanu, M., Ring, C., Kompier, M.

*Behavioural Science Institute, Radboud University Nijmegen*

Motivational Goal Climate, Autonomy Support, and Motivational Responses across Training and Competition in Individual- and Team Sports. Pepijn van de Pol (1), Maria Kavussanu (2), Christopher Ring (2), and Michiel Kompier (1) (1)Department of Work and Organizational Psychology, Behavioural Science Institute, Radboud University Nijmegen, The Netherlands; (2)School of Sport and Exercise Sciences, University of Birmingham, Birmingham, UK. Objectives: This study had two purposes: first, to examine differences in athletes' perceptions of coach-created goal climate and autonomy support across training and competition contexts and individual- and team sports; and second, to determine whether context and sport type moderate the relationships between goal climate, autonomy support, and motivational outcomes: effort, enjoyment, anxiety, and activation skills. Method: Participants were 145 individual- and 203 team-sport athletes, who completed questionnaires measuring task-involving and ego-involving goal climate, autonomy support (interest in athlete's input and praise for autonomous behaviour), effort, enjoyment, cognitive and somatic trait anxiety, and activation skills, in training and competition. We examined our study purposes using Multilevel Modeling (MLM). Results: Perceived task and ego goal climate were higher in competition than in training; the contextual difference in ego goal climate was greater for individual- than for team-sport athletes. Interest in athlete's input and praise for autonomous behaviour did not differ across the two contexts; however, interest in athlete's input was lower in team- than in individual-sport athletes. Effort and enjoyment were associated positively with task goal climate, and praise for autonomous behaviour but only in training. Furthermore, effort was negatively related to interest in athlete's input, while enjoyment was inversely related to ego goal climate only in training. Somatic anxiety was associated positively with ego goal climate in competition, and negatively with task goal climate only in individual sports. Somatic anxiety was also positively associated with interest in athlete's input, but only in individual sports. Cognitive anxiety was unrelated to all outcomes. Activation was associated positively with praise for autonomous behaviour, and with ego goal climate but only in team sports. Finally, activation was negatively related to interest in athlete's input in both contexts. Conclusion: The results of this study indicate that athletes' perceptions of goal climate and autonomy support may differ across training and competition contexts and/or individual- and team sports, and that relationships between goal climate and autonomy support and motivational outcomes may vary depending on the context and/or sport type. Hence, the present findings highlight the importance of making the distinction between training and competition, and individual- and team sports, when examining motivational processes in sport.

## THE RELATIONSHIP BETWEEN MOTIVATION, PERFORMANCE AND AFFECT ON A SITUATIONAL LEVEL

Garcia, P.

*Universitat de Girona*

Introduction The purpose of this study was to test some predictions of the model forwarded by self-determination theory related literature, on a situational level. Specifically, we wanted to test the relations between the autonomous and controlled styles of self-regulation, measured before competition, and cognitive and affective outcomes measured after competition. Methods Therefore, we analysed 94 national competitions of 19 athletes (6 females and 13 males; Mage = 24.58, SD = 4.89) in several team (water polo, soccer basketball and handball) and individual (swimming, triathlon and athletics) sports. Our participants answered to single item scales based on validated questionnaires which assess behavioural regulation, self-talk and emotions. Results Our results generally revealed the expected relations among the different scales of each questionnaire. Moreover, regarding the autonomous types of self-regulation (i.e., intrinsic, integrated and identified), we found positive relations with both positive emotions (i.e., excitement and happiness; both  $r > .29$ ,  $p < .01$ ) and with most positive types of ST (specially, psych up and confidence; both  $r > .20$ ,  $p < .05$ ). Regarding the controlled types of self-regulation (i.e., introjected and extrinsic), we found a positive relation between extrinsic regulation and anger ( $r = .32$ ,  $p = .002$ ), negative relations of extrinsic regulation with both positive emotions (both  $r < -.22$ ,  $p < .05$ ), only two positive relations of extrinsic regulation with negative ST (fatigue and disengagement, both  $r > .37$ ,  $p < .001$ ), and a negative relation between extrinsic regulation and confidence ( $r = -.27$ ,  $p = .010$ ). Finally, we calculated the SDT-index and mean scores for ST and emotions and performed separate lineal regression analysis. According to our results, self-determined motivation predicted positively positive ST ( $R^2 = .07$ ,  $\beta = .28$ ,  $p = .007$ ) and positive emotions ( $R^2 = .31$ ,  $\beta = .55$ ,  $p < .001$ ), and negatively negative emotions ( $R^2 = .15$ ,  $\beta = -.39$ ,  $p < .001$ ). Discussion Consequently, the results of this study evidence the importance of autonomous self-regulation in competitive sport settings, especially for well-being and positive affect.

## EXPLORING ATHLETES' AUTOMATIC SELF INSTRUCTIONS

Valls, A., Broo, N., Font-Lladó, R., Latinjak, A.T.

*Universitat de Girona, School of Health and Sport Sciences (EUSES), Catalonia, Spain*

Introduction In self-talk (ST) literature, some authors distinguished automatic ST and automatic self-instructions. They argue that the latter serves a clear purpose, while the former emerges from the situation. The aim of this study was to explore athletes' automatic self-instructions. Therefore, we used Latinjak's (2012) three-dimensional model of core affect which is defined by valence, arousal and time perspective and describes eight main affective states, commonly called sadness, anger, resignation, fear, relieve, elatedness, confidence and excitement. Methods Fifty-five athletes from different individual and team sports agreed to take part in this study. We asked them to remember one situation they had experienced for each affective state. For each state, we further asked them what they thought in the specific situation when they felt ... (e.g., fear), in order to improve their performance or cope with their emotions. Results Using qualitative content analysis ten categories of automatic self-instructions emerged. Firstly, four categories emerged that were similar to those found by Hatzigeorgiadis, Chroni, Theodorakis and Papaioannou (2009) on a contextual level: some statements referred to self-confidence building (I can do it), some statements referred to psyching up or motivation (Let's go!), some statements referred to positive deactivation (Calm down), and some statements referred to game-specific instructions (Pass the ball). Secondly, a group of three categories comprised statements which referred to coping with specific game circumstances: coping with adversity and negative feelings (Don't be angry), coping with success and positive feelings (Don't relax) and coping with general practice and competition (Keep going). Finally, three more categories referred to self-regulation and achievement orientation: some instructions aimed at creating task involvement (Learn this), some instructions aimed at creating ego involvement (Show them who you are) and some instructions aimed at self-regulation at an introjected level (Don't let your team down). Discussion Regarding the described categories, one should take into consid-

eration that future studies have to test the described categories against new evidence, without discarding the creation of new categories or the redefinition of the presented ones. ### THE RELATIONSHIP BETWEEN MOTIVATION AND SELF TALK

Juan Tavira, B., Ballart, P., Garcia, P., Latinjak, A.T.

*EUSES*

**INTRODUCTION** The aim of this study was to inquire into the relationship between self regulated motivation and automatic self talk (ST). Our hypothesis was that autonomic forms of self regulation would predict positive types of ST, and that controlled forms of self regulation would predict negative ST. **METHOD** One-hundred eighty-nine athletes of several team and individual sports agreed to participate in this study. They answered the Behavioral Regulation in Sport Questionnaire (BRSQ, Lonsdale, Hodge, & Rose, 2008) and the Automatic Self-Talk Questionnaire for Sports (ASTQS; Zourbanos, Hatzigeorgiadis, Chroni, Theodorakis, & Papaioannou, 2009). **RESULTS** Firstly, all scales showed adequate  $\alpha$  values for reliability ( $\alpha > .70$ ) and confirmatory factor analysis showed adequate fit for both instruments:  $\chi^2(731) = 1159.77$ ,  $p < .001$ , RMSEA = .07, CFI = .94 and TLI = .93 for the BRSQ; and  $\chi^2(731) = 1159.77$ ,  $p < .001$ , RMSEA = .06, CFI = .91 and TLI = .91 for the ASTQS. Secondly, we found positive correlations between the self determined types of regulation (i.e., intrinsic, integrated and identified; all  $p < .01$ ), and positive relations between the controlled types of regulations (i.e., introjected and extrinsic) and the amotivation (all  $p < .001$ ). Further, we found negative relations between some self determined types of regulation (i.e., intrinsic and integrated) and introjected regulation (all  $p < .05$ ), and intrinsic regulation and extrinsic and non-regulation (all  $p < .001$ ). Thirdly, we found positive relations among all positive ST scales (all  $p < .01$ ), positive relations among all negative ST scales (all  $p < .05$ ) and positive relations between some types of positive ST (i.e., instruction and anxiety control) and some types of negative ST (i.e., worry and somatic fatigue). Lastly, we calculated the SDT index and found that higher degrees of self-determined regulation are positively related to some types of positive ST (i.e., confidence and psych up; all  $p < .01$ ) and that higher degrees of controlled regulation are positively related to all types of negative ST (all  $p < .01$ ). **DISCUSSION** Overall, these results evidence the relationship between the why of sport engagement and the what of automatic thought content and, therefore, emphasize the importance of promoting self-determined types of motivation. **BIBLIOGRAPHY** Lonsdale, C., Hodge, K., y Rose, E.A. (2008). The behavioural regulation in sport questionnaire (BRSQ): Instrument development and initial validity evidence. *Journal of Sport and Exercise Psychology*, 30, 323-355. ### EXPLORING ATHLETES' AUTOMATIC SELF-TALK

Broo, N., Valls, A., Font-Lladó, R., Latinjak, A.T.

*EUSES*

**Introduction** In self-talk (ST) literature, two main research paradigms have been described: (a) the study of the contents and the structure of automatic ST and (b) the effects of ST interventions on performance and performance-related outcome measures (Hardy, Oliver, & Tod, 2009). The purpose of this study was to explore athletes' automatic ST on a situational level. Therefore, we a conceptual model of emotions and core affect (Latinjak, 2012) which is defined eight main affective states, commonly called sadness, anger, resignation, fear, relieve, elatedness, confidence and excitement. **Methods** Thirty-two athletes from different individual and team sports agreed to take part in this study. After introducing to our participants the conceptual framework of emotions, we asked them, for each emotion, what they thought in a specific situation when they felt ... (e.g., fear). **Results** Using qualitative content analysis a two-dimensional structure of thought content emerged: on the one hand, the athletes' ST ranged in terms of valence from positive to negative and in terms of time perspective from retrospective to anticipatory. Combining both dimensions, we found four main interactions: positive-anticipatory ST (I will win/ I want to play), positive-retrospective ST (I played well/ I was lucky), negative-anticipatory ST (I will lose/ I don't want to play), and negative -retrospective ST (I played bad/ I was unlucky). In between positive and negative were statements we denoted neutral (I will play/ the game is over). In between retrospective and anticipatory we found statements that could be considered miscellaneous in time perspective. These miscellaneous statements could further be differentiated into present-related statements (I play well/ I play bad) and contextual or global statements (I am good/ I suck). **Discussion** Generally, there can be reasonable confidence that the two dimensions proposed are exhaustive, in a sense that all human automatic ST could be located in this structure. Nevertheless, the two-dimensional structure could lack specificity or a different structure could constitute a more useful model of automatic ST. Consequently, there is space for a discussion about the number and nature of the automatic ST dimensions. References Hardy, J., Oliver, E., y Tod, D. (2009). A framework for the study and application of self-talk in sport. In S.D. Mellalieu y S. Hanton (Eds.), *Advances in applied sport psychology: A review* (pp. 37-74). London: Routledge. Latinjak, A. T. (2012). The underlying structure of emotions: A tri-dimensional model of core affect and emotion concepts for sports. *Revista Iberoamericana de Psicología del Ejercicio y el Deporte*, 7(1), 71-87.

### THE CHINESE VERSION OF SCALE FOR EFFECTIVE COMMUNICATION IN TEAM SPORTS - A CROSS-CULTURAL REVISING AND STRUCTURE RE-EXAMINATION

Liao, C., Lee, C., Huang, L.

*National Taiwan Sport University*

**Introduction** In team sports, good team functioning depends on effective team communication. Based on the social exchange theory, Sullivan and colleagues (Sullivan & Feltz, 2003; Sullivan & Short, 2011) have developed a sport-specific multidimensional tool (Scale for Effective Communication in Team Sports; SECTS and SECTS-2) to measure the effectiveness of communication of sport teams. SECTS-2 consists of four subscales, which are Acceptance (acceptance of each other), Distinctiveness (distinctiveness from other social units), Positive Conflict (constructive intra-team conflict), and Negative Conflict (destructive intra-team conflict). The purpose of this study was to develop a Chinese version SECTS based on SECTS-2 and examine its structure. **Methods** SECTS-2 was translated to Chinese (The Chinese version SECTS, C-SECTS) via a standard back-translation protocol with necessary minor revisions. C-SECTS was then administered to 210 youth athletes (male=144, female=66) from 17 elementary school varsity teams of 9 different sports (mean age=11.56, SD=1.03). Item analysis and confirmatory factor analysis (CFA) were conducted to examine the structural validity of C-SECTS. **Results** After deleting one

item from Distinctiveness subscale in the item analysis process, all subscales showed adequate internal consistency (Cronbach's alpha=.80-.88). As data of all items were normally distributed, maximum likelihood method was performed in conducting the CFA. Results showed a good fit of the measurement model (Chi square=182.67, df=84,  $p<.05$ , CFI=.96, NNFI=.95, PNFI=.75, RMSEA=.075), good reliability, convergent validity, as well as discriminant validity ( $\lambda=.63-.91$ ;  $R\ square=.40-.82$ ;  $pc=.81-.89$ ;  $pv=.51-.66$ ). Discussion The results supported the concept of effective team communication proposed by Sullivan and colleagues (Sullivan & Feltz, 2003; Sullivan & Short, 2011). The structure of SECTS was confirmed despite a sample from a different culture. It is worth noting that, in Sullivan and Short' work (2011), Negative conflict was found positively correlated with Acceptance and Distinctiveness. In our work, however, Negative conflict was negatively correlated with Acceptance and Positive conflict. Our data showed more reasonable inter-subscale correlations as Negative conflict, in concept, was destructive in nature. In general, C-SECTS appears to be a valid measurement for cross-culture studies in effective team communication in sport. References Sullivan, P. J., & Feltz, D. L. (2003). Journal of Applied Social Psychology, 33, 1693-1715. Sullivan, P. J., & Short, S. (2011). Journal of Applied Social Psychology, 41, 471-487.

### EFFECTS OF SCHULTZ AUTOGENIC TRAINING ON PSYCHOLOGICAL VARIABLES AND HEART RATE VARIABILITY

Doucende, G., Varraine, E., Durand, F.

*Performance Health and Altitude Laboratory*

Introduction Anxiety is one of the most important psychological factors that can affect sports performances. Athletes have a lot of techniques in order to control anxiety before competition. Autogenic training is one of these techniques that could be used by athletes in order to relax before competition (Schultz and Luthe, 1969). Moreover, heart rate variability is a non-invasive index of the autonomic control of the heart, which has been extensively studied in anxiety (Friedman et al., 1998). The aim of this study is to investigate the effects of the Schultz Autogenic Training (SAT) on psychological and physiological variables. Methods We measured psychological variables by POMS questionnaire on a dedicated software Sphinx © and heart rate using an on-board electrocardiograph (Vital Jacket, Biodevices, Portugal) in 14 subjects before and after a SAT session. Time domain, frequency domain and non-linear analysis of heart rate variability were analysed on dedicated software (Kubios, University of Eastern Finland, Finland). Results State anxiety ( $9.8 \pm 7.1$  versus  $3.3 \pm 3.8$ ,  $p<0.05$ ), depression ( $7.1 \pm 7.5$  versus  $2.0 \pm 3.6$ ,  $p<0.05$ ) and confusion ( $9.6 \pm 4.4$  versus  $6.2 \pm 2.4$ ,  $p<0.05$ ) were significantly reduced after SAT session. Heart rate was not affected by SAT session ( $63.8 \pm 10.1$  bpm versus  $64.6 \pm 8.9$  bpm, NS) whereas non-linear analysis of heart rate variability was increased after SAT session ( $97.6 \pm 45.7$  versus  $146.3 \pm 61.3$ ,  $p<0.05$ ). Discussion SAT session have a positive effect on state psychological factors as anxiety, depression and confusion as previously describe by Friedman et al. (1998). Moreover, our results suggested that SAT session could also increase heart rate variability probably due to a greater parasympathetic influence (Gorman and Sloan, 2000). SAT could represent an easy method in order to reduce psychological and physiological stress before a competition and so increase sports performances. References Friedman BH, Thayer JF. (1998). ### POTENTIAL EFFECTS OF THE HYPOPRESIVE METHOD ON PHYSICAL AND PSYCHOLOGICAL COMPONENTS OF SPORTS PERFORMANCE

Riera, T., Cusiné, B., Carbó, R., Herrera, M.

*Universidad Nacional a Distancia (UNED), Psicoaching,*

INTRODUCTION Scientific evidence of improvements in performance through the use of the Hypopressive Method (HM) already exists (Caufriez, 2010). The objective of this study was to analyze the potential of HM in improving physical and chemical parameters directly related to sports performance: body alignment, flexibility, respiratory parameters and aerobic endurance. From the psychological perspective the objective was to observe modifications in cognitive and somatic anxiety levels in young male athletes who train using the Hypopressive Method in comparison to those who do not. METHODS The participants were young male athletes, ages 17-31, divided into the HM group and the control group. The assessments included body alignment with photographs, flexibility with the Sit and Reach test, respiratory parameters with the measurement of rib cage flare and spirometry, aerobic endurance with sub aquatic apneas measuring static apnea after a full exhale, static apnea with a full inhalation, and time and distance during a dynamic breast stroke swim under water after a full inhalation. A VO<sub>2</sub>max value was also calculated based on the results of the Navette test. The psychological assessments were divided into two phases. The first phase used CSAI-2 evaluation tool prior to commencing HM training. The second phase included observing modifications in somatic and cognitive anxiety and self confidence scores from the CSAI-2 before the Navette and aquatic tests. RESULTS The photos of the intervention group showed a clear improvement in body alignment between the pre and post assessments. The sit and reach test improved by 98,3%, the spirometry values improved by 3% and the rib flare by 2%. These improvements were confirmed for all subjects in the endurance tests: Navette values increased by 1+/-0,5 period, aquatic apnea tests showed an increase of 10+/-0,5 seconds in the static and 15+/-0,5m in the dynamic versions. The HM group had a significant modification in cognitive anxiety levels and self confidence. DISCUSSION The control group did not show any significant changes in any of the variables measured. The HM group showed the following changes: normalization of muscular tensions in the posterior chain which allowed for improvements in body alignment and flexibility; enhancement of respiratory muscle function which explains the improvements in rib flare, spirometry values, Navette test results, and aquatic tests. The psychological tests showed a significant improvement in cognitive anxiety and self confidence after applying HM. ### SELF-CONCEPT ORGANIZATION AND MENTAL TOUGHNESS IN SPORT

Meggs, J., Ditzfeld, C., Golby, J.

*Abertay University*

Mental toughness is a rapidly evolving construct and has generated widespread research interest because of the constructs proposed theoretical links with successful sport performance. This study extended these research enquiries and examined the relationship between individual differences in evaluative self-organization and mental toughness in sport. The purpose of the study was to show that qualities of mental toughness proposed to underlie emotional resiliency in sport extend from difference at the core self. A cross-sectional assessment of 102 athletes competing at a range of performance levels took part in an online study including measures of self-reported

mental toughness (SMTQ) and self-organization (self-descriptive attribute task). As anticipated, overall mental toughness was associated with self-concept positivity, which particularly was true of individuals with positively integrative self-organization, who distribute positive and negative self-attributes evenly across multiple selves. Specifically, positive integration appears to promote constancy, presumably stemming from the emotional stability associated with this self-organization. The potential advancements of the current study include a more subtle understanding of the cognitive-affective variables that underlie mental toughness, subsequently resulting in a more holistic understanding of this salient construct.

### THE RELATIONSHIP OF VOLLEYBALL AND LEVELS OF ANXIETY AND RESILIENCE OF ACTIVE SENIORS.

Fernandes, P.T., Pupo, L.C.A., Yoshida, H.M., Borin, J.P.

*UNICAMP*

**Introduction** The increased longevity is configured as a world reality. Currently, the aging process has an important emphasis in several areas of knowledge, and physical exercise appears as the protagonist relating to better quality of life, including physical, social and psychological areas. But, when the focus is elderly populations, there is little scientific knowledge about it. So, this study aimed to investigate the influence of physical exercise, through volleyball, in anxiety and resilience of the elderly people. **Methods** We performed a survey in 23 healthy athletes (13 male), older than 60 years (60-72 years, SD = 4.65) with average period of training of 49 months (5-168 months). All these subjects were members of the adapted volleyball of Nova Odessa-SP/Brazil. The methodology initiates with a literature research to get a theoretical framework, followed by a survey with the follow instruments: Beck Anxiety Inventory (BAI) and Resilience Scale, composed respectively of 21 and 25 items, which determine scores of anxiety and psychological resilience. The questionnaires were performed in three points: in the first month of training (P1); at three (P2) and six months (P3) after the first application. **Results** The results showed that training, over the six-months, contributed in a positive way to improve the psychological aspects: decreasing the levels of anxiety and increasing resilience scores. Anxiety: P1=9.91 (SD=8.46); P2=7.57 (SD=4.76); P3=4.91(SD=4.11), p=0.03. Resilience: P1=121.30 (SD=37.46); P2=137.04 (SD=20.93); P3=144.65(SD=14.47), p=0.01. **Discussion** With these results, we can say that this specific sport training could help to obtain and maintain the psychological and mental well-being of elderly people. This study enriches a research about this theme and can promote a new way to deal with this population.

#### GAME METHOD AS A WAY TO CORRECT THE PSYCHO-EMOTIONAL STATE

Shklyarenko, A.I, Yakhnik, Y.I, Kovalenko, T.2

*1: Kuban State University, the branch in Slavyansk-on-Kuban (Slavyansk-on-Kuban, Russia), 2: Volgograd State University (Volgograd, Russia)*

**Introduction** Nowadays it is noticed that aggravation of physical conditions shown by teenagers with musculoskeletal system diseases is connected with their psycho-emotional health. To solve this problem we propose to use game forms of physical activity. It helps to create emotional stability, to strengthen good posture, and to form the stereotype of physical activity. The high level of motional activity has a positive influence on the neuropsychiatric processes and the psycho-emotional background; it improves the effectiveness of complex treatment. **Methods** Sixty-nine 11-13 year-old teenagers with scoliosis of the first, second, third and fourth degree were tested. All of them were on a 28-day treatment in an orthopedic sanatorium. The game method used in these experiments was aimed at improving the adaptation ability, developing the stereotype of physical activity and the right perception of the disease and its treatment. To explore the change in psycho-emotional state we carried out prompt estimations of the feeling of well-being, the activity and the mood (Zabrodin, 2010). **Results** The experiments resulted in the following: the well-being index increased in 16.8%, the mood index increased in 16%, the activity index increased in 9.2%. The index values in different age-groups ranged: the well-being index for 11-year-olds was 5.7 points, for 12-year-olds – 5.59 points, for 13-year-olds – 5.77 points. The activity index for 11-year-olds was 5.09 points, for 12-year-olds – 5.1 points, for 13-year-olds – 5.5 points. The index of mood for the 11-year-old was 6.0 points, for the 12-year-old – 5.89 points, for the 13-year-old – 5.5 points. **Discussion** The significant increase in the well-being index and the mood index proves that the game method allows to optimize psycho-emotional state of teenagers. Moreover, the activity index increases, as well. These data correspond with the research by other scientists. The analysis of the ratio of functional indicators under the rise of fatigue in the group of 11-year-olds shows the relative decrease of the well-being and activity as compared with the mood. The fatigue trend has its minimum value for the group of 12-year-olds, and is lacking for the group of 13-year-olds, which shows the optimal suitability of this method for children aged 12 and older. Apart from that, we registered that the feeling of well-being and the mood enhance while the activity tends to significantly lower increase. Considering the specific character of this method, we emphasize the fact that teenagers get accustomed to the stereotype of physical activity, as the children tested conceive the high level of physical activity as norma. **References** Zabrodin Yu. 2010. Moscow, p. 334-412. Stephens M. (2002). *American Family Physician*, 15, p.1033-1035.

#### PSYCHOLOGICAL EVALUATION OF THE JAPANESE NATIONAL TENNIS PLAYERS

Murakami, K., Hirata, D.

*Tokyo University of Science, Senshu University*

**Introduction** Players, coach, and sport psychologists all agree that the contribution of psychology to successful tennis play is significant. This consensus is borne out of game analysis, as well as the mental skills that players and coaches consider important for tennis play. In Japanese Tennis Association (JTA), as a part of the medical and fitness checkup in the training camps, mental skills of the athletes were assessed. One key factor in bringing an athlete's capability into full play is mental skills. Therefore, the purpose of this study was to examine the mental skills of the Japanese national tennis players. **Methods** A total of 26 players were assessed. The national group was

composed of 10 players who were members of a Davis Cup Team at the time of the study. The Universiade group was composed of 16 players who were currently on a university tennis team. The instrument used was the Diagnostic Inventory of Psychological Competitive Ability for athletes (DIPCA.3, Tokunaga, 2001). The questionnaire includes 52 items and 12 mental skills scales grouped under five broader conceptual components. The DIPCA.3 was applied in youth and open players selected for their national teams, while they were either in training camps or on tour. Results Results of analysis revealed several differences between psychological characteristics of athletes as function of their performance level. Significant differences appeared in aggressiveness:  $F(1, 24)=4.75, p<.05$ , volition for self-realization:  $F(1, 24)=6.32, p<.05$ , concentration :  $F(1, 24)=4.64, p<.05$ , confidence:  $F(1, 24)=8.76, p<.01$ , decisiveness:  $F(1, 24)=6.87, p<.05$ , and judgment:  $F(1, 24)=5.61, p<.05$ . Means comparisons revealed that the national players exhibited superior mental skills than universiade players in aggressiveness, volition for self-realization, concentration, confidence, decisiveness, and judgment. Discussion Results indicate clearly that athletes' psychological characteristics differed depending on their performance level. National level tennis players were better than universiade players in aggressiveness, volition for self-realization, concentration, confidence, decisiveness, and judgment. Findings corroborate the results of previous studies (Gould et al., 2002) comparing mental skills of elite and non-elite athletes. These mental skills may be important differentiating variables between elite and non-elite athletes. ## EMOTIONAL REGULATION IN SPORT USING E.M.D.R.

Mate, D.1, Cavallerio, F.2

1: UNITO (Torino, Italy), 2: UR (London, UK)

Introduction Sport psychologists often have to help athletes regulate their emotions. Feelings like pre-competitive anxiety and re-injury worries influence performance negatively and athletes need to develop strategies which will allow them to successfully deal with these emotions. Several strategies try to regulate the arousal through exercises based on the body (e.g., relaxation, imagery) or on rational cognition (e.g., goal setting, self talk). Unfortunately these techniques do not reflect the complexity of human mind and brain, and the role of intra-personal beliefs and emotions, and when the level of stress is particularly high these techniques only become useful after a long time. Nowadays a relatively new therapeutic technique has started to be used with athletes, even though only few cases are reported in the current literature (Graham and Robinson, 2007; Shearer et al., 2011). The Eye Movement Desensitisation and Reprocessing (E.M.D.R., Shapiro, 1989) was originally created to deal with psychological traumas (e.g., Post-traumatic stress disorders), but its protocol has been adapted with the goal of improving sport performance (Foster and Lendl, 1995). This psychotherapeutic technique can reach deep inside the intra-personal beliefs and images of life-events, and appears to regulate emotional activation in a more stable and functional way than other techniques. Methods The E.M.D.R. protocol (i.e., a bilateral stimulation that aims to connect different areas of the brain, with the final goal of helping the person to identify some mental images and guide them through the restructuring of their cognitions, turning those which are negative and counterproductive during performance into positive and empowering ones) was applied during a five session program with a hockey player that was struggling with anxiety during matches. Results The E.M.D.R. protocol has helped the athlete to analyse his own feelings of anxiety during matches and to explain them, and come to terms with what was causing them (being afraid of his father judging and criticising him). The global result was that the athlete reprocessed his disturbing beliefs extremely rapidly, and regulated his arousal without any specific intervention on the body. Results were stable during the follow-up sessions too. Discussion The use of the E.M.D.R. protocol opens new possibilities for sport applied psychologists. This tool offers a chance to obtain quick results in short times, which is a positive aspect when working with athletes who might need to be ready to go back on the competition floor in weeks, or even just days. ## EXPLORING THE EFFECTS OF EMOTIONS ON DECISION MAKING

Ballart, P., Juan, B., Latinjak, A.T.

EUSES

Introduction The purpose of this study was to explore the effects of different emotions on decision making. Methods In regard to the emotions, we used a dimensional model of core affect as a conceptual framework for this study, and selected the eight main affective states represented in the model: these states are commonly referred to as sadness, anger, dejection, fear, relieve, elatedness, confidence and excitement. In regard to the decisions, we presented our participants ( $n = 90$ ; 80 males and 10 females;  $Mage = 19.56$ ,  $SD = 1.85$ ) eight times the same situation where a basketball player had to choose between four different options at the end of a match: (1) keep the ball and wait; (2) perform an easy pass to the best player in the team which, however, is in a worse position; (3) perform a difficult pass to another teammate which is in a good position; or (4) perform a difficult through by yourself. Each time, the situation was introduced by a stem (The player feels ... [e.g., relieved]), that varied in regard to the emotion concept. Moreover, we clearly stated that the chances of scoring are at 15% for each choice, and our participants could choose more than one if they believed they were equally adequate. Results Our results revealed similar choices for different types of emotions. Firstly, when angry or euphoric (both retrospective and highly activated states) most participants (80% and 97%, respectively) would have tried to score themselves. Secondly, when confident or excited (both anticipatory and positive states) our participants would have chosen to try to score (73% and 66%, respectively), perform a difficult pass (51% and 52%, respectively) or even maintain the ball (33% and 30%, respectively). Thirdly, when sad, dejected or anxious (all negative states) most participants (80%, 76% and 78%, respectively) would have tried to perform a simple pass to the best player of the team. Lastly, when relieved most participants (78%) would have maintained the ball and waited for a better option. Overall, our results suggest that affective states not only influence the quality of decisions, the time we spent to take them or the options we consider before we take them, but also the type of decision we take, regarding responsibility and social interactions. Discussion Based on these results, we formulated four hypothesis for future studies: (1) when euphoric or angry athletes tend to assume responsibility so as to proof their value, (2) when experiencing any negative emotion but anger athletes tend to avoid responsibility, (3) when experiencing confidence or motivation athletes tend to assume or share responsibility and (4) when relieved athletes tend to be patient and evaluate before taking their choices.

## THE EFFECT OF EMOTIONAL INTELLIGENCE ON SPORTS EFFECTIVENESS AT HANDBALL TEAMS

Keczeli, D.

*Sport School of Debrecen*

**Introduction** This research examines what role the EQ has in the multifactor sports' efficiency system. The study was conducted on four professional handball team, with the assumption that those players who has high emotional intelligence has decisive role in the team. We supposed that the high EQ is associated with high self-confidence. Further question that what is the relation of performance in situation and between the EQ. The study aims to explore – what psychological factors influence the success of the athlete. **Methods** Two first-class men and two women handball team (N = 65, 34 men and 31 women) took part. During the study four types of questionnaires have been evaluated: The Bar-On Emotional Quotient Inventory animals, Athletic Experiences Survey (ACSI-28/2), State testing meter - (CSAI-27), and more precisely in terms of sociometry. The SPSS statistical program has done the data processing. During the entered variables we used the statistical analysis of the one-sample Kolmogorov-Smirnov test, descriptive statistics, Mann-Whitney test, analysis of variance, and Kruskal-Valis correlation analysis was used. **Results** The comparative statistical calculations resulted in average of 66.15% of the subjects EQ (EQ Sample average = 450). Our hypothesis that the players who have higher EQ than the average have more relationships in the team was not proved. Those who have high EQ has minimum relationship with at the least (1.27 = number of contacts/person), supposedly marginalized. The low EQ players have most relation (2.36 = number of contacts/person). Thus, the hypothesis that a player with high EQ has a decisive role in the team atmosphere was not proved. However, the players who have higher emotional intelligence can struggle with stress, the anxiety-clarity is higher in their case. The EQ and the difficulties have significant relation. There is also a significant relationship between the performance situation and the self-confidence. Moreover, there is a strong correlation between the performance situation and between the optimism. **Discussion** Based on the results we can conclude that the emotional intelligence plays an important role in the view of the athletes' effectiveness. Although, apparently there is no relation between the atmosphere of the team and between the emotional intelligence, but even then in individual level it's improving is quite important. The EQ shows relation with the individual abilities and features that help the athlete to face with the problems, which comes from the competition. The high EQ helps to fight against the surrounding requirements, or to solve the stressful situations. **References** Mayer, J. D., Salovey, P. (1993): *The Intelligence of Emotional Intelligence*. ## VALIDITY AND RELIABILITY OF THE GREEK VERSION OF THE SATISFACTION WITH LIFE SCALE : EVIDENCE FROM PHYSICALLY ACTIVE COLLEGE STUDENTS

Theodoropoulou, E., Karteroliotis, K.

*National and Kapodistrian University of Athens*

**Introduction** Physical activity was positively associated with life satisfaction (McAuley et al., 2008). Such studies frequently used the Satisfaction with Life Scale (SWLS) to assess life satisfaction (McAuley et al., 2008), which is one of the most widely used instruments (Pavot & Diener, 1993). Although this scale has been established to have sound psychometric properties, the validity of this instrument has not been examined in Greece. Therefore, the aims of the current study were to examine the factorial validity and reliability of the SWLS. **Methods** Participants were 340 students that attended the physical education classes. To test the factorial validity, two samples were used. The first sample (N=150) were 77 men and 73 women (24.28±6.32 yrs), whereas the second sample (N=150) consisted of 86 men and 64 women (22.85±5.64 yrs). An Exploratory Factor Analysis (EFA) was conducted with the first sample. The extraction method employed was principal axis factor followed by promax rotation. A Confirmatory Factor Analysis (CFA) (maximum likelihood method) was performed with the second sample to confirm the fit of the model found in EFA. The CFA was conducted using the AMOS 16.0 statistical software (Arbuckle, 2007). Assessment of model fit was based on  $\chi^2$ ,  $\chi^2/df$ , CFI, GFI, IFI, TLI and RMSEA indices. To test the internal consistency, the Cronbach's alpha coefficient was used. To examine the test-retest reliability, 40 students, 21 men and 19 women (28.78±5.647 yrs), completed the scale twice with an interval of 15 days between the two assessments. **Results** EFA yielded one factor accounted for 71.81% of the variance of the model. The item factor loadings ranged from 0.68 to 0.90 (Cronbach's alpha=0.90). Similarly, CFA showed that this model presented a good fit ( $\chi^2=6.214$ ,  $df=4$ ,  $p=0.184$ ,  $\chi^2/df=1.554$ , CFI=0.996, GFI=0.983, IFI=0.996, TLI=0.991, RMSEA=0.062). The item factor loadings ranged from 0.75 to 0.92. The Cronbach's alpha coefficient was 0.93 whereas the intra class correlation coefficient of the scale was 0.77 (0.61-0.87 95% CI). **Discussion** The results of the study indicated that the Greek version of the SWLS was a valid and reliable instrument in physically active students. These findings are consistent with those of previous studies. Future studies are proposed in other physical activity settings in order to increase the knowledge about the validity and reliability of the SWLS. **References** Arbuckle JL. (2007). *Amos 16 user's guide*. Amos Development Corporation, USA. McAuley E, et al. (2008). *Ann Behav Med*, 36, 13-20. Pavot W, Diener E. (1993). *Psychol Assess*, 5(2), 164-172.

## MENTAL TOUGHNESS IN AN RFU ENGLAND RUGBY ACADEMY

Powell, A., Myers, T.D.

*Newman University, Birmingham*

Mental Toughness (MT) is frequently used term in sport but its conceptualisation remains rather ambiguous (Andersen, 2011). Frequently defined in the literature in terms of various aggregates of widely differing aspects of elite performance, it remains unconvincing as a clearly defined psychological construct. This lack of clarity may be the result of MT differing across sports. As such, it is important to clearly establish what MT means in particular sports. The aim of this study was to investigate MT in rugby by exploring the perceptions and experiences of MT and its development in players and coaches at a Rugby Football Union (RFU) academy. **Methods** A purposeful sample of participants (four players and two coaches) were selected from an England RFU Academy. These participants were identified as being the mentally toughest players in the academy, by other players, coaches and the use of a Sports Mental Toughness Questionnaire (SMTQ). All participants were interviewed using a semi-structured format and questioned about their perceptions and experiences of MT and its development in rugby. Interviews were transcribed verbatim. Data were analysed thematically using Interpretive Phenomenological Analysis with trustworthiness established using bracketing and member checking. **Results** Themes and clusters identified a number of characteristics that were associated with MT for Rugby, including confidence, hardiness and the use of specific mental skills. Relishing completion, facing challenges and social support were seen as important in developing MT in Rugby. **Discussion** Findings highlight the importance of key mental characteristics in rugby. A number of these characteristics are shared by other contact sports such as Australian Football (Gucciardi, 2008). In developing MT for Rugby situational factors and social support played a key role at different stages of

players' development, supporting previous findings (Finn & McKenna, 2010). Overcoming setbacks, facing adversity dealing with pressure were important factors. Our findings highlight the importance of coaches creating challenging situations in practice, peers providing rivalry and support in training and competition, and more established players acting as role models. Overall, the findings suggest that to enhance MT at a developmental stage, players should be gradually exposed to, rather than shielded from, demanding situations in a supportive training and competition environment (Parkes and Mallett, 2011). References Andersen, M.B. (2011) In Gucciardi, D.F. & Gordon, S. Mental toughness in sport : developments in theory and research. Oxon: Routledge Finn, J. and McKenna, J. (2011) *Sport Psychol*, 25, 269-287.

### CHILDHOOD HYPERACTIVE TEMPERAMENT PREDICTS LOW PHYSICAL ACTIVITY AND HIGH SCREEN TIME IN ADULTHOOD: THE YOUNG FINNS STUDY

Yang, X.1, Hirvensalo, M.2, Pulkki-Råback, L.3,4, Hintsanen, M.3, Hintsala, T.3, Keltikangas-Järvinen, L.3, Telama, R.1,2, Viikari, J.S.A.5, Raitakari, O.T.5, Tammelin, T.1

1: LIKES – RCHSH (Jyväskylä, Finland), 2: UJ (Jyväskylä, Finland), 3: UH (Helsinki, Finland); 4: FIOH (Helsinki, Finland); 5: UT (Turku, Finland)

**Introduction** No research has investigated the long-term effects of hyperactive temperament in childhood on physical activity and screen time in adulthood. The aim of the present study was to examine an association of childhood hyperactivity with physical activity and screen time later in life based on a population-based sample of boys and girls who have been followed up during 27 years. **Methods** Participants (424 boys and 500 girls) in the three youngest age cohorts (3, 6 and 9 years) were initially enrolled in 1980 and followed up over 27 years until 2007 (aged 30-36 years) as a part of the Young Finns Study in Finland. Hyperactive component of temperament was rated by mother's report at two consecutive time points from 1980 to 1983. Physical activity was measured by mother's reports of 3- and 6-year-olds and by self-reports of 9-year-olds or later until the age of 30-36 years. Screen time was dichotomized into <2 hours/day and ≥2 hours/day. **Results** High hyperactivity temperament in childhood predicted lower physical activity in women and higher screen time for both genders. Girls with a high hyperactivity had a 2.6-fold decrease in adult physical activity than those with a low hyperactivity. Both high hyperactive boys and girls had 2.1- and 1.9-fold higher in adult screen time, respectively, compared to their low activity temperament counterparts. These associations remained significant after adjustment for potential covariates from childhood and adulthood. **Discussion** High hyperactive temperament in childhood is identified as an independent risk factor for the prevalence of unhealthy lifestyle behaviors over 27 years. High hyperactivity in early years predicts lower physical activity and higher screen time in adulthood. A significant dose-response relation is also observed between level of childhood hyperactivity and adult physical activity and screen time. Being high hyperactivity is associated with an increased risk of physical inactivity and sedentary. The effects of childhood hyperactivity on adult physical activity are more pronounced for women than men. Our findings suggest that hyperactivity established during the early years, particularly their maintenance, may be contributing to the problem of the decline in physical activity and the increase in screen time later in life, especially among women.

### PSYCHOMOTOR PERFORMANCE AFTER 30 HOURS OF SLEEP DEPRIVATION AND EXERCISE OF MODERATE INTENSITY

Dabrowski, J.1, Ziemia, A.1, Bogdan, A.2, Zwolinska, M.2, Kozacz, A.1, Mikulski, T.1

1 Mossakowski Medical Research Centre, Polish Academy of Sciences, Poland. 2 Central Institute for Labour Protection – National Research Institute, Poland.

**Introduction** Testing of the psychomotor performance is a good and simple method to evaluate central fatigue in humans. It determines visual motor coordination, speed and accuracy of perception, decision-making under time pressure and fatigue resistance. Such factors play an important role in ultra-endurance exercises, especially ones combined with sleep deprivation. **Methods** Eleven endurance-trained men  $31.4 \pm 2.1$  [yr] performed graded test to volitional exhaustion with workload increased by 50 Watts every 3 min) before (trial B) and immediately after (trial A) 30 hours of prolonged exercise (simulated adventure race) combined with complete sleep deprivation. Subjects were cycling, running, roller-skating, kayaking and swimming with an average heart rate of 100-120/min and a maximum not exceeding 170/min. Multiple choice reaction time (MCRT) testing was conducted at rest and during last 2 minutes of each workload of graded exercise test. In MCRT test subjects are expected to react as fast as possible to 15 positive light and sound stimuli emitted in different time intervals by pressing the corresponding button placed on handlebars of cycloergometer and to ignore 15 negative impulses. **Results** There were no statistically significant differences in MCRT at rest between trial B ( $339.2 \pm 9.5$  ms) and trial A ( $323.1 \pm 11.7$  ms). During graded exercise test MCRT was also similar in trials B and A,  $329.5 \pm 9.5$  ms vs.  $326.5 \pm 7.7$  ms, respectively. **Discussion** Results of the present study are consistent with our previous findings (Mikulski 2006; Dabrowski 2012) involving prolonged exercises of different kind and intensity. Subjects accustomed to sleep deprivation, although suffering from central fatigue, are still capable to concentrate properly, even at rest, on short, slightly complex task like MCRT test. During exercise additional stimulation of sympathetic nervous system improves psychomotor performance. **In conclusion**, healthy, trained men are able to fulfill short tasks involving psychomotor abilities independently from some extent of central fatigue. **References** 1. ### INDIVIDUAL AND TYPOLOGICAL FEATURES OF UNIVERSITY STUDENTS, ENGAGED IN AMATEUR SPORT ACTIVITIES

Tukaiev, S., Vasheka, T., Dolgova, O., Zima, I.

National Taras Shevchenko University of Kyiv

The aim of the given research is to detect the typological and personal differences of the university students, who are engaged in amateur sports. It is well-known that going in for sports, as well as other physical activities in general, contribute to a healthy lifestyle, help to prevent numerous chronic diseases (such as cardiovascular diseases, obesity, hypertension, etc.), and give a therapeutic effect in preventing mental status disorders (such as depression, distorted body image and self-perception, low self-esteem etc.) The first-year students who entered the University having higher level of physical training can be better adapted to new environment and lifestyle what can have a positive effect on their educational results, their feelings and psychological state. 67 students (34 women and 33 men, 17-23 age range, 20.5 mean age) of National Taras Shevchenko University of Kyiv, Ukraine participated in this research. The control group included 281 students (220 women and 61 men) with no prior sport experience except Physical Education classes at schools and universities. The following procedures of tests have been applied: Temperament Diagnostics Test by J.Strelau, EPI Test by H.Eysenck, Manifest Anxiety Scale by J.Taylor, State-Trait Anxiety Inventory by C.Spielberger, Y.Hanin, Differential Diagnostics of Depression by V.A.Zhmurov,

Diagnostics of Neurotization Level by L.Wasserman, Diagnostics of Emotional Response to Environmental Stimuli by V.Boyko, Boston Stress Resistance Test, Psychological Stress Measure (PSM-25), Aggressive Behaviour Test by E.P.Ilyin and P.A.Kovalev, Syndrome of Emotional Burnout test by V.Boyko, Maslach Burnout Inventory, the V.D.Mendelevich Anticipation Consistence Test (TAC), and L.A. Regush technique to diagnose the ability to predict. The experiment has proved that the students who regularly go in for amateur sports demonstrated higher level of activity and mobility of neural processes, and lower level of neuroticism, lower level of neurotization, anxiety, psychic tension and depression. It has been also found that these students had pronounced outward euphoric and less pronounced outward dysphoric reactions to external stimuli, and were more inclined to direct physical aggression. We also found demonstrated significant levels of both general and spatial anticipation. The latter was more pronounced among those practicing team sports (football, volleyball, and basketball). This allows us to conclude that the type of nervous system may define the disposition towards the physical activity, and the strength of nervous system determines the ability to achieve results in sports. Our data indicate that practicing sports prevents the development of burnout, reduces the negative impact of daily emotional stress, and provides a socially acceptable way to express aggression.

#### **INFLUENCE OF PERIOD ON THE DISTANCE FROM THE GOAL LINE TO THE LESS ADVANCED OUTFIELD PLAYER IN SPANISH FIRST DIVISION SOCCER TEAMS.**

Caro, O., Fradua, L., Zubillaga, A., Anon, C., Fernandez-Navarro, F.J.

*GRANADA UNIVERSITY*

**INTRODUCTION** A variable like the distance from the goal line to the less advanced outfield player may help to describe a team's pattern of play (Carling et al., 2005). Teams using an offensive style may play closer to the opposing goal whereas those using a more defensive style may play closer to their own goal (Zubillaga et al., 2011). The venue period of the match could have an influence on his tactical variable like had in other physical components (Bangsbo, Mohr, Krstrup, 2006). The aims of the present study was to analyse the influence of the period of the match on the distance from the goal line to the less advanced outfield defender. **METHODS** A multiple-camera player tracking system (AMISCO Pro, Sport-Universal Process, Nice, France) was used to record the existing distance from the goal line to the less advanced outfield player of the analysed team (metres). A total of 25 matches, 5 per team, of the First Spanish Division were analysed. The matches were recorded and digitalized and the player's position and movements were registered with a frequency of twenty-five records per second (see Zubillaga et al., 2007). A total of 17546 data were collected. **RESULTS** A one-way ANOVA revealed that the distance from the goal line to the less advanced outfield player was significantly smaller in the second period ( $28.85 \pm 13.15$ ) than the first period ( $30.40 \pm 12.47$ ). **DISCUSSION** The distance from the goal line to the less advanced outfield player was found as a tactical variable influenced for the period of the match. Therefore, the different moments of the match could be a factor that doing these different distances from outfield players to their own goal This variable could be a consequence of teams' defensive or offensive minded styles of play (Zubillaga et al., 2011). Results of the present study could be interesting in the preparation of the defensive and offensive phases of matches and its training process Future studies could analyse the influence of other factors, like the result or the local or visitors condition, with the goal to know the football in depth and to improve the training process. **References** 1. #### **THE EFFECT OF TEAM AND OPPOSITION QUALITY ON SELECTED ACTION VARIABLES IN PROFESSIONAL RUGBY LEAGUE**

Parmar, N., James, N., Greenhalgh, A., Hughes, M.D.

*Middlesex University*

**Introduction** There is a lack of research on performance analysis in professional rugby league, even though Gabbett (2005) identified performance analysis as an emerging tool for gaining a further understanding of this sport. Hughes and Bartlett (2002) suggested that studies in performance analysis should provide comparisons of data by relating the observed teams' performances to opposition values. Therefore this study aims to analyse the differences in selected actions, between top, middle and bottom ranked professional rugby league teams in relation to opposition quality. **Methods** OPTA Sports data (<http://www.optasports.com/>) collected from 27 rounds of the 2012 Super League season, amounting to 189 matches, were processed in Microsoft Excel and analysed using a series of analysis of variance (ANOVA) tests using the IBM SPSS statistics package (v19, SPSS Inc., 2010). Teams were ranked based on their final league standings at the end of the 2012 Super League season as being top four (teams finishing in places 1-4), middle six (teams finishing in places 5-10) and bottom four (teams finishing in places 11-14). **Actions analysed in attack** were the number of carries, metres gained, line breaks and successful and unsuccessful offloads and in defence the number of completed and missed tackles. **Results** ANOVA results showed that the top four teams had a greater number of carries, gained more metres, made more line breaks and missed less tackles than the middle six who also performed better than the bottom four teams. The effect of the opposition quality had the same effect i.e. the greater the opposition quality the less well the team performed on each variable. In comparison the frequency of successful and unsuccessful offloads in attack were similar irrespective of the quality of the team or opposition. The top four and middle six ranked teams completed a similar number of tackles however this frequency increased in line with the opposition quality. In comparison the bottom four teams made more completed tackles as the opposition quality decreased. **Discussion** This preliminary analysis of selected variables collected by OPTA over a full season of professional rugby league suggests that significant differences are evident between action variables depending on the quality of both the observed team and opposition. Further independent variables such as match venue and match out-

come need to be analysed in the future. This work will be extended to examine which variables relate to successful performance and hence be deemed performance indicators. References Gabbett T.J. (2005). *Journal of Sports Sciences*, 23(9), 961-976. Hughes M. & Bartlett R. (2002). *Journal of Sports Sciences*, 20, 735-737.

### THE ANALYSIS ON ACTIVITY LEVEL AND NATURE OF THE ORGANIZED TRAINING AND SELF-ORGANIZED TRAINING IN SOCCER

Nybakken, T.I, Ingvaldsen, R.P.2

*Bergen University College 1, The Nord-Trøndelag University College 2*

**Introduction** Both the number of children participating in organized soccer and the number of organized sessions per child, has increased in Norway during the last 10 years. The idea behind this is that by recruiting more children to a structured training environment, this in the long run will help to improve the standard of soccer. The purpose of this study was to compare organized soccer training (Deliberate practice, DPR) with children's self organized football activity (Deliberate play, DPL). One have to ask, in what sense is the organized training sessions different form and potentially more effective for skill development, than children's self organized soccer activities? **Methods** 6 boys playing soccer in their local teams, age 11 to 12 years, volunteered to participate with consent from their parents. The boys were observed in 9 sessions in organized and self-organized soccer activity at different venues. The children's base team coach organized 3 of the DPR-sessions, and the coach for a team of selected young talents (ST) another 3 DPR. The remaining 3 sessions were self-organized trainings in a small sized pitch (Deliberate play). The training sessions for observation were selected randomly within a period of 2 months, registered in a log, and recorded on video. Total observation time was 2650 minutes. Registrations were focused on kind of activity, number of cases, intensity, and time spent in different activities. **Results** The main results of the survey shows differences in what exercises kids choose in self-organized activity (DPL), as compared to activity organized by their trainers (DPR). Differences were found in time to play against each other 90% vs 38 %, activity period attacking the goal 92% vs 53 %, and games in small group 74% vs 19 %. These categories overlap. Another striking result is that the number of ball touches for DPL situation is higher than in the DRL situation, 25,74 against 9,62 (ST) on average per 5 minutes played. Also it is observed 6 times more ball transports, 2,5 times more finishing on goal, and 2,8 times more involvement in 1:1 situations, in the DRL as compared to the DPR. In DPL also higher intensity and considerably less breaks were observed compared to DPR. In DPR the most of the time is spend in set situations for receiving and passing the ball. **Discussion** The results of this study indicate that DPL and DPR activities are very different in many respects. The activity level, the intensity and variability in the activities are higher in the deliberate play as compared to the deliberate practice situations. Based on the findings in this study, previous research (Côté et al, 2003, 2007) and theories of motor development (Vereijken, 2005), one can hardly see that DPR will lead to a greater variability of practice (Schmidt, 1991), as compared to DPL. Higher number of organized sessions at the expense of self-organized activity, might be negative for the quality of the talent development; unless DPL variability is adapted into DPR.

### THE PROFICIENCY OF SPIKING AND BLOCKING OF ADOLESCENT MALE VOLLEYBALLERS' IN ESTONIAN CHAMPIONSHIPS IN 2005 AND 2008

Stamm, R., Stamm, M.

*Institute of Health Sciences and Sports*

**Introduction** The study analyses volleyballers' performance at Estonian championships for U16 (boys up to 16 year-olds) in two tournaments– Tartu 2005 and Rakvere 2008. The participants were members of eight best teams of Estonia at the moment. **Methods** To record the games an original computer program Game was used, which was first introduced in the *International Journal of Volleyball Researches* (Stamm et.al 2000). For simultaneous recording of the performance of two opposing teams, two computers equipped with the program Game were used. Parallel recordings were made by volleyball experts. All together 56 games were analyzed. **Results** From our data we can conclude that the quality of spike has a tendency of improving. In 2005 there were 1221 spikes which earned a point. and in 2008- 1276 spikes. These data were not statistically significant. When we look at the mistakes during the spike we can see that there were also less mistakes in 2008–552 mistakes (SD=10,15) and in 2005–566 mistakes (SD=9,11) The same thing appears when we look at the average of the proficiency index. It has been increased from 0,54 (SD=0,19) to 0,58 (SD=0,18), although the difference was not statistically significant. Now when we look at the blocking values then we can see that the amount of blocks is statistically significantly increased, in 2005–938 (SD=14,75) and in 2008–1057 (SD=17,08). Also the amount of successful blocks in one game in average have increased from 3,81 times (SD=5,01) in 2005 and to 4,75 times in 2008 (SD=5,19). We find out the average of the mistakes during the blocking, that amount was also statistically significantly increased 4,25 (SD=4,33) and 6,85 (SD=5,76). But in conclusion, when we look at the index of proficiency we can see that it is still increased - 0,36 (SD=0,24) in 2005 and 0,44 (SD=0,25) in 2008, although the last date were not statistically significant. **Discussion** The quality of spike has a trend of improving. There were more successful spikes, less mistakes and average proficiency index was higher in 2008 than in 2005, although the difference was not statistically significant. The amount of blocking increased, which is by itself a good indicator already for adolescent players (Gabbet et.al 2007), also increased the amount of successful blocks, but surprisingly increased the amount of the mistakes also and even statistically significantly. But in conclusion when we look at the average of proficiency index we can see that, it was higher in 2008 than in 2005 Championship. **References** Gabbett, T., Georgieff, B., Domrow, N. (2007). *Journal of Sports Sciences*, 2, 1337 – 1344. Stamm R.,Stamm M., Oja A. (2000). *Int. J Volleyball Res*, 2 (1), 18 – 22.

### ANOTHER TEAM TIMEOUT IN HANDBALL WHAT'S THE DIFFERENCE COMPARING WINNERS AND LOSERS TEAMS?

Prudente, J., Cardoso, A., Lopes, H., Fernando, C.

*University of Madeira*

**Introduction** Since the introduction of the team timeout in handball at the Olympic Games in 1996, until the actual situation with three team timeout, some discussion has been made about important is the team timeout in the performance. Despite this discussion, there are scarce studies about the team timeout in Team Handball, namely about the reasons to lead the coaches to call timeout and try to understand how they manage the possibility to call them during the game and verify if there is any differences between winners and losers teams. **Methods** Sixteen games, from the final phase were analyzed using the play-by-play-related statistics from the International Handball Federation (IHF). For each time-out, the events and goals scored in the previous and post 5 ball possessions were registered for the teams that called timeout and for the opponents. Each half time game was divided in 5 periods: 0-10', 10'-20', 20'-25',25'-28', 28'30'. **Results** In all 16 games never the teams called 6 timeouts and only in 9 games (56, 3%) they call for 5 timeouts. The difference

between winners and losers teams is significant concerning the n° of timeouts they call ( $p=0,04$ , losers;  $p=0,06$ , winners), but there are no significant difference between winners and losers teams concerning the period of the game when they call timeout ( $p=0,240$ ). No significant difference exist between winners and losers teams in relation of the effects on the score in the end of the 5 ball possession post timeout ( $p=0,102$ ). Discussion Teams defeated call more for timeouts that the winners teams, and the 3thd team timeout is not considered in the majority of the games by the winning teams. The totality of timeouts possible is not always utilized (Taborsky & Sevim, 2004; Prudente, 2009). The teams call timeouts in the same periods of the game. There is no significant difference as winners and defeated teams call timeout and this result is influenced by the fact that a negative partial score is associated with the coach decision to request a timeout (Prudente, 2009). The greater the difference between goals scored and received at the end of the game larger the number of requests timeouts. However the analysis of the partial score obtained between the moments of the timeout requested and the post 5 ball possessions indicate that is no difference between the winning and the defeated teams, i.e., seemingly does not influence the final result. ### **ANALYSIS OF PACING PROFILES BY MEANS OF MIXED LINEAR MODELLING: NEW INSIGHTS WITH AN ALTERNATIVE STATISTICAL APPROACH?**

Skorski, S.1, Faude, O.2, Caviezel, S.2, Meyer, T.1

*1Saarland University, 2University of Basel*

Introduction: Studies focusing on the stability of pacing from one competition to the next are mostly comparing absolute lap-times between two events. However, in this approach it might occur that the average split times are similar, although the individual athlete shows high variation between events. Therefore, another approach could be analysing the change score between the laps and defining the variance of these scores in different competitions. Furthermore, to estimate the variability in a change, general mixed effect modelling seems to be the proper analytical approach, since it provides modelling of variance and covariance. Hence, the aim of the study was the analysis of pacing pattern by calculating change scores and estimate the variability with mixed general modelling. Methods: Split times of 132 elite male swimmers (age:  $22.8 \pm 2.9$ y) in all 200m strokes (freestyle, butterfly, backstroke, breaststroke) in 2 competitions were downloaded from swimrankings.net. These data was used due to the large number of competitive events and the availability of these data from the internet. Pacing patterns were analysed using the change score between the laps in percent, by calculating the difference between every split time as percent of the preceding lap (e.g.  $\Delta$ lap 1-2 for the difference between split time 1 and 2). Variations of lap changes were analyzed with general mixed effect modelling, according to Vandenberg et al. (2012). Competition was included as fixed effect. The random effects were athlete's identity (between subject variability), lap time and residual (within-subject variability). An additional model was calculated including style and split time as random effects. Results: Mean lap change between competitions ranged between -13.4% ( $\Delta$ lap 1-2; 200m butterfly) and -0.5% ( $\Delta$ lap 5-6; 200m backstroke). The model provided estimates of other effects, as follows: within-athlete SD in lap change ranged between 0.9% and 2.6% (range in 90% CI: 0.8–3.2%), between-athlete SD among <0.001% and 1.8% (CI: < 0.001 and 5.3%). Furthermore, absolute lap time estimates 75%, the different strokes 12.9% of the lap change and residuals are 13%. Conclusion: Analyzing lap changes with mixed general modeling seems to improve the estimation of individual changes in pacing patterns, since within- and between-subject variations can be calculated. The models can, hence, be used as a powerful research design to analyze variations in pacing. The design provides outcomes that explain variation in lap changes more accurately and precise than traditional analysis, by providing random variables which are assumed to affect variability of the data. ### **ORIGIN AND TARGET THROWS IN ELITE LEVEL GOALBALL**

Morato, M.P.1, Furtado, O.L.P.C.2, Galatti, L.R.3, Almeida, J.J.G.2

*1:EEFERP-USP (Ribeirao Preto, Brazil), 2:FEF-UNICAMP (Campinas, Brazil), 3:CDS-UFSC (Florianopolis, Brazil)*

Introduction Goalball is a paralympic team sport that has been receiving growing attention of researchers worldwide, however few have focused on the match analysis of elite players. The knowledge of ball origin (OR) and target (TA) should help determining the most common places of action in the court, providing coaches essential information to organize their teams. The purpose of this study was to verify the OR and TA throws in elite level goalball. Methods Two evaluator with at least 3 years of goalball experience went through a comprehensive training to assure standardization of the observational assessment criteria (Anguera, 1999). The protocol consisted of scoring ball OR (first touch on the floor after throwing) and TA (crossing of defense line) to each attack. Starting from the right wing, both team and landing areas were divided in 6 sectors (SE) of 1.5m (width) and labeled 1 to 6. We analyzed 20 randomly selected matches, 10 per gender, from Beijing 2008 Paralympic Games. A total of 1491 women (W) and 1560 men (M) throws was investigated. Penalty shots were not recorded. The Kappa index for intra and interobserver reliability was 0.94 - 0.89 for OR and 0.95 - 0.91 for TA, respectively. Descriptive analysis was used to determine OR and TA incidence. Results OR incidence in W (SE): (1)24%, (2)18%, (3)8%, (4)11%, (5)17%, (6)21%; in M: (1)24%, (2)20%, (3)10%, (4)9%, (5)19%, (6)17%. TA incidence in W: (1)12%, (2)20%, (3)21%, (4)17%, (5)15%, (6)19%; in M (SE): (1)8%, (2)17%, (3)19%, (4) 20%, (5)17% and (6)12%. The balls thrown out was 7% in both genders. Discussion Our results shows higher OR incidence in the wing sectors for both gender, which was also reported by Amorim et al. (2010) from M European championships. It can be explained due to player position, as the wing players are usually responsible for offensive actions as confirmed by Mora (1993) with a M regional team. TA results demonstrate higher incidence of balls arriving in the central region of the team area (SE3 in W and SE4 in M) and decreases to the extremes. These findings corroborate the defensive balance concept proposed by Morato, Gomes and Almeida (2012). They suggested that teams should organize their defensive system with the wings closer to the center player and move like a triple block accordingly to the throwing OR. References Amorim M et al. (2010). REIFOP, 13(3), 47-57. Anguera MT (Ed) (1999). Barcelona: Edicions de La UB. Mora DH (1993). Barcelona: Revista do INEF. Morato MP, Gomes MSP, Almeida JGG (2012). Rev. Bras. Cienc. ### **BETWEEN MATCH VARIABILITY IN PROFESSIONAL RUGBY LEAGUE COMPETITION**

Kempton, T., Sirotic, A., Coultts, A.

*University of Technology, Sydney*

Introduction The purpose of this study was to assess between match variability of physical performance measures over both the total and sub sections of the match in professional rugby league competition. Methods Global positioning system (GPS) data were collected from 24 players from the same team competing in the National Rugby League (NRL) competition over 23 matches during 2011 season. The GPS

data were categorised into total distance, high-speed running (>15 km h<sup>-1</sup>) and very high-speed running (>21 km h<sup>-1</sup>) distance for discrete reference periods (10 min, 20 min, 40 min and 80 min). The data was then log transformed to provide the coefficient of variation (CV) and the between subject standard deviation (both expressed as percentages). Results The data show that the between match variability is greater for high-speed (CV 14.6 %) and very-high speed (CV 37.0 %) running compared to total distance (CV 3.6 %). Within each speed category, the variability of performance tended to increase as the duration of the reference period decreased. Conclusion While global measures of physical performance such as total distance are relatively stable, higher-speed activities exhibit a large degree of between match variability. In addition, when segmenting the match into short periods of time for analysis, all physical performance measures increased in variability. These findings have implications for determining sample size, identifying reliable performance measures and selecting appropriate time periods for future applied studies that involve observational match analysis.

### WHAT ACTUALLY HAPPENS IN JUNIOR RUGBY LEAGUE: GAME ANALYSIS ACROSS AGE GROUPS

Cotton, W., O'Connor, D.

*The University of Sydney*

Introduction Rugby League is a game played by over 30 nations around the world. In Australia, Rugby League has a strong junior base, with over 100,000 registered junior players. Despite this popularity very little is known about what actually occurs during the junior games. Therefore the aim of this study was to analyse the skills performed, the effectiveness of the performed skills and the errors made during junior Rugby League games and to compare these findings across 5 different age groups. Methods This study was conducted as part of the larger 2012 Rugby League Participation Pathways Review (Australian Rugby League Commission, 2012). This aspect of the review involved the systematic video analysis of 104 junior Rugby League games across 5 age groups: the under 8s, 9s, 10s, 11s and 12s. Forty five different variables were observed and coded for each game. To allow for game time variations, both within and across age groups, the number of variables per game was scaled to a 20min time period. A series of one-way ANOVA's were conducted to compare the variables across the age groups. Results Initial results suggest that there was a statistically significant difference at the  $p < 0.05$  level in the total skill opportunities that junior players have in a 20min period [ $F(6, 205) = 22.09, p = 0.000$ ]. Post hoc comparisons using the Tukey HSD test revealed that these total skill opportunities increased from the under 8s to under 10s, but then plateaued with under 11s and under 12s. A further breakdown of these results and the number and types of errors made will be provided during the presentation. Discussion The results of this study provided a deeper understanding of the skills performed and the number and type of errors made within specific age groups in junior Rugby League. The study also enabled comparisons to be made between age groups and to track how the number and type of skills and errors changed across age groups. This is perhaps the first vital step in obtaining reliable baseline data to inform future interventions and possible rule change experiments with the hope of maximising the true potential of all junior players. References Australian Rugby League Commission (2012) Rugby League Participation Pathways Review

### OFFENSIVE TECHNICAL TACTICAL VARIABLES THAT DISCRIMINATE BETWEEN WINNING AND LOSING TEAMS IN THE U17 WORLD CUP MEXICO 2011

Fritzler, W., Roldan, J., Manzano, J.A.

*University of Football*

Introduction The technical-tactical characterization of successful soccer teams allows the establishment of training objectives (Carling et al., 2005). Although research on tactical aspects has increased in recent years, there is little information on youth soccer. This justifies an exploratory study in order to identify some of the technical-tactical aspects that discriminate statistically between winning and losing teams in the U17 World Cup Mexico 2011 (WC). Methods Using video-analysis, a systematic observation of 10 games in the WC's second phase was conducted. Variables on shots on goal, crosses into the penalty box, corner and free kicks, and offensive duels in opponent's half were assessed. Each of the variables was analyzed by a trained expert, recording the frequency, main characteristics, and outcome of the actions. For statistical analysis, a database was created with details of all actions, grouped by winning and losing teams, regardless of what games were held. Differences were evaluated by testing hypotheses regarding differences in proportions (Hernandez et al., 2006). Results The players of winning teams shot at goal from shorter distances, but with the same overall efficiency as the losing teams. However, most often they shot from zones of greater efficiency. Winning teams crossed more often and with much greater efficiency. Losers crossed more on diagonal, while winners did it from the height of the penalty box. On corner kicks, winners manage to connect with a teammate in half of the cases, while losers only in a quarter, but with no significant difference in the frequency of these kicks. In free kicks, the efficiency of the winners was higher too, but without statistical significance. The offensive duel efficiency of the winners was significantly better, especially in the vertical direction. Winners won more duels in zones close to the goal than losers. Discussion Success in matches was related to the effective implementation of corner kicks, winning offensive duels, and vertical play to cross and shoot on goal. In terms of shots on goal, winning teams did not shoot better, but more often and from shorter distances, that increased the probability to score. In general, teams won their matches because they repeated more often those actions they perform more efficiently than losing teams. According to these conclusions, the offensive tactical training of youth teams should focus on the efficiency of corner and free kicks, on the ability to get closer to the goal by individual and group means, and on penetrating along the sideline before crossing. Research Methodology (4th ed.; original in Spanish). Mexico: McGraw Hill.

### ANALYSIS OF THE ATTACK TEMPO IN DIFFERENT GAME-COMPLEX IN HIGH-STANDARD MEN'S VOLLEYBALL

Hileno, R.1, Salas, C.1, Buscà, B.2

1: INEFC (Lleida, Spain), 2: FPCEE Blanquerna, Ramon Llull University (Barcelona, Spain)

Introduction The tempo of the setting pass is a relevant factor for block construction and attack efficacy in high-standard volleyball (Alfonso & Mesquita, 2011; Buscà & Febrer, 2012). In modern volleyball, game is categorized in five phases (game-complex K1 to K5) taking the first ball contact of the team as a reference (Hileno & Buscà, 2012). In the second ball contact, the setter builds the attack of the team depending on the game-complex and the rally development. The aim of the study was to examine the differences in attack tempo between the different game-complexes. Methods 1418 actions were recorded and analyzed from a randomized sample of the 2010 Panamerican Cup male tournament, held in San Juan (Puerto Rico). Frame by frame analysis was performed to determine the attack tempo while attack was completed. To compare attack tempo means for different game complexes, the nonparametric two-sided Mann-Whitney U test for independent samples was used. All statistical analyses were performed using SPSS. Statistical significance was set at P

< 0.05. Results Mean time ( $\pm$ SD) of the attack tempo in K1, K2, K3, K4 and K5 were  $0.97\pm 0.37$ ,  $1.39\pm 0.34$ ,  $1.34\pm 0.40$ ,  $1.31\pm 0.25$  and  $1.06\pm 0.15$  s, respectively. We found significant differences between attack tempos in K1 and K2, K1 and K3, and K1 and K4 ( $p < 0.001$ ). Moreover, we found significant differences between K5 and K2, K5 and K3 and K5 and K4 ( $p < 0.001$ ). Discussion Performance and game structure are conditioned by the game-complex. Thus, a specific training for the different characteristics of each complex is required (Palao, 2001). In the present study, we didn't find differences between the attack tempos used in K1 and K5, by one side, and between K2, K3 and K4 by the other side. Therefore, training the attack tempo grouping K1-K5 and K2-K3-K4 could be a good strategy for attack performance improvement. Observing the attack tempo of K1 and K5, we didn't find significant differences of the mean values but different SD. This high level of dispersion could be explained by the differences in the quick tempos. In K5, quick tempos are played farther from the setter, respect K1 tendency. ### SHOOTING IN FOOTBALL: FAST OR SLOW, HOW TO DECIDE?

Vicente, A., Fernando, C., Lopes, H.

*University of Beira Interior, University of Madeira, CIDESD*

Introduction Winning games in football is about scoring more than the opponent. But opportunities to score tend to scarce nowadays. And when they do happen they cannot be wasted. Therefore shooting is crucial. It is easy to admit that shooting players (mainly strikers) need to be fast to be successful (shoot with high speeds or dribble faster, for example). However, previous studies (e.g. Vicente et al., 2012) showed that there are time relations between players that must be taken into account in football. Players need to be aware of the opponent's actions (stimulus) and possibilities in order to take decisions and make the right choice. The aim of this study was to verify whether a correlation exists between the velocity of the stimulus in a shooting situation in football and the player's response. Methods We've used a software (MeSIRI.3) designed to measure the relation between the velocity of the stimulus and the time to respond it. The test was based on a stimulus - a goalkeeper (GK) - that moved from the center of the goal to each side at different velocities (1 and 3 meters per second (m/s) randomly). The players (55 university football players) had to press one of four matching letters in the keyboard, previously known, opposite to the goalkeeper displacement (B or V when GK moved right; N or M when GK moved left) for two possible ball velocities (B & N - 50km/h; V & M - 100km/h) for 20 trials. Each test data was automatically collected by the software which provided the response time (and correspondent direction and ball velocity) to each stimulus velocity. Results From the 1100 trials performed, the results showed that players took the right decision (ball to opposite GK displacement) in 86% of the situations. In those, for the fastest stimulus the average response time was 315 milliseconds (ms), and for the slowest stimulus the average time to respond was 362 ms. Players choose the faster ball velocity in 73% of the fastest stimulus, and 76% of the times the slowest ball speed in the parallel slowest stimulus. Discussion The results showed that the stimulus velocity influenced the response time and the response itself (shooting ball velocity). As the stimulus was faster or slower, the response was also faster or slower respectively; also as the stimulus was faster or slower, the ball velocity chosen was also faster or slower; which corroborates previous studies about penalty kick situations (Vicente et al., 2011) and other ecological studies that we are still carrying out. This may suggest that in shooting in football players should be trained to relate with the opponents being aware that they can influence their actions and their response time in order to take advantage and increase the efficiency in shooting. ### PASSING AND DRIBBLING PLAYS LEADING TO SCORING SHOTS AND SCORING CHANCES: ASSESSMENT OF OFFENSIVE PLAYS OF THE JAPAN NATIONAL TEAM IN THE 16TH FIBA WOMEN'S WORLD CHAMPIONSHIPS

Sakuragi, K., Aoyagi, O., Yaita, A.

*Fukuoka University*

Purpose Many kinds of passing and dribbling plays come before shooting the ball in basketball games. Some passing and dribbling plays effectively lead to scoring shots, whereas others contribute to scoring chances that do not result in a score. This study aimed to identify passing and dribbling plays that lead to scoring shots and scoring chances. Methods Sampled offensive plays included 1084 plays conducted by the Japan National Team during 6 games in which they competed with 6 teams at the 16th FIBA Women's World Championships. We examined the following offensive plays: 1) Forward pass moving the ball in the backcourt (fb), 2) Pass changing the side or angle to create a scoring opportunity in the backcourt (pb), 3) Pass to escape the risk in the backcourt (rb), 4) Before-shooting pass (sp), 5) Pass leading to a 1-on-1 situation (po), and so on. In addition, whether the players could make scoring shots (in/out) and whether the players could make scoring chances regardless of a scoring or failed shot (go/not) were examined. These 25 items were cross-tabled by "go/not" and "in/out." Chi-square test was applied to the cross-table, and an adjusted residual was computed if a significant difference was found. Relational trends were estimated considering significantly larger or smaller cells. Results In the cross-table crossed by "go/not" and 25 items, the cell crossed by "go" and the plays of sp, po, dp, da, lb, and or were significantly greater than values expected by marginal frequencies, and that of hp, db, th, pp, and cs were significantly less. The cell crossed by "not" and the plays of hp, db, th, pp, and cs were significantly greater than values expected by marginal frequencies, and that of sp, po, dp, lb, and or were significantly less. The frequencies of other cells were not significant. In the cross-table crossed by "in/out" and 25 items, the cell crossed by "in" and the plays of sp, po, dp, or, and ca were significantly greater than values expected by marginal frequencies, and that of pa was significantly less. The cell crossed by "out" and the plays of sp and dp were significantly greater than values expected by marginal frequencies, and that of pp was significantly less. The frequencies of other cells were not significant. Discussion The fact that the frequencies of "not" and db, pp, and cs were significantly lower indicated that these plays did not lead to scoring shots, even though they are used frequently. For example, in the case of db, it should not be used frequently, and is most successful when used only once. The significant relationship between "in" and ca indicated that when ca was observed, even only once during a game, the defense had already broken their defensive line, so this pass was considered to result in better conditions for a scoring shot.

## Mini-Orals

## PP-PM32 Nutrition [NU] 6

**A SIX MONTH PROGRAM OF PHYSICAL ACTIVITY AND NUTRITIONAL EDUCATION CAN IMPROVE PARAMETERS RELATED TO HEALTH IN CHILDREN.**

Muros, J.1, Zabala, M.2, Morente, J.2, Molina-López, M.1, Oliveras-López, M.J.3, Knox, E.4, López-García de la Serrana, H.1  
 1.University of Granada 2.University of Granada 3.University of Seville 4.University of Loughborough (UK)

**Introduction** Lipid profile is an important predictor of morbidity and mortality, and some studies have shown that it can be optimized by means of physical activity and nutrition programs. The aim of our study was to determine the effects of nutritional education and vigorous extracurricular physical activity both individually and in combination on the lipid profile in children. **Methods** The sample group consisted of 88 children (9-11 years) divided between three groups: 41 students in the control group (G0), 28 students in the physical activity group (G1), and 18 students in the physical activity and nutritional education group with additional substitution of normally used oil for EVOO (G2). The moderate-to-vigorous physical activity intervention program was carried out over 6 months using two weekly lessons of 60 minutes. G2 completed 6 sessions of nutrition education alongside their parents, which lasted approximately 2 hours each. In addition each pupil's parent received 2 liters of EVOO per week in the last month of intervention. The following measurements were taken: glycemia (GL), total cholesterol (TC), HDL cholesterol (cHDL), LDL cholesterol (cLDL), triglycerides (TG), systolic blood pressure (SBP) and diastolic blood pressure (DBP). We performed T tests and Wilcoxon tests for two related samples to compare blood composition, blood pressure, and dietary changes. DietSource 3.0 was used to evaluate macronutrients. All analyses were conducted using the SPSS 19.0 statistics package. Results SBP increased in G0 and decreased in G1 and G2 ( $p < 0.01$ ). DBP increased in G0 and decreased in G1 and G2, with significant reductions in G1 ( $p < 0.05$ ). G1 and G2 achieved reductions in GL ( $p < 0.05$ ) and TC ( $p < 0.05$ ). G2 was the only group showing significant changes in HDL ( $p < 0.05$ ). The LDL level increased in G0 and decreased in G1 and G2 ( $p < 0.01$ ). TG showed a reduction in G1 and G2 ( $p < 0.05$ ) while G0 did not show significant changes. Throughout the intervention, G2 experienced changes in calorie profile, making it more congruent with the Spanish recommended levels. At post-test G2 showed reductions in cholesterol ( $p < 0.01$ ) and fats ( $p < 0.01$ ), and increases in carbs ( $p < 0.01$ ). **Conclusions** Previous studies have shown that level of aerobic fitness in children is inversely associated with body fatness, impairment of several cardiovascular disease risk factors and hypertension (Runhaar et al., 2010). Our research shows that the pupils who increased their vigorous physical activity also experienced reductions in body fatness, SBP and DBP, and parameters related with cardiovascular risk e.g. CT, c-LDL and TG. Interestingly, aerobic fitness level is still not well recognized as a screening tool in pediatric populations. **References** Runhaar J, Collard DC, Singh AS, Kemper HC, van Mechelen W, Chinapaw M. (2010) *J Sci Med Sport*.13(3):323-8.

**A 6 MONTH PROGRAM OF PHYSICAL ACTIVITY AND NUTRITIONAL EDUCATION CAN IMPROVE THE ANTHROPOMETRIC PROFILE OF CHILDREN.**

Muros, J.1, Zabala, M.2, Sánchez-Muñoz, C.2, Garzón, M.2, Oliveras-López, M.J.3, Knox, E.4, López-García de la Serrana, H.1

1. University of Granada 2. University of Granada 3. University of Seville 4. University of Loughborough (UK)

**Introduction** Physical inactivity is considered to be one of the main threats to public health of the 21st century (Blair., 2009) and nutrition has been labeled as one of the main modifiable determinants of chronic diseases (WHO., 2003). The aim of our study was to determine the effects of nutritional education and vigorous extracurricular physical activity both individually and in combination on anthropometric parameters in children. **Methods** The sample group consisted of 88 children (9-11 years) divided between three groups: 41 students in the control group (G0), 28 students in the physical activity group (G1), and 18 students in the physical activity and nutritional education group with additional substitution of normally used oil for EVOO (G2). The intervention program was carried out over 6 months. G1 received two 60 minute lessons a week of moderate-to-vigorous physical activity. G2 received 6 sessions of nutrition education alongside their parents, which lasted approximately 2 hours each. In addition each pupil's parent received 2 liters of EVOO per week in the last month of intervention. The following measurements were taken: height, weight, skinfolds (triceps, biceps, subscapular, suprailiac, supraspinal, abdominal, thigh, and calf), perimeters (waist, hip, relaxed biceps, flexed and contracted biceps, thigh and calf), and diameters (bicondylar humerus, bistoloid and bicondylar femur). We performed T tests and Wilcoxon tests for two related samples to compare anthropometric parameters changes. All analyses were conducted using the SPSS 19.0 statistics package. Results All groups experienced an increase in weight between the pre- and post-test with G0 experiencing the greatest increase ( $p < 0.001$ ). BMI significantly increased in group G0 only ( $p < 0.01$ ). G0 showed a significant increase in the sum of the 8 skinfolds and in fat percentage at post-test. Conversely, we observed a significant decrease in the sum of the skinfolds and fat percentage in G1 and G2. At the same time these groups significantly increased their muscle percentage ( $p < 0.01$ ). G1 and G2 experienced significant decreases in waist circumference and waist-hip ratio (WHR). **Conclusions** A child can improve their body composition with no significant reduction in weight or BMI (DeStefano et al., 2000). This may have occurred during the present study as no significant changes in BMI were detected yet weight increased. We therefore suggest that other body composition indices may be more appropriate for use in future studies. **References** DeStefano RA, Caprio S, Fahey JT, Tamborlane WV, Goldberg B. **ENERGY BALANCE DURING AN ULTRA-ENDURANCE TRIATHLON**

Barrero, A., Carrasco, M., Iruñia, A., Chaverri, D., Iglesias, X., Rodríguez, F.A.

INEFC-Barcelona Sport Sciences Research Group, Institut Nacional d'Educació Física de Catalunya, Universitat de Barcelona (Barcelona, Spain)

**Introduction** The popularity of ultra-endurance triathlon (UET) races (3.8-km swim, 180-km cycle, 42.2-km run) has greatly increased since the first Ironman was held in 1978. The primary determinant of success is the ability to sustain a high rate of energy expenditure (EE) for

prolonged periods of time (O'Toole & Douglas, 1995). We could find only one study reporting data from real competition (Kimber et al., 2002), though lacking direct assessment of the swimming section. This study aimed to provide the first comprehensive characterization of the energy balance during real competition in male triathletes during a complete UET race. Methods Eleven well-trained non-professional ultra-endurance triathletes (mean  $\pm$  SD: age  $36.8 \pm 5.1$  years, mass  $75.5 \pm 6.4$  kg, height  $174 \pm 6$  cm, BMI  $24.8 \pm 1.7$  kg/m<sup>2</sup>, VO<sub>2</sub>max  $66.9 \pm 4.1$  mL•kg<sup>-1</sup>•min<sup>-1</sup>) competed in the Extreme Man Salou-Costa Daurada UET 2011. EE was estimated from heart rate (HR) recordings during the race (Polar RCX5), using the individual HR-VO<sub>2</sub> regressions developed from three incremental tests on the cycle ergometer (Excalibur Sport, Lode, Netherlands), running treadmill (h/p/Cosmos Pulsar, Germany), and 50-m swimming pool. VO<sub>2</sub> was measured using a portable gas analyser (K4 b2, Cosmed, Italy). An observational design, which included weighing and recording all food and fluid ingested and posterior nutritional analysis, was used to assess the energy intake (EI) during the race. Results Mean competition time was  $755 \pm 69$  min at an average HR of  $137 \pm 6$  beats/min. Mean EE ( $46.1 \pm 2.8$  MJ,  $11,009 \pm 664$  kcal) was significantly greater than EI ( $16.9 \pm 4.8$  MJ,  $4,043 \pm 1,141$  kcal;  $P < 0.001$ ). Mean EE rate was  $3.8 \pm 4.8$  MJ/h ( $738 \pm 69$  kcal/h). Energy deficit was  $37 \pm 0.1\%$  of total EE. Solid food provided 83% of EI, and fluids the remaining 17%. Discussion Both total EE and EI were greater than previously reported by Kimber et al. (2002) during an Ironman race (42.0 and 15.5 MJ, respectively), but energy deficit was smaller (40%). Compared to data on a 24-h cycling race competitor (Bescós et al. 2012), EE and EI were smaller (65.0 and 23.3 MJ, respectively), but EE rate was greater (2.7 MJ/h), resulting in a similar energy deficit (36% of EE). Our results confirm the high energy demands of UET races, which are not compensated by nutritional and fluid intake, resulting in a large energy deficit and dehydration which is likely to lead to early fatigue and impaired physical performance, particularly at the end of the race. ### INFLUENCE OF ACID OR ALKALINE FORMING NUTRITION ON PHYSICAL PERFORMANCE AT MODERATE ALTITUDE

Limmer, M., Platen, P.

*Ruhr-University Bochum*

Introduction Exposure to moderate and high altitude induces alterations in the acid-base balance which interfere with physical performance. The present pilot study was conducted to examine the effects of acid or alkaline forming nutrition on physical performance during moderate altitude exposure by the analysis of parameters of the aerobic and anaerobic energy metabolism and on acid-base blood and urine parameters. Methods 12 moderately trained, healthy adults (n=10 males; n=2 females) were exposed to moderate hypobaric altitude (MA, 2434 m to 3772 m) for seven days. Physical performance at altitude was compared between two groups consuming different types of nutrition: ALK (n=6) consumed mainly alkaline forming and ACID (n=6) acid forming nutrition. In order to assess anaerobic and aerobic performance all subjects performed a 15 s skipping test (SKIP) and a modified mCAFT (STEP) to maximal exertion pre MA, during MA and post MA, respectively. Blood acid-base parameters (pH, saO<sub>2</sub>, [HCO<sub>3</sub>]<sup>-</sup>, pO<sub>2</sub>, pCO<sub>2</sub> and ABE) were determined in morning and pre- and post- exercise capillary blood samples. Urine pH values were controlled daily in early morning, post-exercise and evening spontaneous urine samples (pHu). The parameters maximal lactate production rate (VLamax) for SKIP and step frequency, heart rate, RPE value and sO<sub>2</sub> at 2 and 4 mmol/l lactate for STEP were calculated for each subject. Statistical analysis was performed using repeated measures ANOVA and Student's t-test. Results Urine pH showed significantly higher values for ALK versus ACID and declined significantly at MA (morning pHu:  $6.18 \pm 0.55$  to  $5.47 \pm 0.41$ ; evening pHu:  $6.88 \pm 0.74$  to  $5.85 \pm 0.52$ ). No significant difference was found between ACID and ALK in aerobic and anaerobic performance as well as in blood acid-base status. For the total group, VLamax and [HCO<sub>3</sub>]<sup>-</sup> decreased significantly at moderate altitude exposure (VLamax  $0.76 \pm 0.10$  to  $0.60 \pm 0.12$  mmol/l/sec; [HCO<sub>3</sub>]<sup>-</sup>  $25.2 \pm 3.8$  to  $20.0 \pm 1.4$ ) whereas maximum performance during STEP increased after MA ( $120.7 \pm 12.2$  to  $132.2 \pm 9.8$  bpm). Discussion and Conclusions As expected, aerobic performance improved after MA but maximum lactate production rate declined continuously during MA. ACID or ALK did not affect anaerobic or aerobic performance during moderate altitude exposure. The modification of nutrition had a clear impact on urine pH values indicating the influence of the dietary intervention on acid-base homeostasis, however it did not significantly affect blood pH values or bicarbonate concentration.

### ENERGY SUBSTRATE UTILISATION DURING ENDURANCE EXERCISE AFTER 5 DAYS ON HIGH CARBOHYDRATE WITH HIGH AND LOW GLYCAEMIC INDEX DIETS

Hamzah, S.

*University of Malaya*

Introduction Several studies have suggested that glycaemic index (GI) of single high carbohydrate (CHO) meal consumed few hours prior endurance exercise and of mixed high CHO meals during 24 hours recovery between bouts of prolonged exercise might influence energy substrate utilisation (Wu et al., 2003; Trenell et al., 2008). However, limited evidence suggests that energy substrate selection is not influenced by the GI of high CHO diets consumed for 3 days (Chen et al., 2008). The aim of this study was to determine whether the utilisation of energy from fat and CHO during run in the fasted state is influenced by the GI of high CHO diets consumed over 5 days. Methods 9 healthy physically active men and 9 healthy physically active women performed three treadmill runs at 65% of maximum oxygen consumption for 90 min after their habitual diet (Control trial), after 5 days on a high CHO high GI diet (HC-HGI trial), and after 5 days on high CHO low GI diet (HC-LGI trial), in a randomised counterbalanced order. Expired air samples for rates of fat and CHO oxidation measurements and blood samples for glucose, insulin, glycerol and non-esterified fatty acids (NEFA) measurements were obtained at 15, 30, 45, 60, 75, 90 minutes. Statistical analyses were conducted using one-way and two-way ANOVA with a Tukey post hoc test to allocate the differences (Statistica for Window version 6.0). Significance was set at  $P < 0.05$ . Results In men and women, GI of the HC-HGI diet was significantly higher ( $P < 0.001$ ) than HC-LGI diet. The GI in the HC-HGI diet was significantly higher ( $P < 0.001$ ) and GI of the HC-LGI diet was significantly lower ( $P < 0.001$ ) than in the habitual diet. During 90 min run, no significant differences were observed in the rates of fat and CHO oxidation, concentrations of plasma glucose, insulin, glycerol and NEFA between the HC-HGI and HC-LGI trials in both men and women. In comparison to Control trial, in men concentrations of plasma glycerol and rate of fat oxidation were lower ( $P < 0.05$ ) and rate of CHO oxidation was higher ( $P < 0.05$ ) in both the HC-LGI and HC-LGI trials during 90 min run. However in women, plasma glycerol concentration was significantly lower ( $P < 0.05$ ) in both high CHO trials while the rate of fat oxidation was significantly lower ( $P < 0.05$ ) only in the HC-LGI trial. Discussion The consideration of the GI of high CHO diets consumed by the physically active men and women for 5 days had no impact on energy substrate utilisation during endurance running conducted in the fasted state. ### **ELITE SYNCHRONIZED SWIMMERS DISPLAY LOW ENERGY AVAILABILITY AND DO NOT INCREASE FOOD INTAKE DURING INTENSIFIED TRAINING**

Schaal, K., Le Meur, Y., Rebeyrol, J., Louis, J., Casazza, G., Petit, O., Hellard, P., Hausswirth, C.

*National Institute of Sport, Expertise and Performance*

**INTRODUCTION:** Female athletes specializing in sports which emphasize leanness as a key to successful performance often display low energy intake (EI) relative to daily energy expenditure (I). Elite synchronized swimmers endure high volume, high intensity training regimen while facing the pressure of an aesthetic, judged sport; and may be particularly prone to presenting low EI despite intense physical training. This study aimed to quantify changes in the energy availability, (EA, defined as EI – energy expenditure of exercise, ExEE) of elite synchronized swimmers through a typical pre-competition period. We aimed to describe whether EA would decrease below 30 kcal/kg of lean body mass (LBM)/day during IT, a threshold amount below which normal metabolic and hormonal functions become suppressed, in a dose-dependent manner, in order to conserve energy (2,3). **METHODS:** After 1 week of normal training (BASE), 10 elite synchronized swimmers entered a 4-week phase of high intensity training (IT), during which ExEE was increased by 25%. Swimmers wore a heart rate monitor for all exercise sessions during BASE and during the first week of IT to assess ExEE. All subsequent weeks of IT were programmed similarly. Dietary analysis was performed over 4 consecutive days during BASE and at the end of IT using photographs of all meals pre- and post-consumption. Fasted, waking saliva samples were obtained on the first and last day of each week to measure salivary cortisol [Cs] and leptin [Ls] concentrations. Body composition was measured at BASE and IT week 4 using 7-site skinfolds. **Results:** While the IT phase induced a 25% increase in weekly ExEE (21.5±2 vs 26.8± 1.6kcal/kgLBM/day), swimmers did not alter energy intake significantly (44.4±10.9 vs 42.1±2.0 kcal/kgLBM/day during BASE and IT, respectively). Consequently, mean EA decreased from 26.8±3.4 at BASE to 19.9±4.5 kcal/kgLBM/day. [Ls] decreased significantly (-23.7±9.9%), along with body fat percentage (17.3±0.6% vs 16.4± 0.6%), suggesting a state of energy conservation. [Cs] increased significantly from beginning to end of each intensive week, but returned to baseline after 2 days of rest while [Ls] remained suppressed. **CONCLUSION:** During normal training, elite synchronized swimmers display a baseline EA slightly below the previously defined threshold of 30 kcal/kgLBM/day (I), below which signs of energy conservation, including reduced resting metabolic rate, suppressed ovarian function and impaired bone turnover have been reported (1,2). Importantly, the swimmers' failure to increase energy intake during IT, resulting in significantly lower EA, warrants further investigation into the consequences this may have on training adaptations and fatigue in the short term, and on health aspects, such as bone health, in the longer term. 1 Hausswirth and Le Meur (2011) *Sports Med.* 41(10):861-882 2 Loucks et al (2003) *J Clin Endocrinol Metab.* 88(1):297-311. 3 Ihle and Loucks (2004) *J Bone Min Res.* 19(8) 1231-1240.

### **EATING ATTITUDES, HEALTH AND NUTRITION HISTORY AT KING SAUD UNIVERSITY**

Kamel, K.

*King Saud University*

**Introduction:** The EAT-26 has been particularly useful a screening tool to assess 'eating disorder risk' (Garner, Rosen and Barry, 1998). More information collected in health and nutrition history helps nutrition professionals make a thorough assessment of the individual needs and subsequently develop a nutritional program. The purpose of the present study was to estimate two stage screening an eating attitudes, health and Nutrition history for employees and student at King Saud University (KSU). **Methods:** A representative sample of (KSU) Male and Female Employees (N= 123); (N= 64) with mean age (35.9 + 11.2); (30.2 + 6.8) respectively, and Male and Female student (N= 152); (N= 110) with mean age (23.9 + 5.8); (21.7 + 4.0) respectively, were screened using the Arabic version of the EAT-26, and interviewed by a Health and Nutrition History Questionnaire (HNHQ) in order to determine if Male and Female employees and student at King Saud University have an eating disorder risk that needs professional attention. **Results:** Of the total sample, 36.7% were identified as having abnormal eating attitudes. In terms of occupation the Female Employees were found to have the significantly highest rate (56.2%) of positive EAT-26 scores. The mean body mass index (BMI) for Male and Female employees was (31.7 + 6.9); (28.6 + 4.7), and for Male and Female student was (27.6 + 6.5); (27.5 + 6.3) respectively. Of the total sample, 71% reported that they consider themselves overweight, 66% would like to lose weight, 32% have been on a diet for weight loss, and only 16% are currently engaged in an exercise program for 1.8 days per week, 75 minutes light to moderate intensity. **Conclusion:** The Arabic version of the EAT- 26 was found to be a useful tool for screening and identifying eating disorder risk, and there is a need for developing a nutritional and physical activity program for both male and female employees and student at King Saud University.

### **EFFECT OF NUTRITIONAL EDUCATION PROGRAM ON ADHERENCE TO DESIRABLE DIETARY BEHAVIOR IN ELITE ADOLESCENT FOOTBALL PLAYERS**

Urara, S.

*Meiji Co., Ltd.*

**Introduction** It is important for adolescent football players to develop the requisite dietary habits for improving their physical performance and growth. However, there is a lack of effective instructional methods to achieve this goal. In this study, we developed a nutritional education program for elite adolescent football players and evaluated its effect on adherence to desirable dietary behavior. **Methods** This educational program was provided to 23 U-15 elite football players for one year using the print media. The program consisted of a 5-item quiz on the desirable diet for youth football players. This paper was offered every other Wednesday. During nutritional intervention, the lecture for adherence to desirable eating behavior was held 3 times. For their parents, written information on diet and nutrition was provided every other week. After one year, eight of the 23 players (35%) moved on to the next category (U-18) in the same team (Grp 1), and others went to another team because they were eliminated from the selection (Grp 2). Only the subjects in Grp 1 continued to provide information as per the education program in the next year. Twelve of the 23 subjects (52%) completed the self-administered questionnaire consisting of stage of change, decisional balance, self-efficacy, behavioral skills, and social support for proper diet before T1 intervention, immediately after T2 intervention and six months after the T3 intervention program. Data was analyzed using two-way repeated measures ANOVA, and the differences were considered significant when  $p < 0.05$ . **Results** Distributions of stage of change for desirable diet in both groups were not significantly different. Two-way repeated measures ANOVA results indicated that the score of pros, which was a predictor of benefit of changing, self-efficacy, and behavioral skills, was not significantly different between both groups. In Grp 1, the score of cons, which was a predictor of cost of changing at T3, was significantly lower than that at T1. However, this difference was not observed in Grp 2. In Grp 2, the score of social support at T3 was lower than that at T2, but not significantly. **Discussion** These results suggested that the nutritional education program was effective for adherence to desirable dietary behavior. During the intervention

period, distributions of stage of change in later stage increased in both the groups. In Grp 2, distribution of stage of change was maintained through the six month follow-up period. A decrease in the score of social support and increase in the score of cons was observed in this period. Thus, these predictors might be indicators of transition from an early stage of change to a later stage for desirable diet. Reference Sakai K, Ohta A, Sugiura K, Akamatsu R. (2009). ### **ANTHROPOMETRIC PARAMETERS AND NUTRITIONAL INDICES IN CHRONIC DISEASE - PERITONEAL DIALYSIS PATIENTS**

Pajek, J., Bren, A.F., Lindic, J., Bucar Pajek, M.

*University Medical Centre Ljubljana and Faculty of Sport, University of Ljubljana*

**INTRODUCTION** Nutritional status is of critical importance in chronic human disease. It crucially influences physical performance and outcome. Patients on dialysis are one of the best examples of long-term chronic disease. They are daily exposed to glucose load because of glucose contained in peritoneal dialysis (PD) solutions. Several markers of nutrition are available, however many of them have not been validated in the peritoneal dialysis population. Aim of this cross-sectional study was to explore the validity of anthropometric measurements in dialysis patients in relation to standard biochemical parameters of nutrition and to evaluate the impact of peritoneal glucose absorption on nutritional indices. **METHODS** Twenty-three stable patients (9 women) treated with PD were included, their average age was  $54 \pm 12$  years and PD duration was  $28 \pm 25$  months (range 3-81). Exclusion criteria were malignant disease, chronic or acute inflammatory disease, immunosuppressive therapy or recent (less than 3 months) peritonitis. At the regular office visit anthropometric, clinical and laboratory parameters were measured and peritoneal equilibration test was performed which allows the calculation of normalized protein catabolic rate (nPCR). Daily peritoneal glucose exposure and absorption were determined. Using the mid-upper arm circumference and triceps skinfold thickness (TST), the fat-free mid-upper arm surface area (FFSA) and mid-upper arm fat surface area (FSA) were calculated and normalized to  $1.73 \text{ m}^2$  body surface. **RESULTS** Median BMI (range) was 25 (19-30,6) and median values of laboratory parameters were: serum albumin 40 g/l (31-48), high sensitive (hs) CRP 3,37 g/dl (0,24-13,9), total cholesterol 4,8 mmol/l (2,9-7,2), triglycerides 2,1 mmol/l (1-4) and nPCR 0,96 g/kg/day (0,6-1,5). FFSA showed borderline correlation ( $r=0,37$ ,  $p=0,08$ ) with nPCR and no significant correlation with daily glucose exposure or absorption, protein or albumin levels. Albumin and protein levels correlated significantly positively with nPCR and significantly negative correlation was found with hypervolemia and total  $\text{CO}_2$  level (a marker of acidosis). FSA showed significant correlations with triglyceride level ( $r=0,56$ ,  $p=0,006$ ) and borderline correlation with total cholesterol ( $r=0,38$ ,  $p=0,074$ ). Similar results were found for TST. BMI correlated significantly with triglyceride level ( $r=0,45$ ,  $p=0,03$ ) and phosphate ( $r=0,41$ ,  $p=0,05$ ), but not with total cholesterol level. **CONCLUSION** Our results show that TST or FSA are significantly associated with triglyceride levels and as such may be useful in assessing caloric over-nutrition especially as a follow-up parameter. FFSA was statistically borderline related to nPCR as a marker of protein intake. Surveillance of anthropometric indices FSA and FFSA may be useful for long-term management of PD patients. In this study no impact of peritoneal glucose exposure or absorption could be found on protein malnutrition or caloric over-nutrition.

### **A CASE STUDY OF THE NUTRITIONAL PRACTICES OF CLUB LEVEL CYCLISTS BEFORE AND DURING A CYCLOCROSS RACE**

Dixon, D.

*University of East London*

**Introduction** Cyclo cross is an outdoor winter sport consisting of a closed circuit that is 2.5-3.5km long and includes rough terrain, forest paths, steep, muddy hills and man-made obstacles (British Cycling, 2011). This study investigated the pre- and during-race dietary intake of club-level cyclocross cyclist and its effects on performance. **Methods** Eleven male cyclists (age:  $42 \text{ s} \pm 4$  years, stature:  $1.78 \text{ s} \pm 0.08 \text{ m}$ , mass:  $73.2 \text{ s} \pm 9.3 \text{ kg}$ ) took part in this dietary survey and completed a 3-day food and training diary in the days leading up to a field-based cyclocross race (Havemann & Goedecke, 2008). Finishing time was used to measure performance. Mean energy intake (EI), energy expenditure (EE), energy balance and macronutrient intake was calculated for each day. These variables were each compared between days using repeated measures ANOVA with post-hoc Bonferroni adjustment. Pearson correlation was used to identify any relationships between performance and macronutrient intake. Paired samples t-tests were used to compare EI and EE and statistical significance was set at  $P \leq 0.05$ . Results EI was significantly greater 1 day before the race than EE ( $P=0.031$ ), while EI was significantly lower than EE on race day ( $P=0.000$ ). Mean carbohydrate (CHO) intake during the 3 days before the race was  $5.1 \text{ s} \pm 1.7 \text{ g.kg}^{-1} \text{ BM}$  and at the lower limit of the recommendations of 5-7  $\text{g.kg}^{-1} \text{ BM}$  for endurance athletes. Pearson correlation revealed a strong negative relationship between average CHO intake ( $\text{g.kg}^{-1} \text{ BM}$ ) before the event and race time ( $r=-0.821$ ;  $P=0.024$ ). **Conclusion** The results suggest that there appears to be a lack of nutritional strategy amongst cyclist and gaps in their nutritional knowledge were also highlighted (Worme et al., 1990). Thus, the nutritional knowledge of sub-elite athletes must be developed. **References** British Cycling (2011) Cyclo Cross Specific Regulations. [Online]. Havemann, L., Goedecke, J.H. (2008) IJSEM, 18, pp. 551-566. Worme, J.D., Doubt, T.J., Singh, A., Ryan, C.J., Moses, F.M., Deuster, P.A. (1990) AJCN 51, pp. 690-697.

### **NUTRITIONAL PREPARATION OF IRONMAN TRIATHLETES**

Mc Enery, I., Jawadwala, R.

*University of Chester*

**Purpose** 1. To monitor the energy intake (EI) and energy expenditure (EE) of a group of triathletes as they prepare for an Ironman (IM) race. 2. To establish and compare the composition as a percentage and grams per kilogram of bodyweight ( $\text{g.kg}^{-1}$ ) of carbohydrates (CHO), fat and protein and intakes of key micronutrients, iron and calcium. 3. Compare results to the current sports nutrition recommendations. **Method** A longitudinal study design was adopted. Seven day diet diaries, physical activity diaries and training data were used to establish their EI and EE. Five male athletes took part in the study, whose experience of training for an IM race varied from beginners to completing 11 IM races. A case study approach was carried out on each participant, where their EI v's EE was assessed. **Results** The average composition of macronutrients of each participant's diet was 49.84% CHO, 14.87% Protein, and 33.27% fat. When expressed as  $\text{g.kg}^{-1}$  of their body weight CHO was  $4.48 \text{ g.kg}^{-1}$  and protein was  $1.29 \text{ g.kg}^{-1}$ . The average intake of iron and calcium was 16.23 mg and 1276.24 mg. The average EI for the monitoring period was 19706.73 kcal/week and ranged from 17383.33 kcal – 21333.34 kcal/week. The average EE was 25657.03 kcal/week and ranged from 20057.48 – 30673.19 kcal/week. There was a gradual decline in EI over the monitoring period even in the light of increases in EE. **Conclusion** The percentage composition of macronutrients in the participant's diet was more

representative of the recommendations for the general public. However when expressed as g.kg<sup>-1</sup> of bodyweight the intake of CHO and protein were more representative of the current sports nutrition guidelines.

### EXERCISE-INDUCED ANOREXIA IN OBESE TEENAGE GIRLS

Lofrano-Prado, M., Tenório, T.R.S., Calazans, C.T., Barros, T.A.T., Hill, J.O., Prado, W.L.

*University of Pernambuco*

**Introduction** Increasing physical activity is a common strategy to weight loss. However the negative energy balance imposed by exercise may stimulate compensatory eating behaviors which could contribute to countering the exercise-induced energy deficit. The changes in energy intake following exercise may be dependent on changes in circulating appetite-regulating peptides. The aim of this study was to examine the acute effects of aerobic exercise on hunger, leptin, PYY and 24-h energy intake (EI) in obese adolescents. **Methods** This is a crossover study. Nine obese teenage girls (age: 13-18y, BMI: 33.74 + 4.04 Kg/m<sup>2</sup>) randomly underwent two experimental trials: 1) Control, seated for 30 min; and 2) Exercise - exercise at 10% above ventilatory threshold I. Subjective hunger, leptin and PYY were assessed at baseline, immediately after the session and after 2 hours. Afterwards 24h EI was estimated. **Results** After the control session there was an increase in hunger that was accompanied by a reduction in leptin levels; After exercise session, no changes were found for hunger or leptin levels, but there was an increase in PYY (p=0.000) and in protein and carbohydrate intake. **Discussion** The results from this study provide new evidence that the hunger feelings is response to aerobic exercise may be modulated by maintenance of leptin and by increases on PYY levels. However, this transient anorexigenic effect can be reversed by a compensatory increase in carbohydrate and protein intake over the following 24 hours. It is suggested that high intensity exercise reduces the neuronal brain response in food reward brain regions which have a central role in the regulation of eating behavior, in a direction expected to decrease food intake (Evero, 2012). Aerobic exercise improves the central action of some appetite-regulating hormones increasing the responsiveness of the AMP-activated protein kinase (AMPK) and mammalian Target of Rapamycin (mTOR) pathway, contributing to appetite suppression (Ropelle, 2008). In addition, aerobic exercise can make the blood-brain-barrier more permeable to plasma proteins (Hollmann, 2000), as well as to increase leptin receptors binding and leptin gene expression in the arcuate nucleus (Patterson, 2009). Based on these results we suggest that aerobic exercise performed at high intensity induces acute anorexia in obese girls. **References** Evero N, Hackett LC, Clark RD, Phelan S, Hagobian TA. ### THE EFFECTS OF HIGH INTENSITY AEROBIC TRAINING ON FOOD INTAKE IN OBESE ADOLESCENTS ARE MEDIATED BY CHANGES IN PYY LEVELS

Prado, W.L., Gomes, P.P., Freitas, C.R.M., Souza, V.H., Silva, H.J.G., Hill, J.O., Lofrano-Prado, M.C.

*University of Pernambuco*

**Introduction** Physical exercise is a key component of obesity therapy. However the current literature provides very few data regarding the impact of aerobic exercise training on energy intake and peptides involved in central control of food intake in obese adolescents. The aim of this study was to compare the effects of high intensity (HIT) vs. low intensity (LIT) aerobic training on food intake and on anorexigenic and orexigenic hormones in obese adolescents. **Methods** Randomized exercise intervention study. Fortythree obese adolescents (age: 15.72±1.34y, BMI: 34.3±4.1kg/m<sup>2</sup>) participated in a randomized trial of either HIT (above ventilatory threshold I -VTI) or LIT (20% below VTI) for 12 weeks. HIT and LIT sessions were isocaloric (energy expenditure set at 350 kcal). All participants received the same nutritional, psychological and clinical counseling. At baseline and after 12 weeks (12 w) of intervention insulin, leptin, PYY3-36, total ghrelin and food intake were assessed. **Results** Adolescents in the HIT reported a significant reduction in energy intake (p=0.020) and increase in PYY values (p=0.048). Ghrelin values were reduced in both LIT (p=0.001) and HIT (p=0.050) groups. A negative correlation between changes on energy intake and PYY was observed for adolescents participating in HIT (r= -.548; p=0.023). **Discussion** These data provide new evidences that high intensity aerobic training may be able to inhibit food intake in long-term, and that this decrease is mediated by changes in PYY levels. It has been suggested that increased energy expenditure through aerobic exercise, results in no detectable acute increase in energy intake in obese children (Moore, 2004; Dodd, 2008). Alternatively, Thivel et al. (2012) showed that high intensity exercise (75% VO<sub>2</sub>max) promotes a pronounced reduction in 24 hours energy intake in obese adolescents boys. In response to aerobic training, the blood-brain-barrier can become more permeable to plasma proteins (Patterson et al., 2009), improving the anorectic and thermogenic effect of peripheral peptides. The results from the present study should encourage health professionals to prescribe high intensity aerobic exercise aiming not only to increase energy expenditure, but to enhance central control of energy intake. **References** Dodd CJ, Welsman JR, Armstrong N (2008). *Appetite*, 51:482-488. #### FACTORS ASSOCIATED WITH SEVERE GASTRO-INTESTINAL DISTRESS AND MARATHON RUNNING

Pahnke, M.1, Stofan, J.1, Del Campo, J.2, Nyman, L.1, Chiampas, G.3, Jeukendrup, A.1

*Gatorade Sports Science Institute*

1. Gatorade Sports Science Institute (Barrington, U.S.A.), 2. PepsiCo (New Haven, U.S.A.), 3. Northwestern University (Chicago, U.S.A.) Gastro-intestinal (GI) distress is frequently reported by runners and endurance athletes during competition. A variety of causes for GI distress have been proposed such as nutrition, sex, and genetics. The purpose of this field study was to investigate factors associated with GI

distress during a marathon. Approximately 800 runners (399 females, 397 males) participating in the 2012 Bank of America Chicago Marathon completed surveys prior to and following the race. Survey information included self-reported racing history and frequency of GI discomfort during previous races. Incidence of discomfort was reported as at least "fairly frequently" reports of nausea, stomach cramps, intestinal cramps, diarrhea, loose stool, abdominal pain or any reports of vomiting or intestinal bleeding. Participants also self-reported measures of GI comfort and nutritional intake during the 2012 race. Severe GI distress was measured as a score of at least five ("serious problems") on a scale from zero to nine ("no problem at all" to "the worst it has ever been") for the same variables as the pre-survey or of any reports of vomiting or intestinal bleeding. Research participants completed the marathon in 4:20:43±0:52:07 (mean±SD) and 9.4% of the runners reported severe GI distress during the race. Females had a higher ranking of severe GI distress than males ( $p=0.016$ ). During the race, participants consumed 36.9±19.7 g carbohydrate/h and 730.8±1040 ml water/h from a variety of sources (e.g. sports drink, gel). There was a significant relationship between prior history of GI distress and ratings of severe GI distress during the race ( $r=0.247$ ,  $p=0.001$ ). There was also a small, significant relationship between reports of severe GI distress and finishing time ( $r=0.097$ ,  $p=0.006$ ) and a small, negative association between severe GI distress and rate of carbohydrate intake during the race ( $r=-0.078$ ,  $p=0.028$ ). Both rate of carbohydrate and water intake were negatively associated with race finish time ( $r=-0.154$ ,  $p=0.001$  and  $r=-0.134$ ,  $p=0.001$ , respectively). While severe GI distress is likely multi-faceted, during the marathon it was associated with prior incidences of GI distress, rate of carbohydrate intake during the race, and finish time. Finish time was also associated with rate of nutritional intake. Additional research is warranted on potential genetic factors (analysis forthcoming) and on the effect of increasing nutritional intake to current recommendations (up to 90 g multi-transportable carbohydrate/h, Jeukendrup 2011) as lower GI distress and faster finishing times were both associated with higher rates of carbohydrate intake. Jeukendrup A. (2011). *J Sports Sci*, 29:sup1, S91-99.

### CHANGES IN THE RELATIONSHIPS BETWEEN AEROBIC CAPACITY AND HEMATOLOGICAL VARIABLES AFTER A DIET AND EXERCISE INTERVENTION

Calderón, F.J.1, Peinado, A.B.1, Benito, P.J.1, Romero, B.1, Lorenzo, I.1

*Technical University of Madrid (upm)*

**Introduction** The relationships between maximum oxygen uptake (VO<sub>2</sub>max) and hematological variables related to oxygen transportation are obviously established, but it is unknown if these associations are different between responders and non-responders to VO<sub>2</sub>max. The aim of this study was to evaluate whether VO<sub>2</sub>max relate to hemoglobin and hematocrit measured before and after a weight loss program (WLP) intervention, in responders and non-responders to VO<sub>2</sub>max. **Methods** One hundred eighty-six overweight (W) and obesity (O) (body mass index [BMI] 25-34.9 kg/m<sup>2</sup>), aged from 18 to 50 years, performed an incremental test until exhaustion on a treadmill, using a modified Bruce protocol, before (pre) and after (post) the 22 weeks of diet and exercise intervention. Blood samples were taken to measure hematological parameters (1). Responders to VO<sub>2</sub>max were defined as those who achieved an increase higher than 5% in VO<sub>2</sub>max and non-responders those who achieved less than 5%. Relationships between VO<sub>2</sub>max, hemoglobin and hematocrit were measured using Pearson's correlation coefficient in responders and non-responders. The significant level was set at 0.05. **Results** Maximum oxygen uptake was associated with hemoglobin in non-responders, both pre intervention ( $r=0.606$ ,  $p<0.001$ ) and post intervention ( $r=0.596$ ,  $p<0.001$ ). There was also a positive relationship between VO<sub>2</sub>max and hemoglobin in responders, even though this association was greater both pre and post intervention ( $r=0.754$ ,  $p<0.001$ ;  $r=0.623$ ,  $p<0.001$ , respectively). Non-responders had lower correlations between VO<sub>2</sub>max and hematocrit than responders pre weight loss program (WLP) ( $r=0.574$ ,  $p<0.001$ ;  $r=0.732$ ,  $p<0.001$ , respectively), while the relationship was similar in both groups post WLP ( $r=0.567$ ,  $p<0.001$ ;  $r=0.555$ ,  $p<0.001$ ). **Discussion** Applying Fick's law, these results suggest that the improvements in VO<sub>2</sub>max obtained post WLP in responder group could be due to an increase in the use of oxygen and / or an improvement of local vascularization. **References** 1. Zapico et al.: Nutrition and physical activity programs for obesity treatment (PRONAF study). Methodological approach of the project. *BMC Public Health* 2012 12:1100.

### SEX DIFFERENCES IN THE EFFECTS OF MENTAL WORK AND MODERATE-INTENSITY PHYSICAL ACTIVITY ON ENERGY INTAKE IN YOUNG ADULTS

Pêrusse-Lachance, E., Brassard, P., Chaput, J.P., Drapeau, V., Teasdale, N., Sénécal, C., Tremblay, A.

*University of Quebec at Trois-Rivières*

The aim of this study was to examine the acute effects of mental work and moderate-intensity physical activity on various components of energy balance in young and healthy adults. With the use of a randomized crossover design, 35 participants aged 24±3 years completed three 45-min conditions, namely (i) resting in a sitting position (control), (ii) reading-writing (mental work (MW)), and (iii) exercising on a treadmill at 40% of peak oxygen uptake (exercise), followed by an ad libitum lunch. The endpoints were spontaneous energy intake (EI), energy expenditure (EE), appetite sensations, and EI for the remaining day. We observed that the energy cost of the control and MW conditions was about the same whereas the exercise condition increased EE to a greater extent in men than women. Exercise induced a decrease in EI relative to EE compared to the control condition that was more pronounced in men than women. However, women tended to increase their energy intake after the MW condition compared to the control one whereas an opposite trend was observed in men. None of the appetite sensation markers differed significantly between both sexes. In conclusion, men and women have specific food intake patterns when submitted to cognitive and physical stimuli.

### ASSOCIATION BETWEEN OBJECTIVELY MEASURED PHYSICAL ACTIVITY AND SERUM 25-HYDROXYVITAMIN D CONCENTRATION IN JAPANESE ADULTS

Cao, Z.B.1, Sun, X.1, Zhang, Y.1, Ishimi, Y.2, Tabata, I.3, Higuchi, M.1

1: Waseda University (Tokyo, Japan), 2: National Institute of Health and Nutrition (Tokyo, Japan), 3: Ritsumeikan University (Shiga, Japan)

**Introduction:** Although some studies have found an association between physical activity (PA) and serum vitamin D status, most of these studies assessed PA using self-reported measures. Self-reported PA measures are subject to social desirability and recall biases and are inability to accurately assess unstructured and incidental PA. Less is known about the association between objectively measured PA and serum vitamin D status. This may represent one reason why associations of PA with serum 25-hydroxyvitamin D [25(OH)D] levels show weak and inconsistent results. The aim of this study was to examine the association of accelerometer-based PA levels with serum 25(OH)D concentration in Japanese adults. **Methods:** Ninety participants aged 20–69 years took part in this study (57 females and 33 males), and their blood samples were collected at the same laboratory in April. Serum 25(OH)D concentration measured by ELISA, was defined as sufficient ( $\geq 75$  nmol/L), insufficient ( $\geq 50 < 75$  nmol/L), or deficient ( $< 50$  nmol/L). PA was measured by accelerometry, and

outcome variables were time spent (min/day) in light, moderate, and vigorous PA intensities and total PA. Multiple linear regressions were used to assess whether PA was associated with serum 25(OH)D concentrations adjusted for potential confounding variables (gender, age, percentage body fat, smoking status, and vitamin D intake). Results: The prevalence of vitamin D deficiency was 61% in males and 83% in females. Moreover, 33% of males and 16% of females were vitamin D insufficient. After adjustment for potential confounding, total PA ( $P = 0.006$ ) and both light ( $P = 0.003$ ) and vigorous PA ( $P = 0.004$ ) were significantly associated with serum 25(OH)D, but not moderate PA. When all PA intensity components were entered in the same model, light ( $P = 0.02$ ) and vigorous PA ( $P = 0.02$ ) were each independently associated with serum 25(OH)D. Conclusion: Overall, vitamin D deficiency is highly prevalent in our study sample. Objectively measured PA is positively related to serum vitamin D status. In addition, both light and vigorous PA were independent predictors for serum vitamin D concentration. These findings indicate that PA, especially light and vigorous PA, may have important modifiable roles in maintaining an adequate vitamin D levels. Acknowledgement: This study was supported by Grants-in-Aid for Scientific Research (C) from the Ministry of Education Culture, Sports, Science and Technology of Japan (no.23500864).

### EFFECTS OF 2 DAYS SODIUM BICARBONATE LOADING ON SIMULATED FOOTBALL PERFORMANCE TEST

Kurum, O., Jawadwala, R.

*University of Chester*

There is considerable research looking at the role of sodium bicarbonate in sport performance. However, not many studies have examined the effectiveness of this ergogenic aid during a sport specific performance test. The primary purpose of this study was to determine whether a short-term (2 days) supplementation of sodium bicarbonate ( $\text{NaHCO}_3$ ) enhances repeated sprint performance and time to exhaustion in a simulated football performance test (Loughborough Intermittent Sprint Test) which lasts for 90 minutes. Seven healthy males (Mean age =  $24 \pm 1.6$  years and predicted mean  $\text{VO}_2\text{max} = 49.4 \text{ ml kg}^{-1} \text{ min}^{-1}$ ) participated in this experimental study. A double-blind, randomized, crossover study design was used. All participants completed three conditions. Except the control condition, the others included test drinks followed by a 5-day washout period between these two conditions: 1) control (no drinks), 2) placebo/supplement (PI;  $\text{NaCl}$ ;  $0.045 \text{ g.kg}^{-1}$ , Supp;  $0.5\text{g/kg bw NaHCO}_3$ ), and 3) same as 2nd condition. During each condition, sprint times, exhaustion times and rating perceived exertion (RPE) were assessed. In addition to this, before the test day, gastro intestinal (GI) distress questionnaires were used to assess the number and severity of symptoms during the supplementation period. The main findings were; 1) Sodium bicarbonate loading produced slightly (3.2%) but significantly greater ( $p = 0.000$ ) sprint performance than the placebo in some periods of the exercise session (LIST) and 2) Two days of Sb supplementation was sufficient to increase repeated sprint performance compared to the placebo trial. However, in contrast to hypotheses, no benefits from supplementation were observed for time to exhaustion and perception of fatigue (RPE). Considering that this current study found benefits from sodium bicarbonate loading during the 90 minutes simulated football performance test, it suggests that 2 days of sodium bicarbonate supplementation may improve repeated sprint performance. Future research on a larger sample size, a specific athletic population (professionals), and various exercise modes including ball activities would be beneficial in determining if this supplementation is worthwhile.

### SWIMMING EXERCISE INCREASES MAGNESIUM REQUIREMENT IN RATS

Sakai, K., Sugo, T., Shibata, R., Ohta, A.

*JOSAI International University*

Introduction Magnesium (Mg) is an abundant mineral in the human body, and plays a role as a co-factor to activate various enzymes, particularly gluco-regulated kinases. The activities of these enzymes are known to be affected by exercise exertion. However, Mg balance has not been sufficiently elucidated even under sedentary conditions. The present study evaluated Mg requirements in rats with different types of exercise by measuring apparent absorption and urinary excretion, concentrations in serum and skeletal muscle, and expression of TRPM7, which has been identified as a Mg-permeable ion channel that primarily is required for cellular Mg homeostasis in skeletal muscle. Methods Thirty-three 6-week-old male Wistar-Hannover rats were randomly assigned to three equal groups, and fed a purified diet of AIN-93G composition for 15 days (15 g/day). Rats in one group ( $n=11$ ) were housed under sedentary conditions during the experimental period (SED), while the remaining were divided into two exercise-trained groups. One was a low-intensity prolonged exercise group (LIT) and the other was a high-intensity intermittent exercise group (HIT). Rats in LIT swam continuously for 2 h without a load (6 days/week), and rats in HIT swam 14 times for 20 s each time with a load equivalent to 14% of their body weight. Between each 20-s bout of exercise, a 10-s pause was allowed (6 days/week). On day 15, rats were sacrificed and their blood and gastrocnemius muscle quickly removed. Mg levels in serum and muscle were determined using a sequential plasma spectrometer. Amount of TRPM7 expression in muscle was detected with Western blotting analysis. Apparent Mg absorption was calculated from amounts of Mg intake and fecal excretion. Results Blood lactate levels immediately after swimming exertion were 1.05 mM (SED), 5.74 mM (LIT), and 11.09 mM (HIT). Activities of citrate synthase were higher in the exercise-trained groups than in the SED. Apparent Mg absorption in exercise-trained rats was also higher than in sedentary rats. Skeletal muscle Mg level in exercise-trained rats was also higher, whereas serum levels were lower compared to sedentary rats. However, no significant differences in these variables were apparent between LIT and HIT. Amounts of TRPM7 expression in LIT and HIT were higher than in SED. Discussion The present investigation demonstrated that swimming exercise increased the apparent absorption of Mg in rats, regardless of exercise pattern. These results suggest that exercise would enhance Mg requirements in rats. Moreover, we observed the elevation of TRPM7 expression and amounts of Mg contents in exercise-trained rat skeletal muscle, revealing a significant positive correlation between these variables. TRPM7 might represent one of the important ion channels for regulating Mg homeostasis in exercise-trained rat skeletal muscle.

### CARBOHYDRATE INGESTION IMPROVES GROSS CYCLING EFFICIENCY AND SUBSEQUENT TIME-TRIAL PERFORMANCE

1: *University of Gloucestershire, UK*, 2: *University of Kent, UK*, 3: *Canterbury Christ Church University, UK*.

Introduction: Whilst many research studies monitor and report improvements in cycling efficiency (Coyle et al., 2005; Hopker et al., 2009), none state whether nutritional intake was controlled or recorded across the period of assessment. Also, improvements in gross efficiency potentially improve performance (Jeukendrup & Martin, 2001) yet little is known about the impact of carbohydrate ingestion on this. Therefore the aim of this study was to determine whether manipulation of carbohydrate intake would influence gross cycling efficiency and/or time trial performance. Methods: Six trained male cyclists (Age:  $44 \pm 5$  years, Mass:  $81.4 \pm 2.3 \text{ kg}$ ,  $\text{VO}_2\text{max}$ :  $55.7 \pm 8.3 \text{ ml.kg}^{-1} \text{ min}^{-1}$ ) completed two sets of two exercise tests at a steady-state submaximal exercise intensity (60% of Power at  $\text{VO}_2\text{max}$ ). In each set, partici-

pants were required to cycle for 2-hours and a day later, cycle for 1-hour followed by a 16.1km time-trial. These tests were repeated 1-week later. In a randomised cross-over design, participants consumed isocaloric diets (~4000kcal) that contained either a high (70%) or low (20%) proportion of carbohydrate in the 3-days preceding, and 24-h recovery period from, the first cycling tests. Additionally, participants were also provided with 300ml of either water (low) or a 6.4% carbohydrate solution (high) every 30mins during each test. During all submaximal tests, expired air was measured at 30 minute intervals in order to calculate gross efficiency (GE). Results: Mean GE across both days was significantly greater under high carbohydrate conditions (High Carbohydrate GE = 23.75 ± 1.86%; Low Carbohydrate GE = 22.64 ± 1.48%, p<0.001). Additionally, cyclists completed the performance time trial ~5% faster under high carbohydrate conditions (High Carbohydrate = 1490 ± 96secs; Low Carbohydrate = 1568 ± 128secs, p<0.05). Accordingly, when performance was corrected with workload as a covariate, ~49% of the variance in time trial time was explained by changes in performance efficiency. Discussion: Differences in gross efficiency were obtained following alteration of nutritional intake in the 3-days preceding, during and in recovery from, exercise. This suggests that careful control of nutritional intake is required to ensure the validity of gross efficiency measures. Also, the improvement in gross efficiency under high carbohydrate conditions enhanced time trial performance. This strengthens existing evidence that cyclists should increase carbohydrate availability to ensure optimal gross efficiency and performance. References: Coyle, E.F. ## PREFERENCES OF DIETARY SUPPLEMENTS IN LONG DISTANCE TRIATHLON

Hoeden, D., Fladischer, T., Titze, S.

*Karl-Franzens-University Graz*

**Introduction** The number of triathletes is steadily increasing. Due to the huge energetic requirements of long endurance performances athletes tend to take dietary supplements. The aim of this survey was to examine dietary supplements intake among long distance triathletes with focus on prevalence, overdose, reason(s), recommendation, increased performance and guidance by experts. **Methods** The link of our online-questionnaire, which was translated into five different languages, was sent to 30,000 athletes by email. We did this in cooperation with the Austrian Triathlon Association and organizers of several long distance triathlon events. The questionnaire was answered by 1158 athletes, 990 (85%) male and 168 (15%) female, from 43 nations. The survey took place between July 2011 and February 2012. **Results** Sixty six percent of the athletes reported having taken dietary supplements at least once in their life. Those ingredients, which strengthen the immune system and have a scavengers (antioxidative) function are in the first half of the ranking. Surprisingly, those ingredients that are well known in triathlon sport through advertising are not well-used among the long distance triathletes and are found in the last third of the ranking. This is also true for L-carnitine and coenzyme Q10, which are important for long endurance performances (lipometabolism). A clear gender difference in favour of male participants is clear to see in the case of essential amino acids, especially BCAAs, which support muscle generation and regeneration. Thirty nine percent of all participants take dietary supplements on a regular base, 17% straight before competition and 10% as a block dietary course. Concerning the reasons for taking dietary supplements, 67% take them to improve their regeneration, 45% to increase their resistance to disease and 32% in order to prevent injuries. 40% of the participants noticed an improvement in their performance as a result of taking dietary supplements. The intake is mostly governed by the athletes themselves (48%) and/or supported by literature (36%), followed by counselling from a physician, trainer, pharmacist or physiotherapist. Overall, only 12% of the male and 19% of the female participants take dietary supplements under physician supervision and there is in general a tendency of an overdose. **Conclusion** Dietary supplement intake is widely spread among long distance triathletes mainly with the purpose to improve the regeneration. However, overdose of the used dietary supplements occur. As overdose can place an extra burden on the body and can have negative effects, guidance by experts is strongly recommended and more research is needed in this area.

## BODY COMPOSITION AND NUTRITIONAL STATUS IN ELITE SYNCHRONIZED SWIMMERS

Carrasco, M.1,2,3, Iruñia, A.2, Rodríguez-Zamora, L.2, Iglesias, X.2, Brotons, D.3, Vidal, E.1, Rodríguez, F.A.2

1: FCS Blanquerna, Universitat Ramon Llull (Barcelona, Spain); 2: GRCE, INEFC, Universitat de Barcelona (Barcelona, Spain); 3: SGE, Àrea de Medicina de L'Esport (Esplugues de Llobregat, Spain).

**Introduction** Information about the nutritional status and dietary practices and requirements of synchronized swimming (SS) athletes is very scarce (Lundy, 2011). The body composition and somatic profile of current top young elite SS athletes need to be updated (Bante et al., 2007). This study examines the body composition and nutritional status of young elite synchronized swimmers aiming to ascertain whether there are risks associated to their health and performance. **Method** 15 swimmers of the junior Spanish national team (15,8±1,0 y; 54,9±4,3 kg; 168,4±5.0 cm; BMI 19,4±2,0 kg/m<sup>2</sup>) completed anthropometric assessment (ISAK), seven-day food intake record, and haematology and blood biochemistry analysis during a pre-competition period. Food intake was quantified using PCN-GRAMS 1.1 CESNID® software and compared with the European Food Safety Authority (EFSA) recommendations to assess nutritional status. Energy requirements were estimated using the Harris-Benedict formula and Ainsworth's compendium of physical activities. **Results** Anthropometry (mean±SD): Σ6 skinfolds 70,6±10,5 mm; body fat mass 17,7±2,1%; skeletal muscle mass 43,1±2,2%; somatotype 2,8±0,5 / 3,5±0,9 / 3,7±1,1 for endo-, meso- and ectomorph components, respectively. Nutrition: energy intake 2184±406 kcal/d; CHO consumed 4,6±1,1 g/kg; protein consumed 2,1±0,4 g/kg; energy intake from fat 32,8±5,3%. Haematology and biochemistry: haematocrit 37,±1,8%; haemoglobin 12,4±0,5 g/dl; transferrin 261±36 mg/dl; ferritin 24,7±16,4 ng/ml. Estimated energy requirements were 2871±358 kcal/d (12,02±1,5 MJ/d). All the swimmers were not in intake/expenditure energy balance. A high percentage of swimmers failed to meet macro- (CHO: 85,7%; Protein: 64,3%; Fat: 78,6%) and/or micronutrient (Fe, Mg: 92,9%; Zn: 100,0%) recommendations for the general population of their age. **Discussion** SS is characterized by high and complex physiological demands (Rodríguez-Zamora et al., 2012). Young synchronized swimmers must be properly conditioned and properly nourished to perform optimally and to meet developmental requirements. A high proportion of the young elite swimmers studied were not in energy balance and/or failed to meet macro- and/or micronutrient recommendations, which may negatively impact performance and physiological development. More research is needed to understand the unique nutrition needs of this population and to propose general guidelines or recommendations for this high-risk athletic population. **References** Bante S, Bogdanis GC, Chairapoulou C, Maridaki M (2007). *J Sports Med & Phys Fitness* 47, 291-299. ### EFFECTS OF A-GALACTO-OLIGOSACCHARIDES <A-GOS> AND TRAINING ON IMMUNE CELLS IN STREPTOZOTOCIN-DIABETIC RATS

Vincent, S.1, Lefevre-Orfila, L.1, Groussard, C.1, Derbré, F.1, Saligaut, D.1, Efstathiou, T.2, Delamarche, A.1  
*laboratoire*

1Laboratory M2S, Rennes,, France. 2 Sojasun Technologies, Noyal/Vilaine, France Introduction: Type 1 diabetes mellitus (T1DM), a T cell-mediated autoimmune disease, results from the loss of tolerance to insulin and other  $\beta$ -cell-specific antigens. T1DM is associated with an increased risk of death from infectious disease. The etiology of this disease is multifactorial and a recent theory incriminates an autoimmune process which results from disturbed microbiota, leaky gut and altered mucosal immunity. The development and progression of diabetes is linked to changes in B and T cells. Moreover, the therapy management includes nutritional recommendations and exercise training. Training is known to improve glycemia, inflammation and immune response. More interestingly,  $\alpha$ -GOS are prebiotics that selectively alter the composition of gut microbiota and exhibit anti-inflammatory and insulin-sensitive effects in vitro (Efstathiou and Fathi 2010) and in vivo (Boucher et al. 2003). Thus,  $\alpha$ -GOS is a potential functional food for the treatment of diabetes. But, less is known about the effect of training and  $\alpha$ -GOS on immune response in diabetes. In this context, the aim of this work was to study the immune response in a streptozotocin-induced T1DM with two therapeutic means: training and  $\alpha$ -GOS alone or combined. Methods: Forty-eight male Wistar rats were divided into control placebo, streptozotocin-diabetic rat (STZ) groups supplemented or not with  $\alpha$ -GOS (20 mg/kg/day) for 8 weeks and/or following endurance training. The training program was individualized and consisted in a 1h/day, 5d/week running during 8 weeks on a motor-driven treadmill. At the end of the protocol, blood was obtained to measure glucose, insulin, fructosamine and immune responses. Results: STZ rats exhibited higher glycemia, plasma fructosamine levels (a marker of glycated proteins), natural killers (NK), lower T and B cells level and insulin concentration.  $\alpha$ -GOS treatment reduced plasma fructosamine levels and increased B cells compared to STZ rats. Training induced a decrease in plasma glucose, T cells and an increase in B cells and NK in STZ rats. The combined effect of  $\alpha$ -GOS and training didn't potentiate the immune response on B and T cells but inhibited the effects of training on NK Discussion: Our results suggest that training and  $\alpha$ -GOS alter positively plasma glucose and/or fructosamine and the immune response. But the effects of combined treatments only concern limited parameters.  $\alpha$ -GOS effects could be partly attributable to its immunomodulatory activity. Keywords:  $\alpha$ -GOS, training, immune cells, diabetes. Acknowledgment : Brittany region References Efstathiou, T. and D. Fathi. Sojasun Technologies. 2010 Boucher J et al. ### EFFECTS OF EXERCISE ON 24-H FAT OXIDATION DEPEND ON WHEN IT IS PERFORMED.

Kurihara, R.1, Iwayama, K.1, Ogata, H.1, Park, I.S.1, Kawabuchi, R.1, Nabekura, Y.1, Kobayashi, M.1, Yamaguchi, S.2, Hibi, M.2, Tokuyama, K.1

1:University of Tsukuba, Ibaraki, Japan, 2: Health Care Food Research Laboratories, Kao Corporation, Tokyo, Japan

Introduction In emerging 24-hour non-stop societies, people exercise in the morning, afternoon or evening, according to their life style. Depending on nutritional state, exercise performed in the post-absorptive state oxidizes more fat than that performed in the postprandial state. As pointed by Melanson et al., it is also important to account post-exercise changes in energy metabolism to evaluate effect of exercise on body fat balance (J Appl Physiol 2002). Our recent study comparing the effect of exercise performed before and after breakfast on 24-h fat oxidation suggested that exercise performed at low carbohydrate and/or energy balance stimulated 24-h fat oxidation (Shimada et al. Metabolism 2013 in press). This led to the hypothesis that exercise at night, which became a common practice among working people in Japan, might be the least beneficial to reduce body fat. The aim of the present study is to examine how timing of exercise relative to meal ingestion affects 24-h substrate oxidation. Method Healthy men stayed in a room-size respiratory chamber 4 times: control or exercise before breakfast, after lunch and after dinner trials, in a randomized repeated design. Exercise was performed for 60 min at 50% maximal oxygen consumption beginning at 0630h, 1430h or 2030h. Breakfast, lunch and dinner were served at 0800h, 1200h and 1800h, respectively. 24-h substrate oxidation (from 0600h of the exercise day to 0600h of the next day) was compared among the four trials. Results Fat oxidation during exercise gradually decreased as it was performed at later time of the day (before breakfast: 159, after lunch: 67, and after dinner: 42 kcal/h). 24-h fat oxidation of exercise after dinner was also lower than that of exercise before breakfast (before breakfast: 839, and after dinner: 531 kcal/24h). Interestingly, exercise performed after lunch tended to increase 24-h fat oxidation (886 kcal/day). Discussion It is conceivable that exercise performed at the nadir of carbohydrate and/or energy balance (before breakfast) is suitable to oxidize more fat than that performed at the zenith (after dinner). Beneficial effects of exercise to reduce body fat seem to be related to glycogen level when exercise is performed. Unexpectedly, 24-h fat oxidations of pre-breakfast and post-lunch exercise conditions were similar even though post-lunch period was at positive energy balance compared with pre-breakfast period. Factors other than glycogen level to modify exercise-induced 24 h fat oxidation remain to be identified.

### THE INDEPENDENT EFFECT OF EXERCISE INTENSITY ON APPETITE, ENERGY INTAKE AND ENERGY EXPENDITURE: IS THERE A GENDER DIFFERENCE?

Shamlan, G., Robertson, D., Collins, A.

*University of Surrey*

Appetite control (i.e. control of energy intake) is important for weight maintenance. Exercise contributes to the most variable component of energy expenditure but its impact is beyond the energy cost of exercise including physiological, behavioural, and appetite effects (1). Exercise is known to acutely influence effect appetite but evidence as to the independent effect of intensity is lacking (2). This study investigated the role of exercise intensity on appetite, energy intake (EI), appetite related hormones, fat utilisation and subjective measures of appetite. One hour after a standardised breakfast, 14 healthy normal-weight volunteers subjects undertook either 8 repeated 60 second bouts of cycling at 95% VO<sub>2</sub> max (high intensity) or 30 minutes of continuous cycling, at a fixed cadence, equivalent to 50% of the participant's VO<sub>2</sub> max (low intensity) in a randomised crossover design. Glucose, insulin, triacylglycerol (TAG), nonsaturated fatty acids (NEFAs) and glucagon-like peptide-1 (GLP-1) were measured fasted, postprandial, and pre and post exercise. Satiety was assessed Subjectively throughout the study using visual analogue scales. Ad libitum intake of a pasta meal was measured at the end (3-h post-breakfast). No significant effect of exercise was observed on the ad libitum meal or 24 hour energy intake post-exercise. Hunger scores were significantly decreased following high intensity (HI) only. No significant differences in glucose, insulin and TAG between both intensities were observed. HI significantly increased fat oxidation compared to low intensity (LI) at 15 minutes post-exercise with a significant difference in NEFAs level. No significant differences were observed in energy intake of fat for 2 days post-exercise between two intensities. In conclusion, there are mechanisms and consequences of exercise in short and long-term appetite control; however, these mechanisms warrant

further explanation. These results support the need for future research in to the role of in regulation energy balance, especially for obese people. References: 1. Spiegelman BM, Flier JS. Obesity and the Regulation of Energy Balance. *Cell*. 2001;104(4):531-43. 2. Martins C, Kulseng B, King NA, Holst JJ, Blundell JE. ### THE EFFECT OF SHORT-TERM CALORIE RESTRICTION ON EXERCISE PERFORMANCE AND EFFICIENCY IN CYCLISTS

Saunders, S.C., Coleman, D.A., Brown, M.B.

*Canterbury Christ Church University*

**Introduction:** Gross efficiency is a measure of the ability to convert stored energy into power and is, considered a key determinant of cycling performance. Gross efficiency has been reported to improve by 9% in sedentary participants following four months of calorie restriction combined with exercise (Amati et al, 2008). It is yet to be established if improvements in gross efficiency (GE) and net efficiency (NE) can be achieved with only short-term fat mass reduction in habitual cyclists and the effect on time-trial (TT) performance. **Methods:** Seventeen male cyclists; age  $42 \pm 9$  yrs, BMI  $25.6 \pm 3.1$  kg.m<sup>2</sup>, body fat  $22.3 \pm 5$  % were recruited from local cycling clubs. Participants completed four pre intervention baseline visits one week apart and were instructed to maintain their body mass. Resting energy expenditure (REE) and 4-site skinfold were conducted prior to a 16.1km TT on an SRM® cycle ergometer. Gases were measured using the Oxycon® Pro metabolic cart. The intervention consisted of a randomised crossover design where participants either maintained their usual calorie intake or reduced their intake by 500 kcal.day<sup>-1</sup> for a 14 day period. Tests were repeated after each of the two week periods. **Results:** There was a significant reduction in body mass (1.24kg), body fat (0.64%) and fat mass (0.81kg) when comparing immediately pre to post intervention ( $p < 0.05$ , in all cases), with no significant reduction in lean mass ( $p = 0.12$ ). There was also no significant difference in REE ( $p = 0.65$ ), blood urea nitrogen ( $p = 0.55$ ), TT power ( $p = 0.58$ ) or TT power expressed relative to body mass ( $W.kg^{-1}.s^{-1}$ ), ( $p = 0.28$ ). There was a significant increase in TT GE (2.9%) ( $p = 0.008$ ) and NE (2.4%) ( $p = 0.017$ ) following the 14 day intervention. **Discussion:** This study found a significant improvement in both GE and NE following short term calorie restriction, equivalent to approximately 60% of the improvement in GE reported by Amati et al. (2008) in their four month calorie restriction period. Although, a reduction in REE has been reported during more severe calorie restriction and over longer periods (Dulloo & Jacquet, 1998), this study failed to find a significant reduction. Increases in GE and NE did not result in improved 16.1km TT performance, and despite the reduction in body mass the cyclists TT power to weight ratio was also not significantly altered. This data suggests that following short term energy restriction, TT exercise capacity is not compromised in club cyclists. However a reduction in energy expenditure during the performance task is apparent; this has potential implications for the estimation of energy expenditure following reductions in body mass. **References:** Amati F, Dubé JJ, Shay C, Goodpaster BH. (2008). *J. Appl Physiol*, 105, 825-6. Dulloo AG, Jacquet J. (1998). *Am J Clin Nutr*. 68, 599-606.

### SUBSTRATE METABOLISM DURING EXERCISE FOLLOWING TWO WEEKS OF DIETARY CALCIUM SUPPLEMENTATION

Gonzalez, J.T., Green, B., Campbell, M.D., Rumbold, P.L.S., Stevenson, E.J.

*Northumbria University*

**Introduction** Dietary calcium intake is associated with reduced body fat percentage (Tidwell and Valliant 2011) and supplementation with calcium and vitamin D can accelerate fat loss under energy restriction (Zhu et al. 2013). The underlying mechanisms behind these effects are currently unclear. An increase in whole-body lipid oxidation following high-calcium intakes could (in part) account for the relationship with body fat (Gonzalez et al. 2012). Whether the increase in lipid oxidation is evident during exercise is not entirely clear. Accordingly the present study aimed to assess the impact of 2 weeks of calcium supplementation on substrate metabolism during exercise. **Methods** In a randomized, double blind, crossover design, 13 males completed two 14-d supplemental periods during which a control (CON; 400 mg calcium) or high-calcium (CON; 1400 mg calcium) milkshake was consumed daily. A washout period of  $\geq 4$  weeks separated supplemental periods. Prior to and following each supplementation period, substrate metabolism was investigated during an incremental exercise test using indirect calorimetry. Venous blood samples were also collected at the end of each stage in order to determine plasma non-esterified fatty acid (NEFA), glycerol, glucose and lactate concentrations. Values are expressed as means  $\pm$  SEM. **Results** Lipid and carbohydrate oxidation rates were not significantly different between trials at any exercise intensity (all  $P > 0.05$ ). The change in lipid and carbohydrate oxidation did not significantly differ between CON and CAL ( $P > 0.05$ ) Maximal rates of lipid oxidation were  $21 \pm 2$  and  $20 \pm 2$   $\mu\text{mol}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  at baseline, and  $20 \pm 2$  and  $20 \pm 3$   $\mu\text{mol}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  post-supplementation for CON and CAL respectively ( $P > 0.05$ ). The exercise intensity that elicited the maximal rate of fat oxidation did not differ significantly between interventions (baseline, CON:  $52 \pm 2$ , CAL:  $47 \pm 1$  %  $\text{VO}_2\text{peak}$ ; post-supplementation: CON:  $49 \pm 2$ , CAL:  $48 \pm 1$  %  $\text{VO}_2\text{peak}$ ;  $P > 0.05$ ). No significant differences were detected in plasma glucose or lactate concentrations between trials or between interventions as change from baseline (all  $P > 0.05$ ). NEFA and glycerol analysis is currently ongoing but will be completed prior to presentation. **Conclusion** These data indicate that 2 weeks of dietary calcium supplementation does not influence the maximal rate of lipid oxidation, nor does it influence substrate metabolism, across a range of exercise intensities. **References** Gonzalez JT, Rumbold PLS, Stevenson EJ (2012). *Obes Rev*, 13, 848-857. ### MEAL AND BETA-ALANINE CO-INGESTION ENHANCES MUSCLE CARNOSINE LOADING.

Stegen, S.1, Blancquaert, L.1, Everaert, I.1, Bex, T.1, Taes, Y.2, Calders, P.3, Achten, E.4, Derave, W.1

*Ghent University*

1 Department of Movement and Sports Sciences, Ghent University, Ghent, Belgium 2 Department of Endocrinology, Ghent University Hospital, Ghent, Belgium 3 Department of Rehabilitation Sciences and Physiotherapy, Ghent University, Belgium 4 Department of Radiology, Ghent Institute for Functional and Metabolic Imaging, Ghent University, Ghent, Belgium **Introduction.** Beta-alanine (BA) is a popular ergogenic supplement as it can induce muscle carnosine loading. We hypothesize that, by analogy with creatine supplementation, 1) an inverse relationship between urinary excretion and muscle loading is present, and 2) the latter is stimulated by carbohydrate- and protein-induced insulin action. **Methods.** In study A, the effect of 5 weeks slow-release BA (SRBA) supplementation (4.8g/day) on whole body BA retention was determined in 7 men. We further determined whether co-ingestion of carbohydrates and proteins with SRBA would improve retention. In study B (34 subjects), we explored the effect of meal-timing on muscle carnosine loading (3.2g/day during 6-7 weeks). One group received pure BA (PBA) in between the meals, the other received PBA at start of the meals, in order to explore the effect of meal-induced insulin release. Further, we compared with a third group receiving SRBA at start of the meals. **Results and conclusion.** Orally ingested SRBA has a very high whole body retention (97-98%), that is not declining throughout the 5 weeks supplementation

period, nor is it influenced by co-ingestion of macronutrients. Thus, a very small portion (1-2%) is lost through urinary excretion, and equally only a small portion is incorporated into muscle carnosine (~3%), indicating that the majority of ingested BA is metabolized (possibly through oxidation). Secondly, in soleus muscles, the efficiency of carnosine loading is significantly higher when PBA is co-ingested with a meal (+64%), compared to in between the meals (+41%), suggesting that insulin stimulates muscle carnosine loading. Finally, chronic supplementation of SRBA versus PBA seem equally effective.

##### **NEGATIVE EFFECTS OF AIR POLLUTION EXPOSURE ON THE EXERCISE-INDUCED INCREASE OF BDNF GENE EXPRESSION IN THE RAT HIPPOCAMPUS**

Bos, I.1,2, De Boever, P.2,3, Int Panis, L.2,4, Sarre, S.5, Meeusen, R.1

1, 5: *Vrije Universiteit Brussel*; 2: *VITO*; 3, 4: *Hasselt University*

**Introduction** Growing evidence suggests that exercise stimulates synaptic plasticity and cognition by increasing the level of neurotrophic factors, e.g. brain-derived neurotrophic factor (BDNF) (1, 2). Exposure to particulate matter (PM), a component of air pollution, is associated with neuroinflammation and cognitive decline (3). The aim is to investigate the acute effect of PM exposure during exercise on the gene expression of neurotrophic factors (BDNF, IGF-I, VEGFa), a marker of synaptic plasticity (SYN1), and inflammatory and oxidative stress markers (IL1a, IL1b, TNFa, COX-2, NOS2, NOS3, NFE2L2) in the hippocampus of rats. **Methods** Male, Wistar rats (n=6/group) were exposed for 90 min to: ambient air + exercise (group 1), polluted air + exercise (group 2), polluted air + rest (group 3), ambient air + rest (control). A peak PM concentration of 10 000 000 particles/ml was generated by the miniCAST sootgenerator and monitored by the DMS50 Fast Particulate Spectrometer inside an exposure chamber containing a motorized treadmill. The exercise consisted of running at 20 m/min. The hippocampus was collected 24 h after exposure. Gene expression was analyzed with qPCR. The gene expression ratios (R) were calculated for group 1, 2 and 3 relative to the control group and statistically analyzed with the Relative Expression Software Tool using the Pair Wise Fixed Reallocation Randomization Test with 2000 permutations (4). **Results** In group 1, gene expression of BDNF (R=1.54, p=0.03) and NFE2L2 (R=1.41, p=0.03) was increased, and COX-2 decreased (R=0.079, p=0.001) compared to the control. In group 2, there was no increase of BDNF and NFE2L2 gene expression, but a decrease of SYN1 (R=0.67, p=0.008), VEGFa (R=0.68, p=0.045) and COX-2 (R=0.65, p=0.02) gene expression compared to the control. In group 3, gene expression of SYN1 (R=0.67, p=0.03), VEGFa (R=0.41, p=0.007), COX-2 (R=0.53, p=0.006) and NFE2L2 (R=0.58, p=0.02) was decreased and there was a trend towards a decrease of BDNF (R=0.66, p=0.059) expression compared to the control. **Discussion** The expression of genes involved in inflammation and oxidative stress was not increased 24 h after PM exposure. This is the first study that shows a negative effect of air pollution exposure on the expression of genes important for neural plasticity and on the exercise-induced up-regulation of BDNF gene expression in the hippocampus of rats. **References** (1) Christie BR et al. ##### **POLYMORPHISM OF THE IGF-2 GENE SPECIFIES COMPETITIVE CAPACITY OF JAPANESE JUDO PLAYERS**

Itaka, T.1, Hirokawa, S.1, Agemizu, K.2, Aruga, S.3, Machida, S.2

1: *Graduate School of Physical Education*, 2: *School of physical Education*, 3: *Sport Medical Science Research Institute*

**【Introduction】** Many previous studies have reported positive associations between genetic polymorphisms and competitive capacity and/or its-related traits, such as skeletal muscle mass. Insulin-like growth factor-2 (IGF-2) is involved in the differentiation and enlargement of skeletal muscle. A polymorphism of the IGF-2 gene is reported to be associated with skeletal muscle mass, fat mass, and muscle strength. Because judo is an event with body weight divisions, skeletal muscle mass by body weight plays an important role in the competitive capacity. This study aimed to clarify the relationships between the competition levels and IGF-2 gene polymorphism in Japanese judo players. **【Methods】** The subjects were 122 male judo players belonging to top-level universities in Japan. Those who were top-level players of international tournaments, representative players for Japan, and others were classified into S-rank (n=9), A-rank (n=9), and C-rank (n=104), respectively. DNA was extracted from their saliva and genotyping analysis was performed by use of PCR-RFLP technique with Apal to detect the IGF-2 gene polymorphism (rs680) according to the previous study (1). In addition, relationship between IGF-2 gene polymorphism and back muscle strength was investigated. **【Results】** The polymorphism of the IGF-2 gene from the 122 Japanese judo players was composed of 32.8%, 53.3%, and 13.9% of GG, AG, and AA genotypes, respectively. The polymorphism in the S-ranked players was composed of 66.7% (6/9), 33.3% (3/9), and 0% of GG, AG, and AA genotypes, indicating that all subjects possessed G allele. Frequencies of G allele in each competitive capacity are 83.3%, 55.6%, and 41.3% in S-, A-, and C- ranks, respectively, showing high frequency of this allele in top-level judo players. In addition, the judo players with GG (p < 0.05) or AG (p < 0.01) genotype showed significantly higher back muscle strength than those with AA genotype, indicating the correlation between IGF-2 gene polymorphism and back muscle strength. **【Discussion】** A high percentage of skeletal muscle mass in body weight is considered to be an advantage in judo performance, an event with weight divisions. A previous study reported that G allele in the IGF-2 gene polymorphism (rs680) was related to skeletal muscle mass in the general young individuals. In addition of this finding, we observed that the frequency of G allele was not only higher competitive capacity but also higher back muscle strength in judo player of the present study. Thus, IGF-2 gene polymorphism (rs680) is likely to specify competition levels of male Japanese judo players. **【Reference】** 1. Chen J et al, *Obstet Gynecol Int*, 2010, Article ID 965905.

## PLASMA AND SALIVARY INTERLEUKIN-6 RESPONSES TO EXERCISE ARE NOT CORRELATED

Cullen, T.I., Corbett, L.I., Phillips, T.I., Thomas, A.W.2, Webb, R.2, Hughes, M.G.1

*Cardiff Metropolitan University*

**Introduction** Interleukin-6 (IL-6) is widely recognized as an important measure of metabolic, inflammatory and immune responses to exercise stimuli (Fischer 2006). The use of saliva would be an attractive alternative to measuring levels of this protein in plasma, which requires the invasive procedures associated with venous blood sampling. Previous research has demonstrated that there is no correlation between salivary and plasma values of IL-6 pre or post exercise (Minetto et al., 2007). Cox et al., 2008 also measured resting plasma and salivary IL-6 and while they found no correlation, they suggested that the pattern of regulation could be related in response to exercise. This study aimed to investigate the relationship between plasma and salivary IL-6 responses to exercise. **Methods** Five male and five females (mean SD  $\text{VO}_2\text{peak} = 48.4 \pm 7.1 \text{ ml kg}^{-1} \text{ min}^{-1}$ , body mass =  $67.7 \pm 13.7 \text{ kg}$ , age =  $24.4 \pm 3.4 \text{ yrs}$ ) completed a standardised exercise test on a cycle ergometer: 5 x 4 min, 80%  $\text{VO}_2\text{peak}$  interspersed with 3 min relative recovery at 50%  $\text{VO}_2\text{peak}$ . Blood and saliva samples were obtained immediately pre and post exercise. Blood samples were obtained using standard venepuncture techniques. Saliva samples (approx. 1ml) were collected using passive drool techniques. Plasma and salivary IL-6 values were determined using a high-sensitivity enzyme-linked immunosorbent assay (ELISA). Results Plasma IL-6 increased significantly  $2.7 \pm 1.4$  fold post exercise ( $P < 0.01$ ). There was no significant change in salivary IL-6 pre to post exercise ( $P = 0.12$ ). There was no significant correlation between plasma and salivary IL-6 pre ( $r = -0.383$ ,  $P = 0.27$ ), post exercise ( $r = 0.488$ ,  $P = 0.153$ ) or when expressed as a fold change ( $r = -0.491$ ,  $P = 0.149$ ). **Discussion** In this study plasma and salivary IL-6 values are not related pre or post exercise and do not show the same relationship in the context of a standardized exercise stimulus. It is possible that the regulatory pattern of systemic IL-6, produced from working muscles, is different to that found in the saliva. On this evidence saliva samples should not be used as a marker for IL-6 responses when examining the systemic response to exercise. **References** Fischer CP. *Exerc Immunol Rev.* 2006;12:6–33. ## THE EFFECT OF KINESIO TAPING AND CRYOTHERAPY ON PEAK ANAEROBIC POWER RECOVERY AFTER DOWNHILL RUNNING

Szygula, Z., Maciejczyk, M., Wiecek, M., Szymura, J., Kepinska, M., Wiecha, S., Maciejczyk, G., Ochalek, K.

*University School of Physical Education*

**Introduction** It is necessary to apply the evidence-based sports medicine in controlling and planning physical training in sports. That is why currently used methods should be verified and basing on scientific knowledge the new methods should be developed (Barnett, 2006; Hausswirth et al., 2011; Howatson & Someren, 2008; Viithouk et al., 2010). The aim of the study was to evaluate the effectiveness of kinesio taping and whole-body cryotherapy (WBC) on the peak anaerobic power (PP) recovery after downhill running. **Methods** The study was conducted on 9 healthy men aged  $21.2 \pm 1.39$  years old. The mean body height was  $179.7 \pm 4.8 \text{ cm}$ , body mass  $79.9 \pm 14.7 \text{ kg}$ , BMI  $24.5 \pm 3.2$ . The maximal oxygen uptake was measured using incremental test until exhaustion ( $\text{VO}_2\text{max}$ :  $53.23 \pm 5.87 \text{ ml.kg}^{-1}$ ). The peak anaerobic power was measured using Wingate Anaerobic Test (20 seconds, 7.5% body mass) before and next following downhill running (DH): immediately after (20 min), 1h, 24h, 48h and 1 week later. The downhill running (60 minutes) was performed at slope angled 10% with an intensity of approximately 60%  $\text{VO}_2\text{max}$ . The peak anaerobic power recovery was observed after DH when the kinesio taping (quadriceps femoris and gastrocnemius), whole-body cryotherapy ( $-130^\circ\text{C}$ , 3 minutes) and passive recovery were applied after DH (in random order). Kinesio taping was applied for first 48 hours after DH and WBC was done three times (after DH, 24 and 48 hours later). Differences in mean changes between consecutive measures and between 3 methods were analyzed using Friedmans' ANOVA and post-hoc Wilcoxon's signed-rank test ( $p < 0.05$ ). **Results** The peak anaerobic power was significantly decreased after DH. During the passive recovery significantly lowered level of PP was noted till 24 hours. After kinesio taping application the PP was at similar level to baseline already after 1 hour after DH. When WBC was applied the PP recovery time was significantly longer: the PP significantly decreased after 48 hours. **Conclusions** The most effective method of renewal treatment was kinesio taping. Whole-body cryotherapy should not be used for improvement of peak anaerobic power recovery. **References:** Barnett A. (2006). *Sports Med*, 36 (9), 781-796. ## COLD WATER IMMERSION RECOVERY FROM HIGH-INTENSITY SPRINT CYCLING: AN EXAMINATION USING THE CARDIOVASCULAR SYSTEM

Warmington, S.A., Twaddell, C., Gastin, P.

*Deakin University*

**Introduction** Cold water immersion (CWI) is proposed to affect muscle blood flow to enhance recovery from exercise via some unknown mechanism [1, 2]. However, evidence to support any effect of CWI on the cardiovascular system remains speculative. No study has measured cardiac function (cardiac output, CO; stroke volume, SV) in response to CWI during recovery, despite evidence that CWI accelerates post-exercise parasympathetic reactivation [3]. With this in mind it would seem sensible to monitor recovery by assessing aspects of cardiovascular function, rather than often-cited methods of monitoring circulating factors such as blood lactate that repeatedly fail to discern between recovery interventions [4]. Therefore, this study examined CO, SV, HR and BP during CWI following high-intensity sprint cycling exercise, while also attempting to distinguish between recovery interventions by measuring HR kinetics in response to a low-intensity recovery test (LIRT; 100 W cycling) as a non-invasive, non-performance test prior to exercise. **Methods** Participants ( $n=12$ ) completed two exercise trials (randomised cross-over design). Each trial comprised two exercise bouts (Ex1, Ex2) separated by a 30-min recovery period. Exercise comprised a 5-min LIRT followed by three 30-s Wingate tests. Recovery comprised 30 min passive rest (CON) or 15 min CWI plus 15 min passive rest (COLD). HR kinetics were examined during LIRT, and CO and SV at 4 stages during recovery (via rebreathing technique - Innocor, Innovision, DK). **Results** In both trials Ex2 Wingate performance did not return to baseline (Ex1) after recovery. CO and SV during recovery were similar between trials. However, MAP was increased by 5.0% and HR reduced by 6.9% in COLD compared with CON at end-recovery. HR kinetic parameters during LIRT were different between Ex1 and Ex2 as HR did not return to baseline over the 30-min recovery. However, for Ex2 HR at baseline was similar between CON and COLD, yet despite this the plateau was 4.6 bpm lower in COLD compared with CON, with no differences in other kinetic parameters. **Discussion** CWI did not appear to affect

cardiac function during recovery despite a higher blood pressure and lower HR in COLD than in CON at end-recovery. Interestingly, HR kinetics during LIRT provided a means by which different recovery strategies may be detected and, therefore, suggests HR kinetics may be a potential tool to monitor/measure athlete recovery. ### EXERCISE-INDUCED INFLAMMATORY AND GLUCOSE RESPONSES IN INDIGENOUS AUSTRALIAN AND CAUCASIAN POPULATIONS

Mendham, A.E., Duffield, R., Marino, F., Coutts, A.J.

*Charles Sturt University*

**Introduction** Many Indigenous populations have increased prevalence of non-communicable chronic diseases, which contribute to a lower life expectancy compared to non-indigenous populations (Albert 2007; Shaw et al., 2010). However, few studies report cross-ethnicity comparative physiology that underlies these epidemiological phenomena (Albert 2007). This study reports the acute post-exercise inflammatory and glucose responses to aerobic exercise within and between Australian Indigenous and Caucasian populations matched for fitness and body composition. **Method** Sedentary, middle-aged Indigenous (n=10) and Caucasian (n=9) Australian males volunteered to participate who were free from diagnosed cardiovascular disease or diabetes. Following baseline testing, participants completed 1 x 40 min cycle ergometry protocol at 80% maximal heart rate. Fasting venous blood was collected pre, 0, 30, 60 min and then 240 min post-exercise for analysis of glucose, insulin, cortisol, tumor necrosis factor (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$ , IL-6, IL-1 receptor agonist (Ira) and C-reactive protein (CRP). **Results** Resting TNF- $\alpha$  and glucose concentrations were significantly higher in the Indigenous group (P<0.05). IL-6 increased (P<0.05) from 30 to 60 min post-exercise in the Caucasian group, whilst IL-1ra concentration remained elevated 240 min post-exercise for the Caucasian (P<0.05), but not Indigenous group (P>0.05). TNF- $\alpha$ , IL-1 $\beta$  and CRP showed no exercise-induced responses within either group (P>0.05). The immediate (0 min) post-exercise cortisol and glucose increase for Caucasians was significantly (P<0.05) higher than the attenuated responses observed within the Indigenous group (P>0.05). **Discussion** The present study showed that despite the two groups representing their respective middle-aged populations and being matched for aerobic fitness and body composition, differences in baseline pro-inflammatory and glucose concentrations exist between Indigenous Australians and Caucasians. This disparity may have contributed to the post-exercise differences between groups to cycle ergometry; specifically, the blunted post-exercise anti-inflammatory (IL-6 and IL-1ra) and glucose regulatory (glucose and cortisol) response within the Indigenous group. As such, exercise interventions may be of benefit for both groups and should be tailored respective to the cultural and health characteristics present within Indigenous Australian and Caucasian populations. **References** Albert MA. ### EFFICIENCY OF SKELETAL MUSCLE MITOCHONDRIAL COUPLING IS A CRITICAL FACTOR FOR MAXIMAL EXERCISE CAPACITY AND OXYGEN UPTAKE IN RATS

Schlagowski, A., Schlagowski, A.I., Singh, F., Charles, A.L., Favret, F., Piquard, F., Geny, B., Zoll, J.

*Institut of Physiology; UDS, Faculty of Medicine, Strasbourg, France. CHRU, Strasbourg, France.*

**Efficiency of skeletal muscle mitochondrial coupling is a critical factor for maximal exercise capacity and oxygen uptake in rats** **Introduction** The role of mitochondrial uncoupling in the determination of maximal oxygen uptake ( $\dot{V}O_{2max}$ ) and maximal exercise capacity is still unknown. Both, the heart's ability to pump blood and each step in the O<sub>2</sub> cascade, particularly, the mitochondrial level in skeletal muscle seem to be crucial for the determination of endurance performance as well as  $\dot{V}O_{2max}$  (Zoll et al., 2002). Showing the effects of mitochondrial uncoupling on exercise parameters could help to better understand the significance of mitochondrial function for  $\dot{V}O_{2max}$  and maximal running speed. **Methods** Rats were divided in a control group and a group treated with 2-4-dinitrophenol, a mitochondrial uncoupler, for 28 days (DNP; 30 mg/kg/day in drinking water). Gas exchanges were measured during an incremental treadmill test. Basal ( $\dot{V}O$ ) and maximal ( $\dot{V}max$ ) mitochondrial respiration of skinned fibres were measured in the gastrocnemius muscle, and the effects of DNP were tested in L6 myoblasts. **Results** The DNP group presented significantly lower body mass (p<0.05) and a higher resting  $\dot{V}O_2$  (p<0.005). Maximal running speed and running economy (p<0.01) were lower, whereas  $\dot{V}O_{2max}$  was higher in DNP rats during incremental treadmill test, without changes of basal glycogen and triglycerides content. In gastrocnemius skinned fibres,  $\dot{V}O$  was higher (p<0.01), whereas the acceptor control ratio (ACR,  $\dot{V}max/\dot{V}O$ ) was significantly lower in DNP animals (p<0.05), showing a reduction of the OXPHOS efficiency further supported by a positive correlation between ACR and running speed. In condition of high ADP concentration, DNP reduced the mitochondrial capacity of myoblasts to produce ATP (p<0.01). **Discussion** DNP treatment induces a mild mitochondrial uncoupling resulting in the augmentation of basal O<sub>2</sub> uptake and a reduction of weight gain. It has been shown that the efficiency of ATP production is diminished in the absence of the inner mitochondrial membrane solute transporter (SLC25A25), resulting in the reduction of endurance capacities in animals (Anunciado-Koza et al., 2011). This work indicates the importance of mitochondrial ATP production for maintaining the endurance capacity. Our results, and particularly the ACR suggest that an impairment of mitochondrial OXPHOS efficiency in skeletal muscle, independently of oxygen transport system, is sufficient to reduce the maximal exercise capacities. **References** Zoll J, Sanchez H, N'Guessan B, Ribera F, Lampert E, Bigard X, Serrurier B, Fortin D, Geny B, Veksler V, Ventura-Clapier R, Mottauer B (2002). *J. ### EXPLOSIVE ATHLETES ARE CHARACTERIZED BY A LOWERED SERUM CARNOSINASE ACTIVITY AND PROTEIN CONTENT

Baguet, A.1, Everaert, I.1, Yard, B.2, De Heer, E.3, Derave, W.1

*(1) Ghent University, Belgium, (2) University of Heidelberg, Germany, (3) Leiden University Medical Center, The Netherlands*

1 Department of Movement and Sports Sciences, Ghent University, Ghent, Belgium 2 Department of Medicine, University Medical Center Mannheim, University of Heidelberg, Mannheim, Germany 3 Department of Pathology, Leiden University Medical Center, Leiden, The Netherlands **Introduction** Serum carnosinase (CNI), the enzyme responsible for the hydrolysis of the dipeptide carnosine into its constituent amino acids beta-alanine and L-histidine, is highly active in human blood. Circulating carnosine has several health-protective biochemical properties and could possibly attenuate acidosis and oxidative stress in blood during exercise. Therefore, one could expect that a low carnosinase activity is beneficial to athletes who are involved in high-intensity and sprint-type exercise. The aim of this study was to compare different types of elite athletes with controls regarding CNI activity and content. **Methods** A total of 251 subjects (166 males and

85 females) participated in this cross-sectional study. The study population consisted of a not-specifically trained control group (n= 156) and a group Belgian elite athletes (n=95), who all were or had been competing at international level. The 'explosive group' (n=50) included athletes from explosive track-and-field disciplines, short track, judo, gymnastics and short distance swimming. The 'middle to long distance group' (n=45) consisted of middle and long distance runners, long distance swimmers, triathletes and rowers. In all subjects, heparin blood samples were collected to quantify CN1 protein content (by ELISA; Everaert et al. 2012) and activity (by the method described in Teufel et al 2003). Results In the total study population, women had significantly higher CN1 activity (6.11 vs 5.12  $\mu\text{mol/mL/h}$ ,  $p=0.003$ ) and CN1 content (85.61 vs 68.64  $\mu\text{g/mL}$ ,  $p<0.001$ ) than men. Both in males ( $p=0.002$ ) and in females ( $p=0.035$ ) explosive athletes had a lower (27.5 % in males; 30 % in females) CN1 activity compared to controls, within a similar age range. Similar differences were found with regard to CN1 protein content (males  $p=0.002$ , 29.2 % lower; females  $p=0.021$ , 32.7 % lower). Conclusion In conclusion, explosive elite athletes have a lowered CN1 activity and protein content compared to untrained controls. This observation raises the questions whether this characteristic is beneficial for high-intensity exercise and whether this is the result of selection (nature) or training (nurture). References Everaert I et al. (2012) *Am J Physiol Renal Physiol* 302: F1537–F1544. Teufel M et al. (2003) *J Biol Chem* 278: 6521-6531.

### **CALCITONIN-GENE RELATED PEPTIDE PLASMA LEVELS DECREASE DURING A MAXIMAL TEST IN TRAINED INDIVIDUALS**

Sarabia, J.M., Aracil, A., Guillén, S., López-Grueso, R., Pastor, D., Moya, M.

*GLAFIS, Sports Research Centre, Universidad Miguel Hernández de Elche*

**Introduction** The potential contribution of calcitonin-gene related peptide (CGRP) to the acute hemodynamic responses to maximal exercise is unknown. Here we report the preliminary data of a pilot descriptive study aimed to quantify the plasma concentrations of CGRP ([CGRP]p) during a cycle ergometer maximal test, and to correlate them with blood pressure. **Methods** Three trained males (25,3±4,9 years) were subjected to a maximal ergoespirometric test (Cosmed K4b2) on a cycle ergometer (Monark E839), following a modified Bruce protocol. An intravenous catheter was placed at the right antecubital vein connected to a three gauge valve, and blood pressure was measured on the left brachial artery using an automated sphygmomanometer (Tango, Suntech Medical). Before starting, at the maximum and after recovery, blood samples were taken and transferred to tubes containing EDTA. Blood was centrifuged and plasma supernatants were collected and frozen at -80°C up to the moment they were assayed for the quantification of CGRP (human CGRP ELISA kit, SpiBio, France). Blood pressure at the same moments of blood removal was also registered. Results VO2max of the subjects was 50,4±4 ml/Kg/min. In comparison with the pre-exercise measurements, at the maximum: a) SBP increased (188±18 vs 136±10 mmHg;  $p=0,0046$ , paired T test); b) mean arterial pressure (MAP) increased (99,6±8,2 vs 109,8±18 mmHg;  $p=0,0048$ , paired T test); and c) [CGRP]p decreased by around 45% (78,5±36,9 vs 43,9±24,2 pg/ml;  $p=0,0025$ ; paired T test). After recovery, in comparison with the maximum: a) systolic blood pressure (SBP) decreased (136±10 vs 122,7±11,6 mmHg;  $p=0,031$ , paired T test); b) mean arterial pressure (MAP) tended to decrease (109,8±18 vs 80,7 ±10,7 mmHg;  $p=0,088$ , paired T test); and c) [CGRP]p didn't change (43,9±24,2 vs 43,0±23,4 pg/ml; NS, paired T test). After a linear regression fitting, both SBP and MAP tended to decrease with increasing [CGRP]p (SBP:  $y=-0,324x+166$ ;  $R^2=0,0940$ ); MAP:  $y=-0,118x+103$ ;  $R^2=0,044$ ). **Discussion** In contrast with previous reports (Brooks, et al, 1990; Schiffer, et al, 1995) that have found that [CGRP]p increased or didn't change with exercise, in the preliminary experiments described here a sustained reduction of [CGRP]p that correlated with an increase of SBP at maximal exercise was found. This could suggest a role for CGRP in the acute hemodynamic responses to exercise. The mechanism by which exercise decreases [CGRP]p, the duration of this effect and the possibility of a compensatory elevation of CGRP after exercise are other questions arising from this observations. ### **MITOCHONDRIAL FUNCTION ADAPTATIONS IN RAT SKELETAL MUSCLE: A COMPARISON BETWEEN CONCENTRIC AND TWO ECCENTRIC TRAINING PROGRAMS.**

Ennequin, G.1, Sirvent, P.1, Caillaud, K.1, Chavanelle, V.1, Capel, F.2, Morio, B.2, Boisseau, N.1, Richard, R.2

*1: AME2P Laboratory (Clermont Ferrand) ; 2 : UNH Laboratory (Clermont Ferrand)*

**Introduction** A large range of training programs can be performed to trigger mechanical and metabolic signals leading to muscle function adaptations. Most of the studies investigating acute or chronic muscle adaptations to exercise use a combination of concentric and eccentric contractions. If it is well-known that eccentric mode generates a lower oxygen cost compared to the concentric mode at the same mechanical intensity, very little data is available concerning muscle metabolic adaptations following an eccentric program. The aim of this study was to compare mitochondrial function adaptations after a concentric and an eccentric training realized either at a same metabolic power (VO2) or at a same mechanical power (Pw). We hypothesized that 1-both eccentric trainings may improve mitochondrial function in skeletal muscle and 2-eccentric training realized at a same metabolic power than concentric training will induce similar adaptations. **Methods** Fifty six rats male were randomly divided in four groups: Control (CONT), Concentric + 15° (CONC +15; slope + 15°) Eccentric - 15° (ECC -15; slope-15°) and Eccentric - 30° (ECC -30). Speed (15m/min) and slope were previously determined to respect same metabolic responses (VO2) in ECC - 30 and CONC +15. Training sessions (60 min) were performed daily for 26 days. Mitochondrial respiration in permeabilized fibers of Gastrocnemius (Gas) and Vastus Intermedius (VI) muscles was studied. Oxygraphic measurements were performed allowing for maximal ADP-stimulated mitochondrial respiration (Vmax) and ADP sensitivity (Km) assessment. Moreover, expression of genes involved in mitochondrial biogenesis (PGC1- $\alpha$ , PPAR- $\beta$ , Tfam, Nrf-1) and functional regulation (Desmin) was assessed by RT q-PCR. Results After 26 days of training, Km and Vmax were significantly higher in EXC -30 and CONC +15 compared with CONT in Gas and VI ( $p<0.05$ ). No significant change was highlighted in EXC -15 group for mitochondrial respiration. No difference appeared in Km and Vmax between CONC +15 and EXC -30. Quantification of gene expression in VI revealed a higher expression of PPAR- $\beta$  in EXC -15 compare with CONT. Increased PGC-1 $\alpha$  expression was noted in Gas EXC -30 compare with CONT. No difference appeared between CONC +15 and EXC -30. **Conclusion** Our finding supports the idea that eccentric training may induce adaptations of mitochondrial function in similar proportions than the concentric training when performing at the same metabolic power. As weak changes were observed in gene expressions, other investigation should be achieved to deepen the signaling pathways leading to mitochondrial function adaptations following eccentric exercise.

## HIGH INTENSITY TRAINING DECREASES MITOCHONDRIAL ADP SENSITIVITY IN HUMAN ADIPOSE AND SKELETAL MUSCLE TISSUE

Larsen, S., Dohlmann, T., Hindsø, M., Dela, F., Helge, J.W.

*University of Copenhagen*

**Introduction** It has previously been reported that mitochondrial ADP sensitivity decreases (higher  $K_m$ ) with endurance training in human skeletal muscle. This decrease was accompanied by an increased maximal ADP stimulated respiration and an increased maximal oxygen uptake ( $VO_{2MAX}$ ). It is not known whether high intensity training (HIT) has the same effect on mitochondria and if these changes also occur in mitochondria from human adipose tissue. The aim of this project was to investigate mitochondrial ADP sensitivity and maximal ADP stimulated respiration in human adipose and skeletal muscle tissue after six weeks of HIT. **Methods** Eight healthy overweight subjects (6F/2M) (age:  $40 \pm 3$  yrs, BMI:  $32 \pm 2$ ,  $VO_{2MAX}$ :  $2383 \pm 115$  ml/min) were included in the study. The subjects underwent six weeks (3 times a week) of HIT.  $VO_{2MAX}$  was measured pre and post training. Mitochondrial ADP sensitivity ( $K_m$ ) and maximal ADP stimulated respiration ( $V_{max}$ ) was measured pre and post HIT in adipose tissue and permeabilized muscle fibers by high resolution respirometry (Oxygraph-2k, Oroboros, Innsbruck, Austria). The adipose tissue was permeabilized with digitonin and the skeletal muscle fibers with saponin. The protocol used for respirometry was as follows: Malate (2 mM), Glutamate (10 mM) and ADP titrated in the following steps (0.05 – 0.10 – 0.25 – 0.50 – 1.00 – 2.50 – 5.00 mM). SigmaPlot was used to determine  $K_m$  and  $V_{max}$  for ADP. **Results**  $VO_{2MAX}$  was not improved after HIT. Mitochondrial ADP sensitivity was significantly ( $P=0.007$ ) decreased (higher  $K_m$ ) after HIT in permeabilized skeletal muscle ( $0.15 \pm 0.02$  mM vs.  $0.27 \pm 0.03$  mM), and the same trend was seen in adipose tissue although not significant ( $P=0.125$ ) ( $0.12 \pm 0.05$  mM vs.  $0.20 \pm 0.07$  mM). Maximal ADP stimulated respiration ( $V_{max}$ ) was similar after HIT in permeabilized skeletal muscle ( $20 \pm 1$  pmol/mg/sec vs.  $21 \pm 1$  pmol/mg/sec) as well as in adipose tissue ( $0.38 \pm 0.07$  pmol/mg/sec vs.  $0.39 \pm 0.05$  pmol/mg/sec), before vs. after, respectively. **Conclusions** ADP sensitivity decreased in permeabilized human skeletal muscle and the same trend was seen in adipose tissue. This was accompanied by a similar maximal ADP stimulated respiration pre and post training in both skeletal muscle and adipose tissue. This is the first time that ADP sensitivity has been investigated in adipose tissue, and interestingly the HIT training adaptation in adipose tissue mitochondria is similar to that observed in skeletal muscle. The project is financially funded by the EU FP7 program.

## CHANGES IN HAEMATOLOGICAL PARAMETERS OF SCOTTISH PROFESSIONAL YOUNG FOOTBALLERS OF PREMIER LEAGUE DURING PRE COMPETITIVE SEASON

Takas, P., MacLean, J., Hillis, S., Malkova, D.

*University of Glasgow*

**Introduction** Previous evidence suggest that intense sporting activities result in iron deficiency (ID) (Schumacher et al., 2002) which may lead to anaemia: a decrease in the amount of red blood cells or lower than normal amounts of haemoglobin in the blood. In males, non-anaemic ID is defined as ferritin  $<20$  ng/mL and Hb  $>13$ g/dL and anaemic ID as ferritin  $<20$  ng/mL and Hb  $<13$ g/dL (Rowland, 2012). Signs of ID vary from fatigue, headache, to impairment in exercise performance (Landahl et al., 2005). The aim of this study was to investigate blood markers of iron status and anaemia and of Scottish young professional football players prior their competitive year and after a month of intensive training. **Methods** The study participants were 30 footballers aged  $17.4 \pm 0.8$  years and with body fatness of  $8.84 \pm 3.2$  % (values means  $\pm$  SDs). Blood samples were drawn and body composition was measured prior the start of competitive season (PRE) and 4 weeks after participation in intense training of approximately 50 hours per week (POST). Blood samples were analysed for serum ferritin, iron, haemoglobin (Hb), haematocrit (Hct), red blood cell count (RBC). Statistical analysis were performed by applying paired t-test **Results** Participation in training induced significant decrease in concentration of ferritin (PRE:  $65.37 \pm 35.53$  ng/mL; post:  $48.5 \pm 22.2$  ng/mL,  $P < 0.05$ ), Hb (PRE:  $15.3 \pm 1.0$  g/dL; POST:  $14.7 \pm 1.0$  g/dL,  $P < 0.001$ ), Hct (PRE:  $44.8 \pm 2.1$  %; POST:  $43.7 \pm 2.5$  %,  $P < 0.05$ ), RBC (PRE:  $44.8 \pm 2.1$  million cells/mcL; POST:  $43.7 \pm 2.5$  million cells/mcL,  $P < 0.001$ ), but had no effect on concentration of serum iron (PRE:  $18.30 \pm 6.29$  umol/L; POST:  $20.07 \pm 7.79$  umol/L,  $P > 0.05$ ). None of the athletes were found to have either anaemia or ID at both pre and post preseason training periods. **Discussion** This study confirms that intense physical activity leads to significant decreased levels of ferritin, RBC, Hb and Hct. In our study, following one month training markers of ID and anaemia were still above cut-offs for ID which is in agreement with some (Schumacher et al., 2002) but not all studies (Landahl et al., 2005). Taking into consideration that development of ID is quite a slow process and occurs over periods of time, it is extremely important athletes to be monitored for their iron status. Research on mechanisms involved in modification of markers of iron status and anaemia should be considered by future studies. **References** Landahl G, Adolfsson P, Börjesson M, Mannheimer C, Rödger S, (2005), *Int J Sport Nutr Exerc Metab.* 15(6):689-94 Rowland T, (2012), *Am J Lifestyle Med* 6(4):319-327 Schumacher YO, Schmid A, Grathwohl D, Bültermann D, Berg A., (2002), *Med Sci Sports Exerc.* 34(5):869-75

## THE EFFECT OF HIT EXERCISE ON PLASMA VOLUME AND PLASMA VISCOSITY.

Basterra, J.1, Ferioli, D.2, Alis, R.1, Martinez, B.1, Ibañez-Sania, S.1, Latorre, A.2, Orfí, D.1, Romagnoli, M.1, Verdejo, P.

*CATHOLIC UNIVERSITY OF VALENCIA1, UNIVERSITY OF STUDIES OF MILAN2*

**PURPOSE:** High intensity interval training (HIT) is an exercise model that has been seen to cause similar muscle adaptations and improvements in exercise performance to traditional exercise models. This study aimed to examine the effects of low-volume HIT exercise on a hemorheological parameter, the plasma viscosity. **METHODS:** Ten healthy male subjects ( $25.80(3.39)$  years) randomly performed either a HIT exercise protocol (2-min warm up at 8 km/h, 5 2-min bouts at 90% maximal heart rate, separated by 2-min at 8 km/h, finished with another 2-min period at 8 km/h) or an aerobic (AER) exercise (60' running at 55%  $VO_{2max}$ ). Blood samples were drawn before and after exercise, and after 30-minute recovery. Plasma viscosity, hematocrit, fibrinogen, total proteins, triglycerides, total cholesterol and glucose levels were analyzed. Plasma volume loss was calculated from changes in hemoglobin and hematocrit. **RESULTS:** Plasma viscosity rose after HIT ( $p < 0.05$ ) but did not after AER ( $p > 0.05$ ) while hematocrit rose after both exercises. Plasma volume lowered more after HIT ( $-6.35(3.47)$  %) than after AER ( $-3.11(2.49)$  %) ( $p = 0.045$ ). Total-proteins ( $p < 0.001$ ), triglycerides ( $p = 0.013$ ), total-cholesterol ( $p < 0.001$ ) and glucose ( $p = 0.001$ ) concentrations increased after HIT. After AER exercise no statistically significant differences were found in plasma constituents concentrations ( $p > 0.05$ ). **CONCLUSIONS:** A session of low-volume HIT promotes a loss in plasma volume enough to cause a significant increment of plasma constituents concentrations and, therefore, a mild transient rise in plasma viscosity.

**TAPERING STRATEGIES IN ELITE BRITISH ENDURANCE RUNNERS**

Spilsbury, K.L.1,2, Fudge, B.W.2, Ingham, S.A.2, Pringle, J.S.M.2, King, J.A.1, Saini, A.1, Nimmo, M.A.1

*1: Loughborough University 2: English Institute of Sport*

**Introduction** It is common for elite endurance athletes to undertake a period of reduced training load prior to major competition, a practice known as tapering. Despite a plethora of anecdotal evidence, there is a lack of scientific data describing the tapering strategies employed by elite endurance runners. **Purpose** To explore the current tapering practices of elite British runners in events ranging from 800 m to marathon. **Methods** Training information typical of a regular training phase (RTP) and of a tapering period (TP) was obtained from a survey. Inclusion criteria specified that participants had competed at national, international and/or Olympic level in 800 m, 1,500 m, 3,000 m steeplechase (SC), 5,000 m, 10,000 m and/or marathon. A total of 37 participants were included in the analysis (male = 21 and female = 16). Personal best times were within 2-12 % and 1-14 % of the British record for males and females, respectively. Data was pooled from 800 m and 1,500 m to form a middle-distance group (MD; n = 18) and from 3,000 m SC, 5,000 m and 10,000 m in to a long-distance group (LD; n = 9). **Results** Duration of the TP was (mean  $\pm$  SD) 7  $\pm$  3 d, 6  $\pm$  1 d and 15  $\pm$  4 d for MD, LD and marathon, respectively. Continuous running volume was reduced by 29  $\pm$  11 % in MD, 30  $\pm$  13 % in LD and 48  $\pm$  12 % in marathon. Frequency of continuous running during TP ranged from 57-150 % in MD, 71-117 % in LD and 43-88 % in marathon when compared to RTP. A greater total weekly running volume during RTP was associated with a longer TP duration and a greater reduction in continuous running volume during TP ( $R^2 = 0.33$ ,  $P < 0.05$ ;  $R^2 = 0.46$ ,  $P < 0.05$ , respectively). The percentage of continuous and interval running frequencies during TP were related to frequency during RTP ( $R^2 = 0.43$ ,  $P < 0.05$ ;  $R^2 = 0.13$ ,  $P < 0.05$ ). The peak intensity interval training session of TP was not different to race speed in MD runners (102  $\pm$  2 %). Long-distance runners completed the peak intensity interval session significantly faster than race speed (111  $\pm$  13%,  $P < 0.05$ ), despite no difference to MD in proximity of the peak session to competition (3  $\pm$  1 d and 3  $\pm$  1 d, respectively). **Conclusion** In elite British endurance runners, tapering appears to be a fluid and dynamic process and the strategies employed are individualised and determined by previous training. It is clear that LD runners significantly increase interval training intensity above race speed in the final days of the taper, but the possibility of a late physiological and performance benefit from such an increase warrants further investigation.

**SUSPENSION TRAUMA AND TILT-TABLE TEST SYNCOPE: THE SAME AND THE DIFFERENT.**

Lanfranconi, F.1, Barbic, F.2, Pollastri, L.1, Bartesaghi, M.1, Corna, G.1, Furlan, R.2, Miserocchi, G.1

*1Department of Health Sciences, Laboratory of Clinical Physiology and Sport Medicine, University of Milano-Bicocca, via Cadore 48, Monza, Italy. 2Medicina Generale Clinica Medica, Humanitas Institute*

**Introduction** Following a fall, the subject hanging on the harness and waiting for rescue may incur into the risk of a lethal multivisceral hypoxia distress due to orthostatic stasis named "suspension trauma". To this condition are exposed all the workers involved in work at height. The purpose of this study was to evaluate by non-invasive methods the individual risk of developing suspension trauma. **Methods** Forty adults (mean  $\pm$  st.dev: age 39,1 $\pm$ 8,2; body mass index 24,2 $\pm$ 3,03; 85% males, 15% females) were enrolled: 16 were regular users of harness, 14 regularly involved in physical training but were not users of harness and 10 were controls. Each subject underwent: a) an incremental exercise test on treadmill until exhaustion; b) a motionless suspension test until medical signs of orthostatic intolerance appeared or extreme subject discomfort was reported (suspension time recorded); c) individuals with a positive motionless test for syncope underwent to a tilt-table test. Oxygen uptake, end tidal pressure of CO<sub>2</sub>, heart rate and blood pressure were measured, as well as brain oxygenation status by near-infrared spectroscopy. **Results** No difference in the mean suspension time was found in the 3 groups (average of all participants 28.7 $\pm$ 11.4 min (range 8-56), coefficient of variation 40%). No correlation was found between the level of aerobic fitness and suspension time. Four persons revealed a risk of syncope during suspension in harness: a decrease in brain oxygenation was evident before the development of signs of pre-syncope although no oscillatory pattern of cardiovascular response was noticed. In these 4 individuals only a partial hint of syncope's signs was noticed during the tilt table test. **Discussion** The experience in use of harness and the aerobic fitness do not correlate with the suspension time and thus the onset of developing suspension trauma. The cerebral hypoxia is a co-factor and not the main cause of syncope. The discomfort in harness and the loss of control of anti-gravity muscles are the main factors differentiating the suspension trauma from the tilt-table test syncope **References** Amphoux M. (1998). **EFFECT OF GENDER AND SKIN PIGMENTATION ON SPRINT PERFORMANCE AND PLASMA VOLUME CHANGES**

Kebisi, W.1, Ben Abderrahman, A.2, Sellami, M.1, Chamari, K.3, Chaouachi, A.3, Zouhal, H.1

*1 M2S Laboratory, University of Rennes 2-ENS Cachan, Rennes, France. 2 ISSEP, University of Manouba Tunisia. 3 "Sport Performance Optimization Laboratory" CNMSS, Tunis, Tunisia.*

**Introduction** Concerning physical performances several differences were observed between black and white subjects in several sports. While data are available for anaerobic performances as sprinting (Fall and Pirnay, 1989) little is known concerning repeated sprint ability (RS), which represent an important fitness component for team-sports. Consequently, The aim of this study was to investigate the influence of skin color in both sexes in North-African subjects on sprint and repeated sprint performances and PV changes (PVV). In fact, PV is known to play an important role in the recovery capacity (Krip et al 1997). **Methods** Thirty-six North-Africans physical education students agreed to participate to this study. They were divided according to skin color and gender. They are as follow: Black men's group (BM, n=9), White men's group (WM, n=9), Black women's group (BW, n=9) and White women's group (WW, n=9). The participants performed the running anaerobic sprint test (RAST: 6 $\times$ 35m with 10s of recovery between sprints). The haematocrit (Hct) and haemoglobin (Hb) were measured at rest, after warming-up, immediately after the RAST and after 5, 15 and 30 minutes of recovery. The PVV was determined

from the Hct and Hb. Blood lactate concentrations were determined after 3 min of recovery ([La]peak). Results There were no significant differences in RAST's performances and PVV between BM and WM. However, [La]peak was significantly higher ( $p < 0.05$ ) in CM ( $11.8 \pm 2.3$  mmol.L<sup>-1</sup>) compared to BM ( $15.4 \pm 3.2$  mmol.L<sup>-1</sup>). Average power/body mass and average power/lean mass were significantly higher ( $p < 0.05$ ) in BW compared to WW. There was no significant difference in [La]peak between the latter groups. After 5 minutes of recovery PVV was significantly ( $p < 0.05$ ) higher in BW ( $-10.1 \pm 8.4\%$ ) compared to WW ( $+1.1 \pm 5.3\%$ ). Moreover, BM and WM were faster and developed peak power and average power significantly higher ( $p < 0.05$ ) than their women counterparts. PVV was significantly higher ( $p < 0.05$ ) only in WM compared to WW ( $-12.7 \pm 8.9\%$  vs.  $-3.8 \pm 7.0\%$  and  $-10.7 \pm 9.0\%$  vs.  $+1.1 \pm 5.3\%$ , respectively at the end of the RAST and after 5 min of recovery). Discussion The present study showed that skin color influenced neither RAST's performances nor PVV in men. However RAST's performances and PVV were influenced by skin color in women. To our knowledge, this is the first study to show such data. Differences between male and female are well established in the literature, mainly because of sex differences in body composition (Glenmark et al 1992). References Fall A., Pirnay F. (1989). *Médecine du Sport*. 63(5) 266-274 Glenmark B., Hedberg G., Jansson E. (1992). *Acta Physiol Scand*. 146 (2): 251-9. Krip B., Gledhill N., Jamnik V., Warburton D. ## EFFECT OF CARBOHYDRATE SUPPLEMENTATION AT CONTINUOUS INTENSIVE EXERCISE

Tessutti, V.1,2, Salvadeo, C.A.3, Uchida, M.C.2,4, Teixeira, L.F.M.1,2,3

*1UNIFIEO(Osasco,Brazil); 2GEPEFFA(Osasco,Brazil); 3NEPECE(Sorocaba,Brazil); 4UNICAMP(Campinas,Brazil)*

Introduction Generally it is accepted that CHO supplementation during exercise may have an ergogenic effect on long activities of moderate intensity ( $>60'$ ,  $75\%VO_{2max}$ ). However, few studies have investigated the effects of CHO supplementation during continuous intensive exercise ( $30-40'$ ,  $80-90\%VO_{2max}$  or  $95-105\%AT$ ). Therefore, the aim of this study is to investigate the effects of CHO ingestion during continuous intensive exercise. Methods Six well-trained runners ( $30 \pm 6.4$  years;  $VO_{2max}$ :  $49 \pm 3.7$  ml.kg.min;  $AT$ :  $10.8 \pm 0.5$  km/h), performed incremental test to determinate lactate anaerobic threshold (AT) and maximal oxygen uptake ( $VO_{2max}$ ). Posteriorly, all subjects performed two experimental trials, which were conducted in a random order, 4 days apart, at the same time of day for each subject. Experimental trials consisted of exercise session (ES) organized in two stages: SII:  $30'$  in intensity of AT; and SIII: immediately after the SII, speed was increased by 30% and guided to perform evaluated more  $10'$  at higher speed possible with the freedom to change the speed when needed. One day of a trial, subjects received a CHO beverage (1g/kg body mass/hour of exercise at 6% dilution in water), or a coloured flavoured placebo (PLA). The CHO and PLA were ingested during the SII of ES every 5'. During the ES were controlled heart rate (HR) and average speed (AS) every minute. Results Significant differences were identified in AS across the trials (CHO:  $11.4 \pm 0.2$  km/h and PLA:  $11.1 \pm 0.3$  km/h). Specifically, in the SIII of the trials, the difference in the AS was even more relevant (CHO:  $11.70 \pm 0.1$  and PLA:  $11.07 \pm 0.2$  km/h). Both the average intensity during the complete trials (CHO:  $102.1 \pm 0.2\%AT$  and PLA:  $99.5 \pm 0.3\%AT$ ), as the average intensity of SIII (CHO:  $105.3 \pm 0.4\%AT$  and PLA:  $99.4 \pm 0.2\%AT$ ) demonstrated the positive effect of CHO supplementation. Discussion It is established in the literature that the use of CHO promotes positive effects on yield by endurance exercise from  $60'$ , since throughout history several studies were unable to identify the ergogenic effect of CHO supplementation in activity up to  $40'$  (Palmer et al. 1998; Jeukendrup et al. 2008). However, in the present study was identified significant differences with the use of CHO in the performance (AS;  $\%AT$ ) of the ES, and especially the SIII ( $10'$  end) probably because the supplementation with CHO supplied the muscle glycogen depletion promoted by SII. Thus, we conclude that carbohydrate supplementation can promote performance improvement in continuous intensive exercise. References Palmer, G. et al. (1998). *Int J Sports Med*, 19(6), 415-418. ## THE CARDIAC AUTONOMIC MODULATION IS DETERMINED BY GENDER AND IS INDEPENDENT ON AEROBIC PHYSICAL CAPACITY

Souza, H., Dutra, S.G.

*University of Sao Paulo*

Introduction: Aerobic physical capacity plays an important role in reducing morbidity and mortality rates in individuals with cardiovascular diseases. This action is often related to an improvement in the autonomic modulation of the heart rate variability (HRV). However, there are still controversy regarding the effects of physical training on cardiac autonomic control in healthy subjects. (Hautala et al, 2003; Genovesi et al, 2007; Gilder et al, 2008). Therefore, our objective was to investigate whether the aerobic capacity interferes with autonomic modulation of HRV and whether there are gender differences. Methods: Men (N=48) and women (N=48) underwent ergospirometry and divided into groups according maximal aerobic capacity: low (LAC=VO<sub>2</sub>: 22-38 ml kg<sup>-1</sup> min<sup>-1</sup>, medium (MAC=VO<sub>2</sub>: 38-48 ml kg<sup>-1</sup> min<sup>-1</sup>) and high (HAC=VO<sub>2</sub>: >48 ml kg<sup>-1</sup> min<sup>-1</sup>). Autonomic modulation of HRV was investigated by means of spectral analysis at supine position. Results: Both groups formed by men, the groups formed by women, showed no differences in HRV in relation to aerobic capacity. However, women showed a reduction in low frequency oscillations (LF=0.04-0.15Hz) and increase in high frequency oscillations (HF=0.15-0.5Hz) when compared to men, regardless of the aerobic physical capacity. Discussion: The results suggest that aerobic physical capacity does not interfere in the HRV modulation, however the cardiac modulatory balance was different between genders with greater influence of autonomic parasympathetic component in women and sympathetic component in men, respectively. ## TRAINING TRANSFERS FROM RUNNING TO CYCLING: A CASE STUDY OF IMPROVEMENTS IN CYCLING AND RUNNING VO<sub>2</sub>MAX AFTER A BLOCK OF HIGH-INTENSITY AEROBE INTERVAL TRAINING IN AN ELITE CYCLIST

Bratland-Sanda, S., Støren, Ø., Haave, M.N., Helgerud, J.

*Telemark University College*

Introduction Maximal oxygen uptake ( $VO_{2max}$ ) enhancements depend upon exercise modality, although physiological training transfers have been found from running to cycling. The purpose of this study was therefore to examine changes in running and cycling  $VO_{2max}$  after a block of high-intensity aerobic interval training (HAIT) in an elite cyclist. Methods A Norwegian elite cyclist with a baseline  $VO_{2max}$  of  $64.7$  ml.kg<sup>-1</sup>.min<sup>-1</sup> ( $5.5$  l.min<sup>-1</sup>) was tested for  $VO_{2max}$  on both treadmill and ergometer cycle pre, and post a HAIT block (14 sessions of  $4 \times 4$  min running at  $90-95\%$  HRmax in 9 days). During the 9 days with HAIT, no cycling was performed. The post-test were performed 1

day, 7 days and 45 days after finishing the HAIT block. Between post-tests 2 (7 days) and 3 (45 days), the cyclist performed 3 HAIT sessions per week as cycling in addition to his traditional training. Results The HAIT block performed as running led to an immediate increase of 3.4% in running VO<sub>2</sub>max (from 64.3 to 66.5 ml·kg<sup>-1</sup>·min<sup>-1</sup>) and 8.2% (from 64.7 to 70.0 ml·kg<sup>-1</sup>·min<sup>-1</sup>) in cycling VO<sub>2</sub>max post-test (7 days). At post-test 3 (45 days), the improvement from pre-test was 7.0% (to 68.8 ml·kg<sup>-1</sup>·min<sup>-1</sup>) and 15.6% (to 74.8 ml·kg<sup>-1</sup>·min<sup>-1</sup>) in running and cycling VO<sub>2</sub>max respectively. Maximum speed at 5% treadmill inclination (running) increased by 11%, and maximum power (cycling) increased by 10% from pre-test to post-test (45 days). Discussion In this cyclist, a HAIT block performed as running resulted in greater improvement in cycling VO<sub>2</sub>max compared to running VO<sub>2</sub>max. These training transfers from running to cycling may have important practical implications for the preseason training among cyclists.

### BIOELECTRICAL IMPEDANCE VECTOR ANALYSIS AND ALTITUDE TRAINING IN ELITE SWIMMERS: PRELIMINARY RESULTS

Irurtia, A.1, Chaverri, D.1, Barrero, A.1, Carrasco, M.1,2, Zubero, J.3, Nebot, V.4, Štrumbel, B.5, Qiu, J.6, Iglesias, X.1, Rodríguez, F.A.1

1: GRCE, INEFC-Barcelona, UB (Barcelona, Spain); 2: FCS, Blanquerna, URL (Barcelona, Spain); 3: EHU, UPV (Donostia, Spain); 4:UCV (Valencia, Spain); 5:UL (Ljubljana, Slovenia); 6:SISS (Shanghai, China)

Introduction Bioelectrical impedance vector analysis (BIVA) is a relative novel methodology for assessing the hydration status (Lukaski & Piccoli, 2012) without algorithm-inherent errors or requiring assumptions such as constant tissue hydration (Norman et al., 2012). Altitude training (AT) may favor dehydration due to low ambient air humidity, hyperventilation and increased diuresis, particularly at the early phase of altitude acclimatization (Truijens & Rodríguez, 2011). This study aimed to examine the distribution of the bioelectrical impedance vector in male (M) and female (F) elite swimmers using two different AT strategies: live high-train high (LH-TH) and live high-train low (LH-TL). Method 48 elite M and F swimmers lived at altitude (2,320 m) and trained whether at that altitude only (LH-TH, M/F, n=14/20), or also at lower altitude (690 m) two days weekly (LH-TL, M/F, n=9/5). Anthropometric and bioelectrical variables (Z-Metrix®, BioparHom Co, France) were obtained before and during 3-weekly training microcycles (W1, W2, W3). 50 kHz whole-body bioimpedance vectors were analyzed by the resistance-reactance (R/Xc) graphic method and Z mean values plotted (Piccoli et al., 1994). Hotelling's T<sub>2</sub> test was used to determine the difference in the complex localized vector through the 95% confidence and tolerance intervals obtained by BIVA. Results Except for the LH-TL F group, body mass significantly decreased from W1, and further in W2 and W3. BIVA showed different migration patterns of the bioelectrical impedance vector according to the intervention; LH-TH group: R and Xc significantly increased in M and F; LH-TL group: R increased and Xc decreased in F, but there were not significant differences in R or Xc in M. Discussion LH-TH swimmers showed a migration of the vector characterized by a significant increase in length (R) and a decrease in dielectric mass of soft tissues (Xc), likely as a result of moderate dehydration. Contrarily, the vector of both LH-TL groups appeared to reflect the maintenance of an optimal homeostatic status, without any significant bioelectrical changes (M) or showing adequate hydration adaptation (F). Concluding, the LH-TL strategy seems to favor a better maintenance of the hydration status in elite swimmers during AT. References Lukaski HC, Piccoli A (2012). Handbook of Anthropometry. ### IS BIOELECTRICAL IMPEDANCE ANALYSIS ACCURATE TO ESTIMATE FAT MASS IN FEMALES WITH 21-HYDROXYLASE DEFICIENCY?

Gonçalves, E.M., Lemos-Marini, S.H.V., Carvalho, W.R.G., Farias, E.S., Bertapelli, F., Barbeto, V.J.O., Krahenbuhl, T., Ramalho, L.C.B., Samur-San Martin, J.E., Guerra-Júnior, G.

University of Campinas (UNICAMP)

Introduction Congenital adrenal hyperplasia due to 21-hydroxylase deficiency (21OHD) is associated with increase of fat mass (BF). The use of bioelectrical impedance analysis (BIA) to estimate the FM is easy and inexpensive. However, the accuracy of these methods in patients with 21-hydroxylase deficiency (21OHD) has not been explored. The objective of this study was to evaluate the accuracy of BIA equations in assessing FM in individuals with 21OHD using dual-energy X-ray absorptiometry (DXA) as the reference method. Methods Forty-one females with 21OHD, aged six to 27 years, were assessed. Two BIA prediction equations were tested: Deurenberg et al. (1990) and Houtkooper et al. (1992). Results The equation of Deurenberg et al. overestimated significantly the values of fat mass (16.8±7.0 kg, t=3.88, p>0.001) and equation of Houtkooper et al. the values of fat mass were underestimated (14.3±7.3 kg, t=-5.54, p>0.001) compared with DXA (15.7±8.0). The regression analysis demonstrated that both equations had high explanatory power and low error (Deurenberg equation: R<sup>2</sup>=0.96 and standard error of estimation (SEE)=1.59 kg, and Houtkooper equation: R<sup>2</sup>=0.96 and SEE=1.62 kg). Limits of agreement ranged between -2.4 to 4.6 kg and -4.8 to 1.8 kg, for Deurenberg and Houtkooper equations, respectively. Significantly trends were found between the difference and the mean of both methods in both predictive BIA equations (r=-0.57 for Deurenberg equation and r=-0.41 for Houtkooper equation). Discussion In this sample of patients with CAH 21OHD, the BIA equations did not demonstrate accuracy in estimating FM, which may limit their application in clinical settings. Despite the two predictive BIA equations were highly associated. Both BIA equations differ significantly from FM measured by DXA and showed be dependent of adiposity level. These results seem to demonstrate the necessity of using specific models for this population to increase the capacity of bia predict fat mass in females with 21OHD. References Deurenberg P, Kusters CS, Smit HE.(1990). Eur J Clin Nutr, 44, 261-68. Houtkooper LB, Going SB, Lohman TG, Roche AF, Van Loan M.(1992). J Appl Physiol, 72, 366-73.

### WHOLE-BODY BIOELECTRICAL IMPEDANCE VECTOR MIGRATION FOR MONITORING HYDRATION STATUS AFTER AN ULTRA-ENDURANCE TRIATHLON

Irurtia, A.1, Barrero, A.1, Chaverri, D.1, Carrasco, M.1,2, Iglesias, X.1, Rodríguez, F.A.1

1: GRCE, INEFC-Barcelona, UB (Barcelona, Spain); 2: FCS Blanquerna, URL (Barcelona, Spain).

Introduction Monitoring hydration status after an ultra-endurance triathlon (UET) emerges as a priority to safeguard both health and physical performance of the growing tri-athletic population (Knechtle et al., 2008). Bioelectrical impedance vector analysis (BIVA) is a relative novel methodology for assessing the hydration status (Lukaski & Piccoli, 2012). This study aimed to provide the first comprehensive characterization of the whole-body bioelectrical impedance vector migration induced by an UET. Method 11 well-trained non-professional ultra-endurance triathletes (age 37.2±4.6 years, body mass 74.3±6.7 kg, height 174.0±6.0 cm, VO<sub>2</sub>max 67.5±4.2 ml/kg·min) competed in an UET (Extreme Man Salou-Costa Daurada 2011). Body mass (BM) and bioelectrical variables (Z-Metrix®,

BioparHom Co, France) were obtained before, after, and 48 h post-race. 50 kHz whole-body bioimpedance vectors were analyzed by the resistance-reactance (R/Xc) graphic method and Z mean values plotted (Piccoli et al., 1994). Hotelling's T2 test was used to determine the difference in the complex localized vector through the 95% confidence and tolerance intervals obtained by BIVA. Results Changes in BM (74,0±6,8 kg) post-race (69,6±6,5 kg, -5,8±1,9% BM) and 48-h post-race (72,9±6,4 kg, -1,4±1,2%) were significant (ANOVA, p=0,001). BIVA showed Xc/h significant bioimpedance vector migration patterns from pre- (35,4±3,1 Ω/m) to post-race (38,6±4,2 Ω/m, p=0,05), from pre- to 48-h post-race (31,8±2,7 Ω/m; p=0,03), and from post-race to 48-h post-race (p=0,001). There were no significant differences in R/h. Discussion Body mass loss is consistent with previous UET studies (Sharwood et al., 2004). BIVA appears as a sensitive methodology for assessing changes in body water (R) and body soft tissues (Xc) after an ultra-endurance event. Knowing that Xc is inversely related to the dielectric membranes and body tissue interfaces, bioimpedance vector showed a migration characterized by a significant decrease of this dielectric mass after the race and returning to (and even exceeding) initial values thereafter. More research is needed to improve our understanding of bioimpedance vector migration patterns in ultra-endurance competitive events. ## THE EFFECTS OF FLUID DEPRIVATION ON UPPER AND LOWER BODY STRENGTH AND HYDRATION STATUS IN AMATEUR RUGBY PLAYERS

Konstantaki, M., Mitchell, C.

BUCKINGHAMSHIRE NEW UNIVERSITY

Introduction Maximum strength has been shown to be negatively affected by hypohydration in studies that have used exercise heat stress or passive dehydration methods such as heat exposure to manipulate hydration status. However, these methods induce elevations in muscle temperature and impair the contractile properties of the muscle hence exacerbating the negative effects of dehydration on strength (Maughan, 2003). The aim of this study was to assess the effects of hypohydration on maximum strength following a period of fluid deprivation. Methods Ten amateur rugby players (mean ± SD; age: 22 ± 2.7 years, body mass: 91.4 ± 8.5 kg, stature: 182.5 ± 12.5 cm) performed two assessments of upper and lower body maximum strength (1RM barbell bench press and 1RM back squat) under two experimental conditions: a) without fluid restriction (EU) and b) after 6 hours of fluid restriction (DE). Subjects provided a urine sample immediately prior to each testing session from which urine osmolality was assessed using a Pocket Pal Osmo (Vitech Scientific Ltd.) and levels of dehydration were determined (hydrated 0-600 mOsmol/kgH<sub>2</sub>O; mild dehydration: 600-1000 mOsmol/kgH<sub>2</sub>O; severe dehydration: over 1000 mOsmol/kgH<sub>2</sub>O). Body mass (kg) was recorded prior to each testing session. Results Fluid deprivation decreased upper body maximum strength by 2.91% (EU: 107.5 ± 15.85 kg v DE: 104.25 ± 14.81 kg; P=0.00), lower body maximum strength by 3.34% (EU: 126.5 ± 19.05 kg v DE: 122.6 ± 18.05 kg; P=0.004) and body mass by 2.04% (EU: 91.4 ± 8.05 kg, DE: 89.6 ± 7.78 kg; P=0.17) while it increased urine osmolality by 40% (EU: 407 ± 155.4 mOsmol/kgH<sub>2</sub>O, DE: 684 ± 244.6 mOsmol/kgH<sub>2</sub>O; P=0.001). Discussion Six hours of fluid deprivation brought about mild dehydration that negatively affected upper and lower body maximum strength. These results are in agreement with those reported previously by Judelson et al. (2007) who stated that approximately 3-4% hypohydration induced by either exercise heat stress or passive dehydration reduces muscular strength by approximately 2%. The reduction in body mass in his study is similar to that reported by Schoffstall et al., (2001) even though they used passive dehydration. These results suggest that even a relatively short time period of six hours of fluid deprivation can impair maximum strength and cause mild dehydration. ## HYSTERESIS PHENOMENON IN THE RATE OF PERCEIVED EXERTION OF TRIATHLETES DURING CYCLING AND RUNNING

Galán, J.I, Vázquez, P.I, Hristovski, R.2, Balagué, N.1

1: *INEFC Barcelona (Spain)*, 2: *Ss. Cyril and Methodius University, Skopje (Rep. of Macedonia)*

Introduction The hysteresis phenomenon is a sign of nonlinearity in biological systems and it explains the co-existence of different states for the same parameter values. Although the rate of perceived exertion (RPE) is a common parameter for assessing and monitoring training intensity its hysteresis behavior has yet to be tested. The aim of this study was to reveal the existence of the hysteresis phenomenon in the evolution of RPE during progressive increasing/decreasing cycling and running tests. Methods Twenty trained triathletes, M=24,17, SD= 9,31 years old, previously familiarized with the experimental procedures performed in two different days 2 progressive increasing/decreasing tests (cycling and running, respectively) while reporting their RPE values (Borg's RPE 6-20 scale). In the loading phase they pedalled at 100W (with increments of 30W/min) and run at 8 Km/h (with increments of 1 Km/h), respectively, until they reached an RPE≥18. The load was then progressively decreased (30 W/min and 1 Km/h, respectively) like a mirror. The differences of the RPE median values for the same load intensities in the loading and unloading phases were compared using non-parametric Wilcoxon matched pairs test. Results For the cycling task the analysis showed a clear hysteresis phenomenon in the first and the second close to maximum pair of loads (p<0.001; p<0,007), between the loading and unloading phases, with unloading RPE values having larger medians than the loading ones. There were also significant differences between median RPE values in the pair of loads close to the minimum (p<0,05), but this time median RPEs had larger values for the loading phase. No significant differences were found for the rest of the RPE medians. In the running task only the RPE median values of the lowermost three loads showed a hysteresis, being the unloading RPE values lower than the uploading ones (p<0.01; p<0,02 and p<0,005). Discussion The results point to an existence of two types of hysteresis RPE effects in trained triathletes. The first takes a form of a memory of the previous states and the second has the inverse form of a forgetting of the previous states. We hypothesize that the first form is a consequence of a sensitization state, i.e. a state of amplified response to the same amount of load. On the contrary, the second form may be due to a habituation, i.e. the decrease of the response to the same value of input. These results point to the fact that RPE measures may be unreliable associates to the external load when changing load direction, especially close to maximal or minimal values.

**EFFECTS OF TWO DIFFERENT MUSCLE STRETCHING METHODS ON FRONT CRAWL SWIMMING PERFORMANCE**

Fernandes, R., Di Masi, F., Silva, G., Silveira, A.

*Federal Rural University of Rio de Janeiro*

**EFFECTS OF TWO DIFFERENT MUSCLE STRETCHING METHODS ON FRONT CRAWL SWIMMING PERFORMANCE** Fernandes, R.1, Di Masi, F.1,2, Silva, G.3, Silveira, A.1 1: UFRRJ (Seropédica, Brazil), 2: UNIRIO (Rio de Janeiro, Brazil), 3: UFRJ (Rio De Janeiro, Brazil) Introduction Scientific research suggests that the flexibility training (muscle stretching) can be adverse to power and strength production, seem that valences are important to the sports performance. Thus, the aim of the present study was verify the acute effect of static stretching (SS) and proprioceptive neuromuscular facilitation (PNF) stretching on front crawl swimming performance. Methods Thirteen young males ( $22.7 \pm 1.42$  years;  $77.2 \pm 7.25$  Kg;  $172.5 \pm 1.33$  cm;  $25.9 \pm 4.09$  of BMI) was submitted to three randomized select experimental protocol situations, namely: a) 50 meters front crawl test without any stretch training; b) 50 meters front crawl test preceded by SS (2 sets of 30 seconds) for breast and thigh muscles (SS); and c) 50 meters crawl swimming test preceded by PNF (2 sets of 30 seconds by Scientific Stretching for Sports (3S) method) for breast and thigh muscles. Results The One-Way ANOVA with repeated measures was performed to identify differences between groups. When comparison were made between control and the stretching protocols, it was found a significant decrease on performance to time trial in front crawl 50 meters sprint test (CTRL:  $321,2 \pm 29,2$  vs. SS:  $329,2 \pm 25,1$  ms,  $p < 0,05$ ) e (CTRL:  $321,2 \pm 29,2$  ms vs. PNF:  $335,2 \pm 30,7$  ms,  $p < 0,0001$ ). However, when we performed comparisons between stretching protocols, we didn't find any difference on performance to the same dependent variable ( $p > 0,05$ ). Discussion The present study concludes that the SS and PNF, in acute mode, cause a deficit in the front crawl swimming performance. The present study is the first to demonstrate the loss in swimming performance after muscle stretching exercises. Therefore, there are no studies that allow a direct discussion of findings. When considering the stretching acute effects as prejudicial to the physical performance, the present results add up to literature (Nelson et al., 2005; Behm and Kibele, 2007; Rees et al., 2007; Mikolajec et al., 2012). Therefore, it's recommended that the muscle stretching should not be used before central activities, especially those where large strength production is involved, such as of 50 meters in swimming tests. For making definitive conclusions, new studies about the acute effect in flexibility training are suggested. References Behm, D. G. and A. Kibele (2007). **EFFECT ON PERFORMANCE OF ENDURANCE TRAINING COMBINED WITH PIOGLITAZONE TREATMENT. STUDY OF THE SKELETAL MUSCLE ADAPTATIONS**

Martínez-Bello, V.1, Pareja-Galeano, H.2, Olaso-Gonzalez, G.2, Viña, J.2, Gómez-Cabrera, M.C.2

*University of Valencia*

**Introduction** The Peroxisome Proliferator Activated Receptor delta (PPAR-delta) agonist GW1516 and the PPAR delta-AMP-activated protein kinase activator (AICAR -5-aminoimidazole-4-carboxamide-1-beta-D-ribofuranoside) regulate the metabolic and contractile characteristics of myofibers, enhancing thus performance. Thiazolidinediones (TZDs) are PPAR gamma agonists that could induce similar biological changes than PPAR delta and PPAR delta-AMPK agonists. The most common TZDs are rosiglitazone and pioglitazone. The aim of this study was to determine the effect of a pioglitazone on performance and in skeletal muscle mitochondrial biogenesis. **Methods** Twenty male wistar rats were randomly divided into four experimental groups: rest group, treated group, trained group and trained-treated group. Pioglitazone was administered orally three times a week for 4 weeks at a dose of 15 mg/kg/day. Blood glucose levels, protein expression of intermediates involved in the mitochondrial biogenesis pathway and the citrate synthase activity were determined in both gastrocnemius and soleus muscles. We also determined the maximal aerobic velocity (MAV), endurance capacity, and grip strength before and after the training period. **Results** The trained animals (water and pioglitazone groups) significantly increased their maximal aerobic velocity, endurance capacity and grip strength. We found a significant increase in peroxisome proliferator-activated receptor coactivator-1 $\alpha$  (PGC-1 $\alpha$ ), and nuclear respiratory factor 1 (NRF1) protein content in the soleus muscle of the trained animals. Citrate synthase activity was also increased after training in soleus muscle. No changes were found in gastrocnemius muscle in any experimental group and in any protein involved in the mitochondrial biogenesis pathway. **Conclusions** In our study, pioglitazone administration did not increase performance and did not affect physiological adaptations. **Acknowledgments** The authors' work was supported by grant P2011/02 RM to GC.M. from the "Cátedra Real Madrid-UEM".

**15:00 - 16:00****Mini-Orals****PP-PM53 Misc. topics 4****VASCULAR FUNCTION, AEROBIC FITNESS AND PHYSICAL ACTIVITY IN MAINTENANCE HAEMODIALYSIS PATIENTS**

Prescott, S., Traynor, J., Rush, R., Mercer, T.

*Queen Margaret University and Monklands Renal Unit, UK*

**Introduction** Accelerated vascular aging occurs in people undergoing maintenance haemodialysis (HD) resulting in a high prevalence of atherosclerosis and left ventricular hypertrophy (London et al 2011). Low aerobic fitness and physical activity (PA) are highly prevalent and have been implicated in the shorter life expectancies of HD patients (Sietsema et al 2004, Matsuzawa et al 2012). This study explored the relationship between vascular function, aerobic fitness and physical activity (PA) in HD patients. **Methods** Cross sectional study of 19 male haemodialysis patients (6 diabetics): [data are mean (standard deviation); age  $52.9(17)$  years; BMI  $22.9(7.3)$ ; dialysis vintage  $26.4(20.9)$  months; FMD  $4.69\%(2.94)$ ; PWV  $7.9(2.0)$  m/s; VO<sub>2</sub>peak  $19.3$  ml/kg/min, daily steps  $2976(2214)$ ]. Endothelial function was determined by brachial artery flow mediated dilation (FMD) and aortic artery stiffness from carotid femoral pulse wave velocity (PWV). VO<sub>2</sub>peak was determined via cardiopulmonary exercise test and PA levels via triaxial accelerometry (Actigraph GT3X). **Results** PWV correlated with VO<sub>2</sub>peak ( $r = -0.44$ ,  $p = 0.039$ ) and age ( $r = 0.64$ ,  $p < 0.01$ ), with a trend seen for moderate PA ( $r = -0.45$ ,  $p = 0.05$ ). PWV was not correlated with

FMD or dialysis vintage. FMD was correlated with VO2 peak ( $r=0.66$ ,  $P<0.01$ ), age ( $r=0.57$ ,  $p=0.01$ ) and dialysis vintage ( $r=-0.52$ ,  $p=0.02$ ). FMD was positively correlated with PA ( $r=0.63$ ,  $p<0.01$ ) and negatively correlated with time spent sedentary ( $r=-0.60$ ,  $p<0.01$ ). After controlling for age the association between VO2peak and PWV was non-significant but the significant VO2-FMD relationship was retained. Discussion These data indicate that age, rather than VO2peak has a more influential association with PWV in male HD patients. In contrast, VO2peak appears to be strongly related to FMD, even after controlling for the influence of age; an observation also seen in healthy young men (Palmieri et al 2005). Crucially, time spent sedentary as well as time physically active may both influence VO2peak and FMD in HD patients. This is consistent with animal studies showing reduced endothelial function with enforced sedentary behaviour (Suvorava et al 2004). While FMD does not offer prognostic utility equivalent to PWV in HD patients the endothelium controls vascular homeostasis and dysfunction of this organ is the starting point for atherosclerosis. Identifying HD patients with low fitness and sedentary habits may assist nephrologists with management of vascular health. ### PHYSICAL FUNCTION OF UPPER-LIMB AFTER BREAST CANCER SURGERY VARY BY SURGERY TECHNIQUES -A PROSPECTIVE 2.5 YEARS FOLLOW UP STUDY-

Sagen, A.1, Kaaresen, R.2, Sandvik, L.3, Thune, I.5, Risberg, M.A.4

*Oslo University Hospital, Ullevål*

1: DCT, OUS (Oslo, Norway), 2: BC, OUS (Oslo, Norway), 3: EPI/BIO, OUS (Oslo, Norway) 4: NAR (Norway), 5: FHS (Tromsø, Norway) Introduction The introduction of Sentinel Node biopsy (SN) as a part of breast cancer treatment was assumed to minimize side effects compared to Axillary Dissection (AD). However, side effects and unanswered questions still exist in relation to assessment of upper limb function in breast cancer patients. Therefore, the aim of this study was to study upper limb side effects after breast cancer treatment by using validated measurements pre-operatively and after 2.5 years in two groups (SN and AD) of breast cancer patients stadium I to II. Methods One group of breast cancer patients went through surgery with SN only ( $n=187$ , mean age  $57 \pm 10$ ), and one group went through an additional AD ( $n=204$ , mean age  $55 \pm 10$ ). Outcomes were; Arm lymphedema ( $\geq 10\%$  increased arm volume relative to control arm volume), grip strength (kg), shoulder mobility and timed shoulder abduction endurance (sec), pain (VAS mm) and BMI ( $\text{kg}/\text{m}^2$ ). Parametric /non-parametric tests for hypothesized changes and differences and regression analysis for confounding factors were employed. Results We observed more adverse side effects in women treated by AD in comparison to women treated with SN after 2.5 years ( $P < .05$ ); Arm lymphedema (17% vs 3%), grip strength reduction (12% vs 2%) and pain (increase of 6% vs decrease of 50%). The side effects were similar for affected and control upper limb for all outcomes except for Arm lymphedema, occurring only in the affected side. Both groups increased their BMI ( $P < .05$ ), but with less than one unit. Discussion Side effects were observed after 2.5 years follow-up in both AD and SN groups, but a higher prevalence was observed in the AD group. The results were in accordance to other reports using validated pre-operative measurements (Sagen A. et al., 2009; McLaughlin SA. et al., 2008;). Thus, specially women who go through AD as part of breast cancer treatment may benefit from preoperative upper-limb assessments for both affected and control side and further post-operative physical therapy focusing on muscle strength exercises (McNeely ML., 2010, Cantarero-Villanueva I, 2012). Both groups may benefit from physical activity programs including information on a healthy lifestyle to avoid weight gain (Demark-Wahnefried W., 2012). ### EFFECTS OF CONTRAST BATHING TREATED BY DIFFERENT ORDER OF COLD AND HOT WATER IMMERSION ON RECOVERY FROM MUSCLE FATIGUE AFTER STRENUOUS ACTIVITY

Noriko, I.1, Mana, O.2, Yasuaki, S.3, Chiaki, N.3

*1) Waseda University, School of Sport Sciences 2) Waseda University, Graduate School of Sport Sciences 3) Waseda University, Faculty of Sport Sciences*

Introduction In competitive sports, accumulated muscle fatigue caused by daily practice and games often lead to sports injuries. For the purpose of injury prevention, rapid recovery from muscle fatigue seems crucial. Recently, contrast bathing has been frequently used as one of the modality to recover from muscle fatigue. But, the standard protocol for contrast bathing has not been established yet. The appropriate water temperature, immersion duration, and the order of cold and hot water bathing remain unclear. The purpose of this study was to investigate whether the order of cold and hot water immersion in contrast bathing (where temperature and duration are preset) influences recovery from muscle fatigue after strenuous activity. Methods Six healthy college students (21.3yrs, 63.3kg) with no habit of resistance training were asked to apply two conditions of contrast water therapy; one finished with cold water (HC condition), the other finished with hot water (CH condition) in limb to limb comparison model. Before contrast bathing, each subject performed calf raise exercise until totally exhausted. Muscle stiffness, range of motion, circulatory conditions of popliteal artery, and visual analogue scale (VAS) were measured as indexes of muscle fatigue. Each measurement was performed before exercise (pre), right after exercise (post), immediately after contrast bathing (ACB), and at every 15 minutes after ACB over 75 minutes (15, 30, 45, 60, and 75minACB). Analyses A two way factorial analysis of variance was used to examine the difference between two conditions and time series variation of them. Then, comparison of the simple main effect by Bonferroni method was used to examine the difference between the two conditions on each measurement phase throughout the all data collection period, and between pre, post and the other measurement phases on each condition. Results No significant difference was found on interaction between the two conditions and time series variation of them. Muscle stiffness showed significant differences between post and 60minACB, 75minACB on HC condition, and between post and 75minACB on CH condition. Blood vessel diameter was significantly bigger only on 45minACB in HC condition than in CH condition. Discussion The physiological effect caused by contrast bathing in this study is assumed to be result of stimulation of superficial temperature receptor of skin. In this study, it was observed that decreasing of muscle stiffness was higher on HC condition than on CH condition. It is assumed that this result was brought because superficial temperature receptor is more sensitive to cold stimulation than to hot stimulation. Then, it is considered that pressure to vessel by muscle was lessened on HC condition and it led to greater vasoconstriction compared to CH condition. Conclusion Difference in order of cold and hot water immersion in bathing does not effect on recovery from muscle fatigue after strenuous activity.

## FACTORS RELATED TO KNEE ADDUCTION MOMENT DURING GAIT DIFFER WITH GAIT PATTERNS IN PATIENTS WITH KNEE OSTEOARTHRITIS

Koyama, Y., Tateuchi, H., Goto, Y., Otsuka, N., Kobayashi, M., Ichihashi, N.

*Graduate School of Medicine, Kyoto University*

**Introduction** Gait analysis in patients with knee osteoarthritis (OA) is frequently performed for assessment. Previous studies described knee adduction moment (KAM) as a factor closely related to the symptoms and severity (Kito N, et al. 2010) of knee OA. However, none of these studies investigated the differences in the factors related to KAM in patients with different gait patterns. The aim of this study was to classify gait patterns in patients with knee OA, and to investigate the factors related to KAM in each gait pattern. **Methods** Thirty women with knee OA were recruited. The participants' gait was analyzed at a self-selected speed by using a three-dimensional gait analysis system. Sagittal kinematic data of the affected knee were collected for gait classification. Simultaneously, gait speed and the impulse of KAM in the stance phase were calculated. In addition, the following parameters were measured as static factors: range of motion (ROM) of knee flexion/extension, isometric muscle strength of knee flexor/extensor, femorotibial angle (FTA), and the lumbar lordosis angle. Using kinematic data, hierarchical cluster analysis was applied to classify the gait patterns into groups. Then, partial correlation coefficients between KAM and static factors adjusted for gait speed were calculated for each group. **Results** Cluster analysis showed that gait patterns could be divided into 3 groups (G<sub>1</sub>~G<sub>3</sub>). The knee angle pattern observed in G<sub>1</sub> showed the greatest similarity to the pattern in healthy subjects. Patients in G<sub>2</sub> showed reduced knee excursion. In G<sub>3</sub>, greater knee flexion at foot strike and decreased knee extension at terminal stance were observed. In the partial correlation analysis the factors that correlated with KAM were, lumbar lordosis angle, FTA and knee extensor strength, FTA and knee extension ROM for G<sub>1</sub>, G<sub>2</sub> and G<sub>3</sub> respectively. **Discussion** Previous studies that attempted to reduce KAM during gait with exercise did not achieve the desired effect (Sled EA, et al. 2010, Lim BW, et al. 2008). The present study indicated that patients with varied gait patterns showed differences in the factors related to KAM. The failures in previous studies may be partially because they used the same recruitment and treatment approaches for patients with different gait patterns. The results of this study suggest that when clinicians attempt to reduce joint loading in knee OA patients, it can be more meaningful to categorize these patients into groups corresponding to homogeneous gait patterns. **References** Kito N, et al. (2010). *Clin Biomech* (Bristol, Avon). 25(9), 914-919. Sled EA, et al. (2010). *Phys Ther*. 90(6), 895-904. Lim BW, et al. (2008). *Arthritis Rheum*. 59(7), 943-951.

## THE SEVERITY OF ANEMIA IS ASSOCIATED WITH LOW EXERCISE CAPACITY IN PATIENTS UNDERWENT CARDIAC SURGERY

Lai, Y.L.1, Tsai, M.W.2, Hsu, C.L.1, Lin, Y.S.1, Huang, H.Y.1, Chen, J.C.1, Kuo, L.Y.1, Chen, B.Y.1, Tsai, H.Y.1, Chiu, Y.C.2

*1: Cheng-Hsin General Hospital, 2: National Yang-Ming University*

**Introduction** Postoperative anemia is a common complication after the cardiovascular surgery. Low oxygen transport is suspected to affect oxygenation and function of tissues that may affect exercise capacity. Thus, the purpose of this study was to investigate the effect of severity of postoperative anemia on exercise capacity of patients after cardiac surgery. **Methods** This is a retrospective cohort study. We analyzed patients underwent cardiac surgery and completed cardiopulmonary test (CPX) in 2010 in a Heart Center in Taiwan. We included adult patients with postoperative anemia and excluded those with preoperative anemia. The concentration of hemoglobin (Hb) less than 12.5 g/dL was defined as anemia. The [Hb] was collected before discharge and the patients were classified into 3 groups: mild (11-12.5 g/dL), moderate (9-11 g/dL), and severe (<9 g/dL) anemia. Exercise capacity and responses were acquired from CPX, including peak oxygen consumption (VO<sub>2</sub>), heart rate (HR), blood pressure (BP), and oxygen pulse (O<sub>2</sub> pulse). One-way ANOVAs were used to compare the variables among different groups. The significant level was set at p<0.05. **Results** There were 202 patients (73.8% male, 61.30±12.62 year-old) being recruited. The rate of postoperative blood transfusion was 34.9%, and most patients did not recover at discharge. There were 37 (18.3%) patients with mild, 124 (61.4%) with moderate, and 41 (20.3%) with severe anemia. Older age tended to increase the severity of anemia (p=0.051). Patients in the severe group had significantly lower peak VO<sub>2</sub> than moderate and mild groups (15.08±4.81 vs. 17.94±6.02 and 18.71±4.97 ml/kg/min, p=0.010); lower peak HR (p=0.040), O<sub>2</sub> pulse (p=0.041) and higher resting systolic BP (p=0.040) were also found. **Discussion** Our findings highlight a high prevalence of postoperative anemia persisting with moderate-to-severe level at discharge, especially elders. Lower [Hb] was related to lower exercise capacity and worse cardiovascular responses to exercise. That may play a vital role of poor prognosis and quality of life in patients underwent cardiac surgery comorbid with postoperative anemia. Further study should follow up the recovery of the postoperative anemia and exercise capacity for a longer period; especially elders underwent cardiac surgery. **References** Westenbrink, B.D., et al., (2011). *Heart*, 97(19), 1590-1596. ## A PROSPECTIVE STUDY ON FULL-BODY KINEMATIC RELATED RISK FACTORS IN THE DEVELOPMENT OF EXERTIONAL MEDIAL TIBIAL PAIN

Verrelst, R.

*Ghent University*

**ABSTRACT Objective:** To prospectively determine risk factors contributing to the development of exertional medial tibial pain (EMTP). **Methods:** Data were prospectively collected on healthy female students in physical education, who were freshmen in 2010-2011 and 2011-2012. Eighty-six female students aged 19.38±0.85 years, were tested at the beginning of their first academic year. Kinematic parameters in the frontal and transverse plane were measured during a single leg drop jump (SLDJ). For further analysis, the SLDJ task was divided in 2 phases: touchdown (TD) until maximal knee flexion (MKF) and then MKF until take-off (TO), representing landing and push-off phase, respectively. The injury follow-up of the subjects was assessed using a weekly online questionnaire and a three-monthly retrospective control questionnaire. EMTP was diagnosed by an experienced M.D. (Doctor of Medicine). Cox regression analysis was used to identify the potential risk factors for the development of EMTP. **Results:** During injury follow-up (1-2 years), 22 subjects were diagnosed with EMTP. The results of this study identified that increased range of motion (ROM) in the transverse plane of both hip and thorax during landing (P=0.010 and P=0.026 respectively) and during push-off (P=0.019 and P=0.045 respectively) are predictive parameters for the development of EMTP in females. **Conclusions:** Increased ROM values of hip and thorax in the transverse plane, which can be interpreted as impaired ability to maintain DJS, are significant contributors to the development of EMTP in females.

## THE RELATIONSHIP BETWEEN TOE EXERCISES AND THE MEDIAL LONGITUDINAL ARCH OF THE FOOT

Shiroshita, T.1, Fukubayashi, T.2

1: Gumma Paz College, 2: Waseda University

**Introduction** Although toes play an important role, toe flexor strength is poorly understood. We have previously published clinical (Shiroshita 2011) and electromyogram (EMG) studies (Shiroshita 2012) of the toe exercises developed by us. However, these studies did not involve measurement of morphologic variations; as a result, the morphologic relationship between these toe exercises and the medial longitudinal arch (MLA) remained unclear. The purpose of this study was to examine the relationship between the toe exercises and MLA. **Methods** The subjects were 28 participants (20 men, 8 women) with a mean age of  $21.0 \pm 0.7$  years. The participants were classified 3 groups, which were a great-toe-flexor exercise group (GTE), a lesser-toe-flexors exercise group (LTE) and a towel-gathering exercise group (TGE). The toe exercise groups performed isotonic contractions (10 times) of the greater toe flexor (IP extension) in the GTE or lesser toe flexors (DIP extension and PIP flexion) in the LTE. The TGE performed 3 minutes. The GTE and LTE performed the toe exercises seated; a 3-kg weight was placed on their distal thigh and they tilted their trunk forward. The subjects tried to raise their heel with their toes to perform the toe flexor exercises. We assessed the navicular drop test (NDT) (Body 1982) results obtained using a three dimensional foot form device (3DFOOT SCANNER standard type JMS2100CU, DreamGP company, Japan), before and after the exercises were performed. For statistical analysis, we performed Wilcoxon signed-rank tests using IBM SPSS Statistics 20. The results are presented as mean (SD) and were considered significant at p values less than 0.05. This study was performed with the consent of the Ethics Committees for Human Research of Waseda University and Gumma Paz College. **Results** The NDT results for the TGE and the GTE group changed from 4.2 (1.4) mm to 4.8 (1.3) mm ( $p = 0.138$ ) and 4.9 (1.7) mm to 5.2 (1.7) mm ( $p = 0.173$ ), respectively, with no difference before or after the exercises. On the other hand, the NDT results for the LTE significantly changed from 5.7 (0.9) mm to 3.6 (1.2) mm ( $p = 0.005$ ). **Discussion** The TGE and the GTE did not show a morphologic relationship with MLA. In fact, they showed a tendency to reduce the rigidity of MLA. On the other hand, the LTE increased the rigidity of MLA. We consider that it is necessary to study the toe exercises we have developed using a longitudinal research method. **Keywords:** toes, navicular drop test, the medial longitudinal arch **References** 1. ## COMPARISON OF DUAL TASK PERFORMANCE ON OBSTACLE CROSSING AMONG NON-FALLERS, SINGLE AND MULTIPLE FALLERS

Huang, Y.S., Cho, C.Y.

National Cheng Kung University

**Introduction** Falls have been a major health problem in the elderly population. Previous studies indicated that older adults with only one fall experience were more similar to non-fallers when compared to multiple fallers (Lord et al., 1994). For elderly, tripping over or stepping on obstacles is a common reason of falling (Campbell et al., 1990). In real-life situation, people often perform two things simultaneously which is referred as dual task paradigm. Using dual task paradigms with a more challenge motor task may be an effective way to evaluate the ability of older adults with different fall experiences for fall prevention. Therefore, the purpose of this study were to investigate whether the dual task paradigm would influence the spatiotemporal parameters during obstacle crossing in older adults and to examine the effect of different fall experiences on obstacle crossing ability under dual task condition. **Methods** Community-dwelling older adults who aged 65 years old were recruited in this study. Individuals were divided into three groups based on their fall experiences over previous 12 months; older adults (OA, n=14), single fallers (SF, n=13) and multiple fallers (MF, n=5) group. The dual task paradigm was used in this study. The primary task was to cross an obstacle at the middle of walkway. The secondary task was to perform serial 7 subtractions. Six motion capture cameras were used to collect the three dimensional movement data of lower extremities. Two-way ANOVA with repeated measures was used to analyze the outcome measures. **Results** From single to dual task, participants significantly decreased their leading heel-obstacle distance, crossing length and velocity ( $p=0.006$ ;  $p=0.014$ ;  $p<0.001$ ). For trailing toe-obstacle distance (TTD), there was a main effect of group ( $p=0.041$ ). Post hoc analysis revealed that TTD of OA group was significantly greater than SF group ( $p=0.038$ ). **Discussion** The present study demonstrates that dual task significantly affected the obstacle crossing ability of the participants and the finding is similar to previous study (Kim and Brunt, 2007). The results suggest that older adults adopt a more cautious way when encounter a more challenge condition. In addition, older fallers performed shorter TTD indicated that they were much closer to the obstacle in order to accomplish the task. However, group effect is not remarkable in the current study. It may due to participants' number was not equivalent and we will recruit more multiple fallers in the future. **Reference** Campbell AJ, Borrie MJ, Spears GF, Jackson SL, Brown JS, Fitzgerald JL. ## POLYMORPHISMS IN BETA ADRENERGIC RECEPTOR GENES DIFFER BETWEEN ATHLETES AND NON-ATHLETIC CONTROLS

Polster, P., Bachl, N., Wessner, B.

UNIVIE (Vienna, Austria), Institute of Sports Sciences

**Introduction** Beta adrenergic receptor (ADRB) gene polymorphisms have been associated with elite endurance performance (Moore et al., 2001; Santiago et al., 2011; Sawczuk et al. 2012; Wolfarth et al., 2007). Up to now there is no study focussing on ADRB variants within strength and team sport athletes. Therefore, the aim of this study was to compare the allelic and genotype frequencies of ADRB genetic variants between athletes engaging in power-oriented sports, athletes engaging in team sports and non-athletic controls. **Methods** The study population consisted of 56 sprint/power athletes (SPA), 144 team sport athletes (TSA) like handball and soccer players, and 223 healthy controls (HC). Athletes were included in the study sample only if they had participated on the highest national or international level. The International Physical Activity Questionnaire was used to assess the physical activity level of the control group. Genotype and allelic frequencies were analysed for ADRB1 Ser49Gly (rs1801252), ADRB2 Arg16Gly (rs1042713), ADRB2 Gln27Glu (rs1042714) and ADRB3 Trp64Arg (rs4994) polymorphisms by Real-time PCR using TaqMan® SNP genotyping assays (Life Technologies, Carlsbad, California). The Chi-square test was used for statistical comparisons between the groups and a  $p<0.05$  was considered as being statistically significant. **Results** We observed significant differences in genotype frequencies for the ADRB1 Ser49Gly ( $p = 0.013$ ) and the ADRB2 Gln27Glu ( $p = 0.044$ ) polymorphisms between HC and SPA with higher frequencies of the ADRB1 Gly49Gly and ADRB2 Gln27Glu genotypes in SPA. Furthermore, we found a significant difference in the genotype distribution for the ADRB3 Trp64Arg polymorphism ( $p = 0.079$ ) between

TSA and HC with a higher frequency of the 64Trp allele in TSA. Discussion The main findings of our study were that the ADRB1 Gly49Gly and the ADRB2 Gln27Glu genotypes seem to be favourable for power-oriented sport performance. Interestingly, there is no significant difference between TSA and SPA which could be due to the fact that strength is an important skill for professional handball and soccer players. This would be in accordance with the findings of Santiago et al. (2008) showing that soccer players have a higher frequency of the sprint/power-associated variant of ACTN3 (R allele). As this is the first report revealing a positive association between team sport performance and the ADRB3 Trp64Arg polymorphism the results need to be replicated in similar populations. ### THE INFLUENCE OF ACETAMINOPHEN ON REPEATED SPRINT CYCLING PERFORMANCE

Foster, J., Watkins, S.L., Taylor, L., Mauger, A.R.

*University of Bedfordshire*

Introduction During exercise, increases in intramuscular metabolic by-products (bradykinin, prostaglandins, potassium, hydrogen ions) correlate with increases in work rate during repeated sprint activity. Consequently, type III and type IV afferent fibres send nociceptive signals to the central nervous system (CNS) regarding actual or potential tissue damage (O'Connor et al., 1999), where these signals are interpreted as pain. It is speculated that high nociceptive activity elicits reductions in work rate during intense physical exercise (Mauger et al., 2010). Whilst this has been demonstrated in moderate duration cycling exercise, there are no studies where this hypothesis has been tested in repeated sprint activity. Therefore the aim of this study was to investigate the efficacy of acetaminophen (an analgesic) on improving overall work rate during an all-out repeated sprint protocol. Methods Nine recreationally active male subjects (age:  $21 \pm 2$  yrs, height:  $175 \pm 7$  cm, weight  $75 \pm 14$  kg,  $VO_{2max}$ :  $47 \pm 6$  mL/kg/min) completed a graded exercise test, a familiarisation set of wingate anaerobic tests (WAnT) and two experimental sets of WAnT's (8 x 30 s sprints, 2 min rest intervals). In the experimental WAnT's, subjects ingested either 1.5g acetaminophen or a placebo in a double blind, randomised, cross-over design. During the WAnT trials, subjects provided ratings of perceived pain 20 s into each sprint. Average power output (APO), fatigue index and heart rate (HR) were measured following each sprint. Results Subjects cycled at a significantly greater APO ( $p < 0.05$ ) following the ingestion of acetaminophen ( $397W \pm 32$ ) when compared with the placebo trial ( $367W \pm 55$ ). This was due to a significantly greater APO during sprints 6, 7, and 8 ( $p < 0.05$ ). Fatigue index was significantly reduced ( $t_8 = 5.79$ ,  $p < 0.05$ ) following acetaminophen ingestion ( $22\% \pm 11$ ) when compared with the placebo trial ( $31\% \pm 7$ ). No significant differences in perceived pain or HR were observed between conditions ( $p > 0.05$ ). Discussion This study provides evidence that repeated sprint ability can be improved following the ingestion of acetaminophen. Acetaminophen may have induced an ergogenic effect through the reduction of pain for a given work rate, thereby enabling subjects to exercise closer to a true physiological limit (Mauger et al., 2010). This suggests that individuals may regulate their work rate according to a fixed level of pain or discomfort, which may constrain performance below that which is physiologically achievable. ### THE INFLUENCE OF VIBRATION FREQUENCY AND AMPLITUDE ON THE CO-ACTIVATION DURING A DYNAMIC EXERCISE UPON AN UNSTABLE VIBRATORY PLATFORM

Cabello, R., Rodríguez-Jiménez, S., Moras, G.

*INEFC Barcelona*

Introduction The co-activation increase during whole body vibration (WBV) is considered to have a positive effect on joint stabilization associated with postural control strategies (Berschin and Sommer, 2004; Pollock et al., 2010; Roelands et al., 2004). The most well investigated indirect method, a subject stand on a stable vibration platform. On the other hand, an increasingly popular exercise modality involves the use of labile surfaces (Hupperets et al., 2009). Both methods have shown to induce increases on co-activation separately. However, the effects on co-activation combining vibration and a labile surface has not been investigated. The aim of this study was to analyze the influence of vibration frequency and amplitude on the co-activation during a dynamic movement on a unstable vibratory platform. Methods Thirty male physical education students volunteered to participate in this study. Subjects were asked to move the unstable vibratory platform oscillating uniformly to the left and right side of the fulcrum following a metronome programmed at 60 cycles min<sup>-1</sup> at four different vibration frequencies (0, 25, 35 and 45 Hz), and two peak-to-peak displacements (low; 1.2 mm and high; 2.2 mm). Surface electromyography (EMG) of gastrocnemius lateralis (GL), anterior tibialis (AT), biceps femoris (BF) and rectus femoris (RF) were recorded. Co-activation ratios were calculated as GL/AT and BF/RF. Two-ways analysis of variance for repeated measures were used to assess the effect of frequencies and displacement. Results Increasing vibration frequency (from 0 to 45Hz) resulted in a progressive increase in GL/AT ratio. The analysis revealed a significant frequency main effect ( $p < 0.001$ ) only for GL/AT ratio. Post hoc tests showed a significant higher GL/AT at 25, 35 and 45Hz vibration frequencies compared with 0Hz. Discussion The present findings are unique because co-activation was assessed during a dynamic oscillating movement upon an unstable vibration platform. Our results are in line with previous WBV studies including static and dynamic exercises demonstrating an increase in co-activation of lower extremity extensor and flexor muscles in response to an increase in vibration frequency (Roelands, 2004; Pollock et al., 2010). However the effect of vibration frequency was only evident at the GL/AT ratio. This could be explained firstly, because GL and AT are most proximal to the generation of the WBV stimulus and secondly, because GL presumably plays a more important stabilizing role of the ankle to maintain the body balance. ### EFFECTS OF A CIRCUIT FOR SENSORY STIMULATION ON ISOKINETIC PEAK TORQUE AND DYNAMIC BALANCE IN OLDER WOMEN

Avelar, B., Costa, J., Oliveira, P., Dutra, M., Safons, M., Lima, R.

*University of Brasilia*

Introduction Age related changes in postural control contribute to instability and increased risk of falls in older adults. Muscle peak power and dynamic balance are critical components of functional performance and should be included in exercise strategies to improve postural control. The potential positive effect of a sensory stimulation circuit (SSC) on muscle power and dynamic balance is unknown. The purpose of this quasi-experimental trial was to assess the effects of a SSC on muscle power and dynamic balance in elderly women.

**Methods** The sample consisted of 23 sedentary elderly women divided into sensory stimulation group (SSG) N=10 (70.10± 6.64 years) and control group (CG) N=13 (66.92±4.50 years). The SSG performed a protocol designed by Costa et al. (2010) that emphasized static and dynamic balance exercises with opened and closed eyes, addition of obstacles and unstable surfaces during 1 hour, twice a week, over 13 weeks. The CG was instructed to maintain their habitual activities. Measurements of isokinetic knee extensors peak torque (180°/s) and Timed Up & Go test (TUG) were obtained before and after the intervention period. ANOVA with group (SSG vs. CG) and time (baseline vs. post) as factors was performed with Bonferroni adjustments. Statistical significance was set at p=.05. Results At baseline, groups did not differ in terms of age, height, weight and outcome measures (p>.05). Exercise compliance was 91%. Peak torque at 180°/s showed a significant between groups interaction (p=.041) but not the TUG test (p=.159). Post hoc analyses revealed significant effects of time within SSG for peak torque (p=.021) and TUG (p=.032) on average by 10,7% and 6,4%, respectively. No significant changes were noted in the CG. **Discussion** Although the primary goal of the SSC protocol proposed by Costa et al. (2010) was to promote improvements in dynamic balance, the current study provided further important information regarding skeletal muscle power gains in older women. Importantly, available studies suggest that muscle power is a better predictor of functional performance than muscle strength in the elderly (Correa et al. 2012; Pereira et al. 2012). These findings suggest that 13 weeks of the studied SSC induce increases on muscle power and dynamic balance in older women and constitute a low cost and efficient option for this population. ##### ASSOCIATION OF PERSISTENT STAPHYLOCOCCUS AUREUS NASAL CARRIER WITH HIGH FREQUENCY SKIN ABSCESS IN AMERICAN FOOTBALL PLAYERS

Suzuki, K.1, Shiba, H.1, Arai, N.2, Gochi, K.1, Matsumoto, T.1, Tagami, K.1

*University of Tsukuba*

1 : Institute of Health and Sports Sciences, University of Tsukuba 2 : Health and Sports Sciences major, Department of Education, Faculty of Education, Hakuoh University Introduction Staphylococcus aureus (SA) is an emerging cause of infection in players of physical contact sports (Nguyen et al. 2005). Nasal colonization by SA is a well-established risk factor of acute cutaneous infection (Kluytmans et al. 1997). To understand the basis of the SA infection of physical contact athlete, we compared the SA infection among three distinct carriers based on nasal carriage and skin lesions in University American football team. **Methods** University American football players who took part in this study were 36 male members. Nasal samples were collected by the same person over a 9-month interval from January 2012 to November 2012. Swab samples were obtained from the right or left anterior nares by using a sterile swab. The samples were impregnated with 100µl of PBS. After 10µl of PBS samples were inoculated and incubated at 37C for 24±2 h on the compact Dry X-SA media (CD-XSA; Nissui Pharmaceutical Co., Ltd., Tokyo, Japan) (Teramura, et al. 2010). The specific SA colonies were counted. A questionnaire that captured basic demographic and clinical data was administered to all the players concerning their date of abscess, player position and skin lesions. **Results** 1) According to our definition, there were 6 (16.7%) persistent, 3 (8.3%) intermittent, 17 (47.2%) occasional, and 10 (27.8 %) non carriers in this team. 2) By comparing their colony number of three distinct carrier groups, the persistent carrier (117.7 CFU/ml) showed a significantly larger count than a mean count of the intermittent carrier and occasional carrier (65.4 CFU/ml) (P<0.05). 3) Skin abscess was more frequently identified in the persistent carrier (P<0.05). **Discussion** Major findings are that persistent SA nasal carrier was 16.7%, and coincident with high frequency skin abscess. Additionally, number of SA colonies in the nose was significantly higher in persistent carrier than others. Thus, persistent carrier may act as a 'SA reservoir' that facilitates transmission to the uninfected players. References Kluytmans, J., A. van Belkum and H. Verbrugh (1997). ##### COGNITIVE DIETARY RESTRAINT: PREVALENCE AND ASSOCIATION WITH MENSTRUAL DYSFUNCTION IN FEMALE RUNNERS

Belski, R.1, Clarke, G.2, Borkoles, E.3, Cooke, M.2

*1: La Trobe University, 2: Victoria University*

**Introduction** Female athletes are particularly vulnerable to certain undesirable health outcomes, the most well known is the Female Athlete Triad, incorporating the combination of: menstrual dysfunction, disordered eating and compromised bone health. Some evidence exists that cognitive dietary restraint (CDR) may lead to disordered eating, low energy availability and also possibly menstrual dysfunction (Pollock et al. 2010). Limited research has been conducted on the Australian population, more specifically on how CDR impacts on menstrual function. Therefore, the aim of this study was to assess the prevalence and degree of CDR and menstrual dysfunction among sub-elite female runners. Furthermore to establish if CDR is a contributing predictor for those females experiencing menstrual dysfunction. **Methods** Adult female members of Athletics Victoria (Australia) were invited to complete an online questionnaire that included previously validated, standardized scales designed to assess eating behaviours and cognitive dietary restraint (Three-Factor Eating Questionnaire) (de Lauzon et al. 2004) and further internally designed questions investigating physical activity and menstrual patterns. Athletes with diagnosed eating disorders were excluded from the study. Analysis of the data was carried out using SPSS version 16.0 (SPSS, Inc., Chicago, IL, USA). **Results** Female runners (n=104) completed the online questionnaire. There was a high prevalence of CDR of varying degrees and menstrual dysfunction amongst the cohort, with 71% of the cohort reporting medium to high CDR restraint scores with a linear trend of higher weekly kilometres (-12.67km/week (p=0.007)). 25% of the participants reported currently experiencing menstrual dysfunction and 51% of the participants reported having been amenorrhoeic (loss of menses for >3months) in the past. CDR did not appear to be a predictor of menstrual dysfunction in this cohort r = 0.0107 (p=0.1092) **Discussion** The high levels of CDR and menstrual dysfunction observed in this cohort are a concern for female runners, placing this population at a high risk for fertility problems, poor bone health and serious injuries such as stress fractures. More longitudinal investigations, with larger cohorts are required along with better identification

and management systems and processes for females who at risk or presently suffering from one or more elements of the female athlete triad. References de Lauzon, B, Romon, M, Deschamps, Vr, Lafay, L, Borys, J-M, Karlsson, J, Ducimetire, P & Charles, MA 2004, 'The Three-Factor Eating Questionnaire-R18 is able to distinguish among different eating patterns in a general population', *The Journal Of Nutrition*, vol. 134, no. 9, pp. 2372-80. Pollock, N, Grogan, C, Perry, M, Pedlar, C, Cooke, K, Morrissey, D & Dimitriou, L 2010, 'Bone-mineral density and other features of the female athlete triad in elite endurance runners: a longitudinal and cross-sectional observational study', *International Journal Of Sport Nutrition And Exercise Metabolism*, vol. 20, no. 5, pp. 418-26.

### THERAPEUTICAL USE EXEMPTIONS OF ELITE ATHLETES - GLUCOCORTICOID USE AND ABUSE

Andjelkovic, M.1,2, Dikic, N.1,2, Baralic, I.2, Vesic Vukasinovic, M.1,2, Antic, T.2

<sup>1</sup>Anti-doping agency of Serbia, <sup>2</sup>Sports Medicine Association of Serbia

**Introduction** Athletes may have illnesses or conditions that require to take particular medications. Use of substances from Prohibited List for medical reasons requires an approved Therapeutic Use Exemption (TUE). To gain approval, an athlete must submit the appropriate application form along with substantial medical justification at least 30 days in advance of intended use. Athletes have obligation to get approval before using any medication that can cause doping positive result. One of criteria for granting a TUE points that there is no reasonable therapeutic alternative for prohibited substance or prohibited method. Methods In this cross sectional study, 150 TUE applications from elite Serbian athletes were analyzed, in period of 2007. to 2012. by using official data of Anti-doping agency of Serbia (ADAS). These applications had been processed by TUE Committee of International sports federations or ADAS. Results TUE was requested from 116 athletes with average age  $29.6 \pm 7.6$  and men to women ratio 70:30%. More than once 16.4% athletes applied for TUE with maximum of 5 TUE/athlete. The highest prevalence of TUE requests came from athletics (20.1%), basketball (19.5), football (12.1), archery (6%) and tennis (4.7%). The musculoskeletal disorders (80%) and asthma (14.8%) were dominant pathological conditions among Serbian athletes. Enthesiitis, lumbar syndrom and lumbar disc herniation had highest prevalence among musculoskeletal disorders. Only 8% applications were related to chronic diseases (diabetes, colitis ulcerosa, infertility, chronic renal insufficiency, hypertension and neoplasma). Most commonly used medicines were glucocorticosteroides (GCS) represented by 72% and salbutamol with 9.8%. Betamethasone (27.3%), dexamethasone (16.8%) and triamcinolon (14.7%) were the most frequent administrated GCS. Intramuscular (32.9%), inhalation (15.4%) and intraarticular (12.8) routes of drug administration were mostly represented in treatment of athletes. Discussion This study can be useful for perceiving medical conditions of elite athletes which require TUE. Low number of TUE in Serbia implies that the education of athletes and sports federations should be on a higher level. Frequent use of GCS, without valid medical indication and thinking about alternative drugs and methods that could be equally effective, can cause severe side effects leading to decreased sports performance. Since illegitimate consumption of these medicines can cause doping positive result, the importance of reporting TUE should be stressed out. ### AEROBIC EXERCISE RECOVERS DOPAMINERGIC AND SEROTONERGIC DYSFUNCTION IN METHAMPHETAMINE-INTOXICATED MICE

Fontes Ribeiro, C., Neves, A.F., Freitas, H.J., Dias, A.I., Mendes, S.M., Viana, S.D., Nunes, S., Pereira, F.C.

*Faculty of Medicine*

**Introduction** Methamphetamine is an illicit psychostimulant drug widely abused in the world that leads to long-lasting neurodegenerative changes in monoaminergic brain regions. Exercise has stood out because of its rehabilitation properties in drug addiction settings. In this study, we sought to investigate whether physical exercise can repair injured dopamine (DA) and serotonin (5-HT) terminals in the frontal cortex and striatum from methamphetamine (METH)-exposed mice. **Methods** A total of 24 C57BL/6 mice (12-week-old; 23-26 g) were divided into four groups: the exercise groups were submitted to a seven-week treadmill exercise regimen post-METH injection (30 mg/kg METH, i.p.). The sedentary groups were exposed to the treadmill as well. The animals were sacrificed 48 hours following the exercise protocol. Frontal cortical and striatal DA, its metabolites (DOPAC+HVA) and 5-HT total levels (HPLC-ECD) as well as tyrosine hydroxylase (TH; Western Blotting) were determined as monoaminergic terminal markers. Glial fibrillary acidic protein (GFAP; Western Blotting) levels were also measured as an astrogliosis marker. All values were expressed as means  $\pm$  SEM and statistical significance was evaluated by ANOVA followed by Bonferroni's multiple comparison test or by Student's two-tailed t test (GraphPad Prism 5.00.288). The significance level was set at a p value less than 0.05. **Results** Neurodegeneration of both frontal cortical and striatal dopaminergic terminals was still in place 7 weeks following METH single injection, as evidenced by the decreased values of dopamine/metabolites and TH levels ( $p < 0.05$ ). On the contrary, GFAP levels were normal in both regions. Although METH had depleted 5-HT in frontal cortex ( $p < 0.05$ ), it failed to impact striatal 5-HT levels. Exercise not only restored striatal dopaminergic markers levels (METH-exercise vs. METH-sedentary,  $p < 0.05$ ) but also increased total striatal 5-HT contents (Saline-exercise vs. Saline-sedentary,  $p < 0.05$ ). Although exercise fostered 5-HT cortical recovery (METH-exercise vs. METH-sedentary,  $p < 0.05$ ), it failed to restore cortical dopaminergic markers. **Discussion** This study is highly suggestive of exercise being endowed with repairing/trophic properties towards DA/5-HT striatal and frontal cortical terminals. The mechanism underlying this positive effect warrants further scrutiny. One can suggest that treadmill exercise has potential to be a non-pharmacological strategy of neuronal repair in METH addicts. ### PLATELET-RICH PLASMA TO TREAT CHRONIC UPPER PATELLAR TENDINOPATHIES

Kaux, J.F., Croisier, J.L., Bruyère, O., Rodriguez, C., Daniel, C., Godon, B., Simoni, P., Alvarez, V., Brabant, G., Lapraille, S., Lonneux, V., Noël, D., Collette, J., Le Goff, C., Gothot, A.

*University and University Hospital of Liège*

**Background:** Upper patellar tendinopathies remain often chronic and rebel to a thorough conservative treatment. Moreover, the option of a surgical treatment could be disappointing. New treatments are being developed. Injection of PRP is one of these. Platelets contain lot of growth factors which would have the potentiality to enhance the healing process of tendons. Even if in vitro and animal experiments have demonstrated this stimulation of tendon healing process, clinical series are subject to controversy. **Methods:** Twenty patients with chronic upper patellar tendinopathy were enrolled. Assessments [VAS, clinical examination with an algometer, algofunctional scores (IKDC and VISA-P), functional assessments (isokinetic and Optojump) and imagery (ultrasounds and MRI)] were made before infiltration of PRP, and 6 weeks and 3 months after. The PRP was obtained by an apheresis system (COM.TEC, Fresenius). Six millilitres of PRP were injected without local anaesthetic. One week after infiltration, patients started a 6-week standardised sub-maximal eccentric reeducation. **Results:** We observed a very significant improvement of the algofunctional status as soon as 6 weeks after the infiltration of PRP, and

continued to a lesser extent up to 3 months. During functional evaluation, pain decreased as well, but without significant improvement of performances. No significant improvements in the imagery were observed. Interestingly, patients who had a VAS equal or below 1 after 3 months post-infiltration were younger (24.7 vs 32.2 y.o.). Moreover, these younger patients had a significant increase of the IKDC score ( $p=0.003$ ), a significant improvement of pain during isokinetic evaluations ( $p<0.05$ ), and during Optojump assessments ( $p=0.01$ ). Seventy-five percent of subjects were able to return to sport, even if only half of these patients recovered the same level than before the tendinopathy. Discussion / Conclusions: This study demonstrates that a local infiltration of PRP associated with a submaximal eccentric protocol is efficient to improve symptoms of chronic upper patellar tendinopathies, non-responsive to classical conservative treatments. However, up to now, there is no consensus on the method to prepare the PRP. Indeed, each technique could provide a very different PRP (variations in the platelet concentrations and of the amount of red and white cells). References: 1. Effects of platelet-rich plasma (PRP) on the healing of Achilles tendons of rats. *Wound Repair Regen* 2012; 20:748-56. 2. ### THE INFLUENCE OF HORMONAL AND BIOCHEMICAL PARAMETERS ON THE CHANGES OF VO<sub>2</sub>MAX IN PROFESSIONAL FOOTBALL PLAYERS

Handziski, Z., Handziska, E., Milenkova, M.

*Faculty of medical sciences, Un.Goce Delce-Stip, Republic of Macedonia; PZU Kineticus-sports medicine and exercise science-Skopje, Republic of Macedonia*

The aim of this study was to evaluate the influence of some hormonal and biochemical parameters on changes of VO<sub>2</sub> max in professional football players during a training and competition football process. This study included 30 professional football players from one of the teams of the first football league. The investigations were made at three points: in the beginning of the preparation period, after the preparation period, and after competition period. Each of the investigations was performed in three phases. The following parameters had been determined: VO<sub>2</sub> max (ml/kg/min), heart rates (b/min), blood lactates (mmol/l), serum levels of testosterone (nmol), plasma levels of cortisol (mmol/l) and ACTH (pg/ml) by RIA method and plasma levels of creatine kinase (CK U/l) by DEROM method during a maximal treadmill test in the first phase; AnT (km/h and beat/min) with Conconi method in the second phase; blood lactates during a specific designed high intensity football training session on the field in the third phase. There were significant changes of VO<sub>2</sub> max ( $48,31\pm 4.08$ ;  $51,31\pm 4.16$ ;  $49,5\pm 4.81$ ) during the season, with insignificant changes of AnT ( $12,7\pm 0,80$ ;  $12,73\pm 1,71$ ;  $12,2\pm 1,47$ ). CK plasma levels changed significantly during the season (decreasing at the end of the season). There were significant changes of testosterone serum levels (decreasing at the end of the season) and cortisol and ACTH plasma levels (increasing at the end of the season) during the season. The blood lactates levels during maximal treadmill test changed insignificantly and on the field changed significantly (increasing at the end of the season) at the end of the season. The changes of VO<sub>2</sub> max were significantly influenced by hormonal and biochemical parameters in each period of training and competition period. The significant changes of some parameters and their correlations indicate disadaptation and depletion of the adaptation mechanisms at the end of season. The significant increasing of VO<sub>2</sub>max, decreasing of CK exercise induced answer and the lower levels of blood lactates after preparation period indicate a beginning of adaptation of some systems, although there is no increase of AnT and cortisol exercise induced answer as signs for an improvement of sport performance. Some biochemical and hormonal changes during the football training and competition period could be the markers of VO<sub>2</sub>max changes.

### DIFFERENT TYPES OF EXERCISE AND LIBERATION OF CIRCULATING PROGENITOR CELLS IN PATIENTS WHO SUFFERED A TRAUMATIC BRAIN INJURY. A PILOT STUDY

Conde, L., Guillamó, E., Álamo, J.M., Gaitán-Peñas, H., Blasi, J., Juncadella, M., Viscor, G., Ventura, J.L., Javierre, C., Corral, L.

*Barcelona University*

Introduction: physical exercise may improve cognitive function and attention, and decrease cognitive deterioration and depression. The mechanisms involved are not clear. The objective of this study is to improve physical or psychological sequelae of patients who suffered a Traumatic Brain Injury (TBI) with a program of physical exercise and muscle electrical stimulation, and measure circulating progenitor cells (CPC) in peripheral blood. Methods: a pilot study was carried out with five patients, but only two of them ended a nine week exercise program with aerobic endurance, resistance and proprioception exercises (five sessions per week: three in the Exercise Physiology Unit and two at home). During these sessions two electrical muscle stimulation series of 20 minutes were applied (Electro-stimulation group, EG). Another group of five patients followed a twelve weeks program (Cycling group, CG). Inclusion criteria: 1) Patients who suffered a TBI more than one year ago with physical or psychological sequelae, 2) No epilepsy 3) Males 20-60 years old. Psychological tests and physical stress tests were done before and after the program. CPC (CD34+) were measured in peripheral blood several times along the protocol. Results: In EG, the results of psychological tests did not change, aerobic capacity improved according physical tests data, increasing VO<sub>2</sub> uptake, and CPC levels increased in the last three weeks. In CG the psychological tests failed to show any change, aerobic capacity improved in physical test increasing VO<sub>2</sub> uptake, but CPC in peripheral blood did not increase. Discussion: In our study all patients improved aerobic capacity, but only two patients increased CPC in blood. One reason may be that the two subjects carried out a higher workload although we could not be able to measure it, and another reason could be that the two patients did a localized effect with electrical muscle stimulation (and probably much higher muscle micro-injuries) while the other group followed a generalized exercise with bicycle activity. Psychological tests did not detect any change, but patients reported subjective improvement, so that we could search for different tests in order to detect these changes in TBI patients. ### THE EFFECT OF ACUTE AEROBIC EXERCISE ON SERUM CORTISOL AND COGNITIVE FUNCTION IN YOUNG ADULTS WITH DIFFERENT CARDIORESPIRATORY FITNESS LEVELS

Tsai, C.L., Chen, T.C., Chou, F.Y., Chen, F.C.

*National Cheng Kung University*

Tsai, C. L.1, Chen, T. C.1, Chou, F. Y.1,2, Chen, F. C.3 1: National Cheng Kung University (Tainan, Taiwan), 2: Chi Mei Medical Center (Tainan, Taiwan), 3: National Pingtung University of Science and Technology (Pingtung, Taiwan) Introduction Although numerous studies have

demonstrated that physical fitness and acute aerobic exercise are positively related to the cognitive functions. To our knowledge, none of studies addressed the neuroelectric and biochemical mechanisms that may underlie the positive effects on cognition associated with acute aerobic exercise and with physical fitness. Therefore, the present study was aimed to examine possible biochemical effectors involved in the impact that moderately intense aerobic exercise has on cognitive functions in young adults with different cardiorespiratory fitness levels. Additionally, the relationship between changes in cortisol levels and cognitive performance was examined. Methods On the first visit thirty-eight young adults were separated into higher- and lower-fit groups according to their maximal oxygen consumption after performing a graded exercise test. On the second visit in the same week, cognitive performance (behavioral and electrophysiological indices) via an endogenous visuospatial attention task test and biochemical index were measured before and after an acute bout of 30-minute moderate intensity aerobic exercise on a motor-driven treadmill. All independent variables (e.g., reaction time, P3 amplitude, and cortisol level) from the acute bout of moderate aerobic exercise were separately analyzed with a repeated-measures ANOVA. Results Higher-fit group exhibited shorter RTs compared to lower-fit one as well as larger P3 amplitudes before acute exercise. Shorter RTs and reduced cortisol levels were shown following acute exercise for both groups. However, only higher-fit group exhibited greater P3 amplitudes after the acute exercise. In addition, only reduced cortisol levels and increased P3 amplitude were significantly correlated in the higher-fit group. Discussion The findings that young adults with higher cardiorespiratory fitness exhibited better behavioral and electrophysiological performance before acute exercise support the cardiovascular fitness hypothesis that greater fitness benefits various aspects of cognitive functioning. However, cardiorespiratory fitness positively modulates the relation between acute exercise and electrophysiological performance in younger adults with higher cardiorespiratory fitness when performing the cognitive task, suggesting higher-fit individuals showed particular efficiency with regard to attentional resource allocation after acute exercise, which means that the mechanisms underlying the effects of such exercise on cognitive functioning may be fitness dependent. The cortisol reactivity before and after acute aerobic exercise could be one of the underlying mechanisms for the beneficial effects of aerobic fitness.

## SECONDARY HYPOGONADISM IN MALE ATHLETES USING ANABOLIC-ANDROGENIC STEROIDS

Jóźków, P., Mędraś, M.

*University School of Physical Education*

Introduction Illicit use of AAS is widespread in many parts of the world. Eg. in Sweden the number of users is estimated to be between 10 000 - 100 000 a year (Lood et al., 2012). AAS suppress the hypothalamo-pituitary-gonadal (HPG) axis leading to decreased production of testosterone (T) and spermatozoa. Although the gonadal function usually recovers after the withdrawal of AAS, in a growing number of cases AAS induced hypogonadism (ASIH) of unknown pathophysiology is observed (Tan and Scally, 2009). Our aim was to assess the HPG axis in adult men with a history of long-term exposure to AAS. Methods The study was performed in 13 men (aged 25±4) who were referred to an andrological clinic because of hypogonadism (T <3 ng/ml, symptoms of T deficiency). They received AAS in a similar manner (3-4 cycles of eg. Deca Durabolin 4000 mg, Omnadren 7000 mg, Metanabol 1200 mg and/or Oxandrolone 5000 mg during a year) for 3.9±1.6 years. The drug-free interval was 2.1±1.0 years. Each studied man underwent an andrological examination with basal evaluation of: LH, FSH, T, E2, SHBG, PRL. Then a clomiphene stimulation test (CST) was performed (50 mg of clomiphene/daily for 7 days). We compared concentrations of LH, FSH and T. Results Mean concentrations of LH, FSH and T before and after clomiphene were respectively (mean±SD): 3±1,2 and 8,3±2 mIU/ml; 3±1,1 and 10±14,6 mIU/ml; 2,3±0,6 and 7,2±1,7 mmol/l (p<0.001). It was equal to an increase by respectively: 3,4±2,2; 3,2±4,1 and 3,3±0,9 times. Discussion ASIH is usually temporal. In most cases the androgenic milieu restores within a year after cessation of AAS, though in some athletes hypogonadism and sperm production disturbances may persist suggesting a failure of the HPG (van Breda et al., 2003). In our investigation clomiphene stimulation demonstrated a proper function of the HPG in hypogonadal athletes. It induced the same increases of gonadotropins and T concentrations as observed in healthy subjects. The reaction to an antiestrogen appeared to be intact even in long-term doping users. The results of CST indicate that application of clomiphene can be considered as a therapeutic option in such cases. Whether it also translates into sperm count changes remains to be established. ## AWARENESS SURVEY CONCERNING ANTI-DOPING ON TOP-LEVEL HANDBALL PLAYERS OF SEVERAL GENERATIONS IN JAPAN.

Kainuma, K., Sakuma, K., Sakamoto, S.

*Japan Handball Association*

Introduction For athletes, awareness of anti-doping is indispensable. In 2012, in two players belonging to our association, results of doping tests to them were positive, and they were imposed penalties. It was considered that they performed violations even though inadvertent, and were suspended qualification for three months. Therefore, we carried out the survey of current awareness to anti-doping in top-level players. Subjects and Methods We administered a questionnaire survey regarding anti-doping knowledge to 2250 top-level players of each generation. The contents of the questionnaire include the awareness, the way to deal with illness or injury, medicine (prescription and over-the-counter), some energy drinks, supplements, Chinese herbal medicine and anti-doping education. Result Overall, 1624/2050(79.2%) questionnaires (922 male and 702 female) were returned and available for analysis. And 263 of all (16.2%) had been selected as the member of national team once or more over. National players had a significantly higher level of awareness for anti-doping than non-national players. Especially, it was remarkable to check whether it is possible to take medicines, supplements, and drinks or to do self-learning for anti-doping by using JADA web site and so on. Compared male with female, female had a significantly higher awareness than male. Conclusion Previously, doping test was performed only for elite-level players. But in recent, in addition to them, even under category players have been often the target for the purpose of enlightenment. The recent situation has occurred because inadvertent violations were increasing. Of course, elite-level players have more opportunities to obtain some information about anti-doping. But non-national players have no opportunities except for self-learning. By a violation, the player may be disqualified forever. So we have to structure systematic anti-doping education, and make more opportunities to educate every player, especially junior generation.

**SALIVARY BETA-DEFENSIN 2 INCREASES AFTER YOGA EXERCISE**

Eda, N., Shimizu, K., Suzuki, S., Tanabe, Y., Lee, E., Akama, T.

*Waseda University*

**Introduction** Yoga stretching can be done comfortably and easily by beginners and the elderly to compensate for lack of exercise or poor health maintenance. The aim of this study was to determine the effect of yoga stretching on mucosal immune functions, primarily human  $\beta$ -defensin 2 (HBD-2) in saliva. **Methods** 15 healthy adults ( $60.4 \pm 8.0$  yr) participated in this study. Each of them was at rest for 90 min on the first day, and performed yoga exercise for 90 min on the second day. During yoga exercise, they first massaged their legs and pressed acupressure points for 20 min. Then, they held yoga poses (Warrior Pose, Extended Triangle Pose, Downward-Facing Dog etc.) for 65 min, and finally lay supine (Corpse Pose) for 5 min. Saliva samples stimulated by chewing a sterile cotton at a frequency of 60/60s were collected. HBD-2 concentration was measured using enzyme-linked immunosorbent assay (ELISA), and HBD-2 expression rate was calculated by multiplying HBD-2 concentration by saliva flow rate. **Results** Saliva flow rate showed no significant change by rest and yoga exercise. HBD-2 concentration after yoga stretching ( $165.4 \pm 127.1$  pg  $\cdot$  mL<sup>-1</sup>) was significantly higher than that before yoga stretching ( $84.1 \pm 63.4$  pg  $\cdot$  mL<sup>-1</sup>;  $p < 0.01$ ). HBD-2 expression rate after yoga stretching ( $232.8 \pm 192.9$  pg  $\cdot$  min<sup>-1</sup>) was significantly higher than that before yoga stretching ( $110.7 \pm 96.8$  pg  $\cdot$  min<sup>-1</sup>;  $p < 0.01$ ). HBD-2 concentration ( $p < 0.05$ ) and HBD-2 expression rate ( $p < 0.01$ ) at post on the second day (Yoga) was significantly higher than that on the first day (Rest). **Discussion** In this study, salivary HBD-2 concentration and HBD-2 expression rate significantly increased after yoga exercise. Recent studies have reported that yoga has a relaxation effect (Hartfiel et al., 2011; Telles et al., 2009). Additionally, several studies investigated the suppressive effect of mental stress on the expression of HBD-2 (Tomita et al., 2002; McDermott et al., 2003). Taken together, the relaxation effect of yoga stretching likely decreases mental stress, which in turn increases salivary HBD-2 expression. We conclude that yoga exercise aimed at relaxation might enhance mucosal immune function and be useful for the elderly and athletes to maintain their health. **References** Hartfiel N, Havenhand J, Khalsa SB, Clarke G, Krayer A. **CONTRIBUTING FACTORS OF THE MOTIVATION FOR RECEIVING THERAPY ABOUT ACUPUNCTURE IN ATHLETES**

Terada, K.1, Wada, T.2, Miyamoto, T.2, Shiraiishi, A.1, Murakami, K.1, Nakatani, T.1

*1: Tenri University (Nara, Japan), 2: University of Tsukuba (Ibaraki, Japan)*

**Introduction** Acupuncture is a traditional therapy that is used widely around the world (Mao et al., 2010), and can control muscle pain and prevent the decline in physical performance. Therefore, acupuncture has been recently applied as an enhancer of sports performance (Ahmedov, 2010; Lin et al., 1999; Terada et al., 2001). The purpose of this study was to examine factors of the motivation for receiving therapy about acupuncture in athletes. **Methods** Three-hundreds-twenty-eight university students (210 men and 118 women; mean age,  $20.2 \pm 1.1$  years) majored in physical education provided consent to participate in survey that using questionnaire quantifiable fears and knowledge of the acupuncture therapy and attitudes about receiving acupuncture treatment. **Results** Two-hundred and seventy-six of 328 people (84.1%) had the experience of the sport-related injuries, and 191 of 328 people (69.2%) had experience of the acupuncture treatments. We divided them in two ways; one whose members play whether team (team group,  $n = 169$ ) or individual (individual group,  $n = 159$ ) sports, and one whose members play interpersonal (interpersonal group,  $n = 251$ ) sports or competitive athletics (competitive group,  $n = 77$ ). Analysis of covariance (ANCOVA) was used for comparisons of the data between the groups, it showed that between-group significant differences, when compared interpersonal group and competitive group ( $p=0.03$ ). In stepwise multiple regression analysis, fear of the acupuncture therapy, knowledge of the acupuncture therapy, family members with experience of the acupuncture therapy and interpersonal sports or competitive athletics were independently and significantly associated with the motivation for receiving therapy. **Conclusion** It was shown that athlete's personality including the sport event type characteristic influenced the attitude about the acupuncture treatment. **References** Ahmedov S. **15:00 - 16:00****Mini-Orals****PP-PM15 Health and Fitness [HF] 9****OLDER ADULT'S QUADRICEPS STRENGTH IN DEEP WATER RUNNING PROGRAM**

Tamborindoguy, A., Freitas, C.R.

*Universidade Federal de Santa Catarina*

**Introduction** Strength impairments in elderly have been fairly studied once it's related to functional capacity limitations. Especially attention has been given to quadriceps strength since it's one of the muscle groups with higher decline in older people. After that, loss of quadriceps strength has been related to decrease of balance and increase of falls. Therefore, the aim of this study was to verify knee muscles force production in older adults after an aqua fitness program. **Methods** 7 older adults (4 women and 3 men), mean age  $62 (\pm 3)$  years old, participated to a 12 weeks (2 hours per week) deep water fitness program. Exercises were basically shifts, similar to deep water running, associated with upper and lower limb movements. Right knee torque production was evaluated in an isokinetic dynamometer at sit position during 0, 60 and 180 degrees per second before and after the training program. After 5 minutes warming up in a cycle ergometer participants were positioned on the dynamometer and prepared according to manufacturer instructions. The test consisted in

3 maximal voluntary isometric contractions (5 seconds) at 70° of knee flexion; 5 maximal voluntary concentric flexion and extensions at 60 and 180 degrees per second. The interval between repetitions was 120 seconds. Before each velocity test one bout was performed to familiarization. Participants were informed of the study protocol and all risks and possible harms as described in the consent form. Knee extensors peak torque (PT) during isometric and concentric torque-angle curve was analyzed by means of Student's *t* test for paired samples. Results Isometric extensor PT was higher after training (180,4 ±64,7 Nm) than before (163,2 ±51,4 Nm). PT at highest isokinetic speed was higher after training (90,6 ±35,6 Nm) than before (80,5 ±30,6 Nm) as well. But no difference was observed between pre (116,5 ±40,2 Nm) and post training (115,3 ±39,5 Nm). Discussion After 12 weeks of deep water exercises extensors strength increases were observed at isometric and 180 degrees per second isokinetic test. Specific speed muscle adaptations has been reported (Frasson et al. 2007) and can be an explanation to the strength gain observed at isokinetic results since its considered a medium speed (Terrerri et al. 2001), similar to movements speed usually performed during aqua fitness sessions. Those findings are important considering elderly quadriceps strength impairments (Samuel et al. 2009) and possibility of health promotion. ## EFFECTS OF COMBINED STRENGTH AND ENDURANCE TRAINING ON PHYSICAL PERFORMANCE AND HEALTH IN YOUNG WOMEN

Kyröläinen, H., Salminen, R., Repola, J., Häkkinen, K., Haimi, J.

*University of Jyväskylä*

Introduction Cardiovascular fitness has decreased (e.g. Santtila et al., 2006) and obesity (e.g. Ekelund et al., 2007) increased in youth during the last ten years especially in Western countries. Regular physical activity can have beneficial effects on physical performance, body composition and health (e.g. Blair and Church, 2004). Therefore there is an urgent need to find out optimal training program for improving physical performance and health outcomes. We tried to clarify effects of combined strength and endurance training on physical performance, hormonal responses and some health markers. Methods Subjects were 25-30-year-old females with very low physical activity, and 65 % of them were overweight (BMI >25). They performed strength and endurance training three times a week during nine weeks. Independent strength training was performed at the gym and instructed endurance training by indoor cycling. Several experimental measurements were assessed before, in the middle and after the training period. No nutritional guidelines were given to the subjects. Results The 9-week training period led to 8.5 % increase in maximal oxygen uptake. Resting heart rate and heart rate variability (HRV) remained unchanged with the exception of a decrease of 48.2 % in high-frequency power (HF). Isometric maximal strength of the leg and arm extensors increased by 28.9 % and 7.8 %, respectively. No changes in rate of force development were noticed. Maximal isometric trunk flexion and extension increased by 27.2 % and 16.1 %, respectively. Total cholesterol values lowered by 7.6 %, while HDL (high density lipoprotein) increased by 8.8 %. LDL (low density lipoprotein), hemoglobin, fasting plasma glucose and triglyceride remained unchanged. Plasma cortisol increased by 22.7 % but no changes in plasma testosterone, estradiol or sex hormone binding globulin (SHBG) were observed. The skeletal muscle mass increased by 0.8 %, but there were no changes in body weight, fat mass, or fat percentage. Discussion Our results indicate that the 9-week strength and endurance training period, including three training sessions in a week, improve maximal endurance and strength capacity as well as some health outcomes. Thus, combined strength and endurance training itself can induce significant health benefits without any changes in dietary habits. References Blair SN, Church TS. (2004) *JAMA* 8, 292: 1232-4. ## EFFECTS OF CONCURRENT TRAINING ON CAROTID INTIMA-MEDIA THICKNESS OF MIDDLE-AGE OBESE MEN

Cavaglieri, C., Oliveira-Silva, M.V., Gáspari, A.F., Rossi, G., Nadruz, W.J., Brunelli, D.T., Bonganha, V., Libardi, C.A., Chacon-Mikahil, M.P.T.

*State University of Campinas*

Introduction Atherosclerosis is an inflammatory chronic disease and one of the major causes of death in the world. Atherogenesis is the development of atheromatus plaques in inner lining of the arteries, specifically in the intima-media wall. This process is related to hemodynamic changes, inflammatory mediators increase and deterioration in the lipid profile, which in turn are common elements in obesity. Large part of the medicine drugs have failed in treating this disease (1), however, long time intervention (more than one year) whit aerobic training have been shown to decrease intima-media thickness. But Tanaka (2002) did not find decreased IMT whit aerobic training intervention of 6 months, and nowadays the recommendation for this age group are Concurrent Training, because it can interlock the benefits of both trainings. Thus, the aim of this study was to analyze the effect of Concurrent Training on carotid IMT of middle-age obese men. Methods Eight men (48.03 ±5.15 years and 31.61 ±2.37 km/m<sup>2</sup>) were analyzed. The carotid IMT measures were made by ultrasonography with the equipment Vivid 3 Pro, the carotid artery images were obtained by linear transducer whit frequency of 10MHz. There were Six months of Concurrent Training, comprised by Resistance and Aerobic training in the same training session. The comparison between pre- and post-training for maximal upper and lower body strength (One Repetition maximum test), oxygen peak consumption (Cardio-pulmonary test) and IMT were made by paired T-test. Results After the training period were observed significant increase in upper body strength (74.6 ±9.7 to 87.5 ±16.4 kg, p=0.01) and lower body strength (323.8 ±49.8 to 375.6 ±37.0 kg, p=0.002) were observed. However, no training effects occurred on oxygen peak consumption (28.03 ±4.07 to 28.12 ±2.87 ml/kg/min, p= 0.32) and IMT (0.6 ±0.1 to 0.6 ±0.1 mm, p=0.68). Discussion Different authors showed the effects of exercise training on the IMT of various arteries, however positive effects on Carotid IMT have been reported only in long time studies (3). Studies with short time intervention, lower than one year, have showed similar results to our research, even with aerobic training (2) considered more effective (4). Conclusion The training protocol proposed wasn't effective to decrease the IMT after 6 months, probably a larger intervention time is necessary to promote changes in this variable of middle-aged obese. ## LOWER EXTREMITY AND CORE MUSCLES ACTIVATION DURING AN AQUATIC RESISTANCE EXERCISE PERFORMED WITH DIFFERENT DEVICES

Borreani, S.1, Colado, J.C.1, Calatayud, J.1, Moya, D.1, Martin, F.1, Furio, J.2

1. University of Valencia, Valencia, Spain. 2. Catholic University of Valencia, Valencia, Spain

Water environment is an effective tool to improve the strength and may increase the muscle mass both in older and younger physically active people. Many different devices are used in aquatic resistance training. There are two kinds of devices: floating and drag, which may be of different sizes. However, little research has been reported regarding the effects of using different devices during the performance of resistance exercises in a water environment. PURPOSE: To compare lower extremity and core muscles activation during leg adduction performed at maximum velocity with 4 different aquatic devices. METHODS: 24 physically fit and healthy subjects (23.2 ± 1.18 years) took part in a randomized, within-subject design assessment. The maximum isometric voluntary contraction (MIVC) was evaluated for the normalization of the electromyographic measures. Latissimus dorsi (LD), Rectus Abdominis (RA), External Oblique (EO) and Erector Spinae (ES) muscular activity were recorded and the maximum root mean square values were calculated for each condition. Surface electromyography was isolated and the activity was analyzed during 3 repetitions of leg adduction performed with 4 aquatic devices: Drag Hydroboot (DH), Drag Aquafins (DA), Floating Boot (FB), and Floating Support (FS). All values were expressed as the %EMG and compared using Analysis of Variance with repeated measures. Significance level was set at  $p < 0.05$ . RESULTS: For all muscles analyzed in the present study, no significant differences were found [AL:  $F(1,73,27.70) = 1.322$ ,  $p = 0.280$ ; RA:  $F(3,30) = 1.138$ ,  $p = 0.124$ ; EO:  $F(3,39) = 0.680$ ,  $p = 0.570$ ; ES:  $F(3,30) = 1.138$ ,  $p = 0.350$ ] between performance of the aquatic exercise under the four conditions (DH, DA, FB and FS). CONCLUSION: When training in a water environment, different sizes and kinds (drag and floating) of devices can lead to similar muscle activation when the movement is performed at maximum velocity. Therefore, if maximum muscle activation of the extremities and core muscles is required the kind of device is not relevant.

## EFFECTS OF STRENGTH TRAINING ON OBJECTIVELY RECORDED PHYSICAL ACTIVITY IN ELDERLY MEN

Berntsen, S., Stea, T.H., Bjørnsen, T., Salvesen, S., Lohne-Seiler, H., Hellelid, K.J., Paulsen, G.

University of Agder

Introduction It is unclear whether participation in strength training programs specifically developed for elderly translates into a more physically active lifestyle. In addition, in few studies physical activity (PA) is objectively recorded and conclusions are typically based on PA self-reports. The aim of the present study is to determine whether changes in muscle strength and mass during a 12 weeks strength training period are associated with changes in the PA-level, in elderly men. Methods Fifty elderly males (60 – 81 years old) participated in a double blinded randomized placebo controlled trial (SARA-elderly). The main aim was to investigate the effect of supplementation of antioxidants (C and E vitamin) and a multivitamin (i.e., omega-3 and whey protein) on muscle mass and maximal strength during 12 weeks (3 times/week) of strength training (2/wk 8-10RM, 1/wk between 3-5RM or 13-15RM). The load was weekly adjusted, and the volume increased progressively throughout the 12 weeks. Muscle mass was assessed as changes in lean mass with Dual Energy X-ray absorptiometry (DXA) and thickness of rectus femoris and vastus lateralis with ultrasound imaging. Strength was measured as 1 Repetition Maximum (1RM) in leg press and knee extension. PA was recorded by the activity monitor SenseWear™ Pro3 (BodyMedia inc, US) for four consecutive days (2 weekdays and 2 weekend days). Results are presented as median. Results There were significantly ( $p < 0.001$  for all changes) increases in lean mass in the legs (3.3%), muscle strength (18.5% in leg press and 16.0% in knee extension) and muscle thickness (13.1% for rectus femoris and 7.4% for vastus lateralis). There was a significant ( $p < 0.001$ ) reduction in moderate- to- vigorous-intensity PA (MVPA) from Autumn to Winter (from 5.7 to 1.7 hours/day); however, percentage change in lean mass in the legs was significantly and negatively ( $r = -0.32$ ;  $p = 0.03$ ) associated with change in MVPA. Changes in neither muscle strength nor muscle thickness were associated with changes in MVPA. Discussion As known, season (e.g. Winter with snow) appears to have large influence on the physical activity level in Norway. However, participation in a strength training program accompanied by an increase in lean mass in the legs, seems to influence MVPA. Our findings have to be confirmed in a randomized controlled setting with a control group not participating in strength training.

## INFLUENCE OF PILATES TRAINING ON CHRONIC NON-SPECIFIC LOW BACK PAIN

Hautier, C.1, Jaulneau, A.F.1,2, Descours, M.2

1: CRIS, University Lyon 1, Lyon, France, 2: FLORE&SENS Pilates Center, Crest, France

Introduction Most conventional intervention have modest efficacy for the management of low back pain. On the other hand, regular therapeutic exercise seem to have significant benefits in patients with chronic low back pain (CLBP). Hayden et al. (2000) concluded therapeutic exercise has a significant impact on pain and function in this population. More recently, Sorosky et al. (2008) focused on the scientific and theoretical basis of using yoga and Pilates in the management of CLBP. They proposed some intervention principles that may be applied for managing patients with CLBP. The aim of this work was to evaluate the effects of five weeks Pilates training on pain intensity and force in women presenting CLBP. Methods Two groups of 10 women volunteered to participate in this study (mean age 51 years). All the subjects presented CLBP symptoms for at least 2 years. Control group (CG) performed initial and final evaluations and followed medical treatment in between. Pilates Group (PG) followed two Pilates training sessions (1 hour) per week during five weeks. Initial (T0) and final (T1) evaluations contained pain intensity evaluation (Dallas questionnaire), erector spinae and abdominal muscles endurance (Sorensen and Shirado tests). Comparisons were performed using a one way analysis of variance (group) for repeated measures (T0 and T1). Linear regressions were calculated between force improvement and pain decrease. The level of significance was set at  $p < 0.05$ . Results No differences have been observed in pain intensity, erector spinae and abdominal muscles endurance in CG between T0 and T1. On the contrary, PG demonstrated a significant decrease in pain intensity (5.8 vs 3.4,  $p < 0.01$ ) and a significant increase in erector spinae and abdominal muscles endurance (+100% and +60% respectively,  $p < 0.01$ ). No relationship was obtained between muscles endurance improvements (express in percentage of initial values) and pain intensity decrease. Discussion This study confirmed the analgesic effect of Pilates training on CLBP. Specific active exercises reduced significantly pain intensity and increased trunk muscles endurance whereas control group didn't observe any changes. Despite the fact that no relationship was obtained between muscle force improvement and pain intensity decrease, these results confirm the clinical relevance of Pilates as an appropriate treatment for CLBP. Neurophysiologic and mechanical mechanisms should be investigated more thoroughly to determine the optimal training dose and the most appropriate exercises. References Hayden JA, van Tulder MW, Malmivaara A, Koes BW. (2000). Cochrane Database Syst Rev. Sorosky S, Stipl S and Akuthota V, (2008). Curr Rev Musculoskelet Med. 1:39–47

### BONE DENSITY AND STRENGTH INDEXES IN ADOLESCENT SWIMMERS

Gómez-Bruton, A.1,2, González-Agüero, A.1,3, Gómez-Cabello, A.1,2, Matute-Llorente, A.1,2, Julián-Almárcegui, C.1, Casajús, J.A.1,2, Vicente-Rodríguez, G.1,2

1. Genud Research Group, Universidad de Zaragoza, Spain 2. Universidad de Zaragoza, Spain 3. Aberystwyth University, UK

**Introduction:** It is generally accepted that sport is beneficial to bone mass[1]. However, not all sports have the same effect. In fact, non-weight bearing sports such as swimming have been shown to have no, or even negative effect on bone mineral density (BMD). **Aim:** To evaluate bone mass and structure in order to view BMD and bone strength indexes of adolescent swimmers and compare them to sex- and age-matched controls. **Material and methods:** A total of 66 male and female adolescent swimmers (38 males)(14.6±1.5 y) were compared to 23 controls (12 males) (15.4±1.8 y) who practiced less than 3 hours of physical activity per week. Subtotal whole body, upper and lower limbs BMD was measured with dual energy X-ray (DXA). Peripheral Quantitative Computerized Tomography (pQCT) was used to evaluate volumetric BMD (vBMD), cortical thickness and to calculate several strength indexes at radius and tibia. ANCOVA analyses were performed in order to view differences between groups for BMD adjusted by age, height and subtotal whole body lean; and for stress indexes adjusted by age. **Results:** Swimmers presented lower BMD at the lower limbs (1.04±0.08 vs 1.09±0.08 g/cm<sup>2</sup>, p<0.05) and higher at the upper limbs (0.70±0.03 vs 0.68±0.03 g/cm<sup>2</sup>, p<0.05) compared to controls when evaluated with DXA. Swimmers also presented lower tibia vBMD and lower tibia cortical thickness than controls (all p<0.05). However, at the radius, swimmers presented higher stress strain index (136.26±32.26 vs 117.77±34.29 N, p<0.05) and resistance to fracture load for the X axis (490.55±116.09 vs 423.99±123.09 N, p<0.05). The measured stress strength indexes were similar between groups at tibia. **Conclusion:** From these findings, it seems that the radii of the swimmers might be stronger than those of controls. No differences were found for tibia regarding strength indexes suggesting that although swimmers present lower BMD at this area, bone structure makes this bone as strong as that of the controls. The higher stress strength indexes of the radius in swimmers could be due to the constant effort that the forearm muscles perform during the practice of swimming. The higher stress strain index and fracture load values presented by the swimmers are of special interest due to the fact that swimmers that are only evaluated by DXA may be thought to have a higher risk of suffering osteoporotic fractures later in life. However, if bone structure is taken into account, swimmers seem to have stronger or similar bones and therefore may have a lower risk of suffering this kind of fractures. 1. Vicente-Rodríguez G. How does exercise affect bone development during growth? *Sports Med.* 2006;36(7):561-9.

### AEROBIC EXERCISE TRAINING LOWERS CEREBRAL PULSATILITY INDEX AFTER ACUTE AEROBIC EXERCISE IN MIDDLE-AGED AND OLDER WOMEN

Nobuhiko, A., Ra, S.G., Matsubara, T., Choi, Y., Tanahashi, K., Miyaki, A., Higashino, R., Kumagai, H., Oikawa, S., Ajsaka, R., Maeda, S.

*University of Tsukuba*

**Background:** A pulsatility index (PI) reflects vascular resistance of peripheral small vessel. The vascular resistance in cerebral circulation is low, providing a robust blood flow to the brain throughout systole and diastole. Increase in PI of cerebral artery contributes to the progression of cerebrovascular disease and has been identified as a risk factor for cerebrovascular disease. Although aerobic exercise affects vascular function, little is known to the effect of acute exercise on cerebral pulsatility index. We investigated whether cerebral artery pulsatility changes after acute aerobic exercise, and whether this change in pulsatility is enhanced by aerobic exercise training. **Methods:** Six healthy middle-aged and older women participated in 12 weeks exercise training intervention study. We measured PI of middle cerebral artery by means of transcranial Doppler method before and after a cycling aerobic exercise bout at their individual oxygen uptake at ventilatory threshold for 30 min, before and after 12 weeks of aerobic exercise training intervention. **Results:** After the aerobic exercise training, oxygen uptake at ventilatory threshold significantly increased (P < 0.05). Before exercise training, there was no significant change in the PI of middle cerebral artery between before and after acute aerobic exercise, however, after the exercise training intervention, the PI of middle cerebral artery significantly decreased 30 min after exercise (P < 0.05). **Conclusion:** The present study demonstrated that aerobic exercise training lowers cerebral pulsatility after acute aerobic exercise. This result suggests that aerobic exercise may reduce cerebrovascular resistance, thereby contributing to improvement of cerebral perfusion.

### THE EFFECTS OF ACCELERATION TRAINING ON KNEE FUNCTION AND PHYSICAL PERFORMANCE OF MIDDLE-AGED AND ELDERLY WOMEN WITH CHRONIC KNEE PAIN: ONE YEAR INTERVENTION WITH ACCELERATION TRAINING

Yoon, J., Tsuji, T., Aiba, T., Tsunoda, K., Kanamori, A., Okura, T., Tanaka, K.

*University of Tsukuba*

**Introduction:** Acceleration Training (AT) is a type of whole body vibration (WBV) training where participants maintain a variety of positions or perform specific activities on a 3 dimensional platform. With AT one can expect the same beneficial effects of resistance training without imposing heavy weight or executing dynamic actions. There is considerable research that supports the correlation between AT and improvements in lower limb muscle strength. Hence, AT can be an effective training method for people who have difficulty practicing dynamic training methods due to osteoarthritis, especially in the knees. In this intervention study, we evaluated the effect of AT on knee function in middle-age and elderly women with osteoarthritis and chronic knee pain. **Methods:** We observed 21 women (62.0 ± 5.6 yr) with chronic knee pain for one year. We held 45 minute AT sessions using the Power Plate Pro5, 3 times per week for 8 weeks followed by once weekly training. The women were evaluated 3 times: the beginning of week 1, the beginning of week 9 and at the end of the one year intervention. We used Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) to evaluate knee joint function, and we measured timed-up-and-go (TUG), 5-m habitual walk (5-m HW) and sit-and-reach (SR) to evaluate physical performance. We compared measurements from the 3 evaluations using an ANOVA. **Results:** Over the one-year period, the average total WOMAC score went from 12.6 ± 12.2 points to 9.4 ± 10.9 points to 34.3 ± 14.7 points (P < 0.01). The average SR score went from 36.3 ± 8.05 s. to 46.55 ± 9.71 s. to 44.8 ± 9.1 s. (P < 0.01), TUG went from 5.86 ± 0.71 s. to 5.17 ± 0.71 s. to 5.41 ± 0.81 s. (P < 0.01) and 5-m HW went from 3.78 ± 0.47 s. to 3.65 ± 0.59 s. to 3.29 ± 0.39 s. (P < 0.01). We found significant improvements between weeks 1 and 9, but not between week 1 and the end of the year-long intervention. The multilayered comparison indicated significant differences for the following time periods: between week 1 and end of one-year for WOMAC score (P < 0.01); between week 1 and week 9 and between week 1 and end of one-year for SR; between week 1 and week 9 for TUG; and between week 1 and end of one-year for 5-m HW. **Conclusion:** These results suggest that AT helps improve or maintain physical abilities of middle-aged and elderly women with knee pain. As for the frequency of the exercise, 3 times a week proved to be more effective than once a week. There was no objective evidence showing significant improvement in knee

function. The measurements from week 9, however, indicated improvement compared to week 1, implying that 3 times per week training is effective.

### ACCELERATION TRAINING FOR IMPROVING PHYSICAL FITNESS AND WEIGHT LOSS IN OBESE WOMEN

So, R., Eto, M., Tsujimoto, T., Tanaka, K.

*University of Tsukuba*

**Introduction** Acceleration training (AT) was initially used by elite athletes to improve speed-strength performance. Although AT is now becoming a popular alternative training method, it is unclear whether combining AT with a diet provides sufficient physical stimulation for improving muscle strength and physical fitness in obese individuals. The present study aimed to determine the synergistic effects of AT on body composition and physical fitness with our weight-loss program in obese women. **Methods** Twenty-eight obese, middle-aged women were divided into two groups as follows: dietary plus aerobic exercise group (DA; BMI: 29.3±3.0 kg/m<sup>2</sup>); and dietary plus aerobic exercise and acceleration training group (DAA; BMI: 31.2±4.0 kg/m<sup>2</sup>). Both groups included a 12-week weight-loss program. Body composition, visceral adipose tissue (VAT) area, physical fitness elements (hand grip strength, side-to-side steps, single-leg balance with eyes closed, sit-and-reach, and VO<sub>2</sub>max) were measured before and after the program. **Results** Anthropometric measures, abdominal adipose tissue and body composition had decreased significantly by the 12-week program in both groups. While BMI, VAT and total fat mass showed a significantly greater reduction in the DAA group. The program induced a significant increase in VO<sub>2</sub>max in both groups. Hand-grip strength (+2.1±3.0 kg), single-leg balance (+11.0±15.4 s) and the sit-and-reach test (+6.5±4.8 cm) improved significantly only in the DAA group after the program. However, no significant difference existed between the groups in the training effect on physical fitness variables. **Discussion** Although the reasons for AT's beneficial effect on VAT remain unclear, one possible factor is the activation of the central sympathetic nervous system (SNS). A major effect of SNS innervations on white adipose tissue is the triggering of lipolysis, a previous study (1) reported that acute exposure to AT activated the SNS. Also, the other reason why the AT improves muscle strength and muscular performance may be the influence of acceleration created by the minute vibration of the platform (2). AT can modulate force by changing acceleration through a change in frequency (Hz) and amplitude (mm) of vibration and it mechanically produces fast and short changes in the length of the muscle-tendon complex. **Conclusion** AT may be effective in weight-loss intervention for reducing VAT and enhancing muscle strength and performance in obese women. **References** 1. Ando H et al. (2003). *Scand J Work Environ Health*. 2003; 29 (3):216-9. 2. Van der Meer G et al. (2007). *Handbook of Acceleration Training Science, Principles and Benefits*.

### STRENGTH TRAINING IMPROVES FATNESS, FITNESS AND GLYCEMIA IN APPARENTLY HEALTHY OLDER ADULTS

Wanderley, F., Oliveira, J., Carvalho, J.

*Faculdade Estácio FAL; Centro Universitário CESMAC; Research Center in Physical Activity, Health and Leisure*

**Introduction:** Impaired glycemic control, dyslipidemia, proinflammatory markers and obesity are related abnormalities implicated in the early stages of cardiovascular disease. All of them have high prevalence with increased age. Since a demographic trend to the increasing in the number of older adult population has been observed, there is an enormous public health interest in identifying factors that promote an independent and healthy state. Although strength training is well known to improve functionality there is scarce evidence concerning its effects on cardio metabolic profile in apparently healthy older adults. **Purpose:** To investigate the effects of a 4-month strength training program on body composition, fitness, fasting glycemia, lipid profile, and C-reactive protein of older adults with no diagnosis of chronic conditions. **Methods:** twenty community-dwelling old age individuals (seven men; 66.5 ± 4.3 years; BMI=27.4 ± 3.9 kg/m<sup>2</sup>) were randomized into two groups: 1) strength training (ST; n=10, nine exercises, 1-2 sets, 8-12 repetitions, 3 days/wk) or 2) control (CG; n=10, no exercise). Weight, height, body composition (lean mass, trunk fat and %body fat - %BF, assessed by DXA), fitness (assessed by 6-minute walk test - 6MWT, sit-to-stand five-times, and hand-grip strength), fasting glycemia, lipid profile (total, LDL and HDL cholesterol), and high sensitive C-reactive protein were evaluated at baseline (M1) and after the four months (M2). To assess mean changes between the two moments the t test to repeated measures was used (p<0.05). **Results:** After 4 months of strength training, older adults presented: reduced %BF (M1=33.5 ± 7.4 vs. M2=31.6 ± 7.3; p<0.01) and trunk fat (11.9 ± 4.5kg vs. M2=10.5 ± 3.9kg; p<0.01), better performance on 6MWT (M1=641.9 ± 62.7m vs. M2=693.1 ± 76.3; p<0.01) and sit-to-stand five-times (M1=8"10 ± 1"35 vs. M2=7"32 ± 2"29; p=0.04) as well as a reduced fasting glycemia (M1=85.4 ± 6.8 vs. M2=73.3 ± 7.1; p<0.01). Surprisingly, CG presented lower levels of total cholesterol at M2 (M1=240.2 ± 31.7 vs. M2=211.2 ± 44.8; p=0.02) but this result seems to be due a significant reduction on HDL cholesterol (M1=63.3 ± 18.8 vs. M2=48.8 ± 11.1; p=0.02). **Conclusions:** Strength training reduced fat but did not improved lean mass in healthy older individuals. However, even with no significant gain in lean mass, strength training improved fitness and glycemic control of older adults. ### EFFECT OF RECREATIONAL SWIMMING IN PERFORMANCE OF 200M FREESTYLE

Lampadari, V.1, Thanopoulos, V.1, Dopsaj, M.2, Rozi, G.1, Ktena, S.1, Geru, E.3

*1: National & Kapodistrian University of Athens, 2: Faculty of Sport and Physical Education, University of Belgrade 3: Swimming Coach, Panellinos Club of Athens*

**Introduction** Swimming as a physical activity enables the proper functioning of all body systems. Exercise in the water helps maintaining and improving aerobic capacity (Tanaka et al., 1997). The measurement of heart rate is an indicator of exercise intensity (Klisouras, 2007). The aim of this study was to improve the performance in 200m freestyle swimming of men and women, through a recreational swimming program of 8 weeks, one hour per day and at least three times a week. **Methods** The sample consisted of 30 sedentary subjects aged 45.2±4.0 years. Of these (n= 15) were men aged 46.07±4.43 years, height 177.33±4.13cm and weighing 86.6±8.23kg and (n= 15) women aged 44.33±3.46 years, height 165.2±3.67cm, weight 66.89±8.48kg. At the beginning, all participants swam 200m freestyle swimming with maximum intensity. Afterwards they followed a systematic swimming program in order to improve their performance in the distance of 200 meters. The intensity ranged from 60-90% of maximum heart rate. At the end of 8 weeks, the participants repeated the same test. Immediately after the end of both tests total performance time and heart rate were recorded. **Results** The results showed that total performance time of the sample was significantly lower in the final in comparison to initial measurement (347.8±68.6 initial, 332.4±66.3 final) which was the objective of the study. In heart rate difference was not observed for the whole sample. In relation to gender, men had better performance times and higher heart rate in both measurements in comparison to women. At individual level, men showed significantly improved performance time (296.5±33.7 initial, 283.5±31.9 final) while heart rate showed no significant differences (144.8±9.31 initial, 143.6±9.74 final). Statistical significant difference was also observed in performance time of women (399.2±54.4

initial,  $381.4 \pm 54.3$  final) as well as in heart rate ( $125.6 \pm 12.3$  initial,  $130.4 \pm 9.4$  final). Discussion For the participants of our research, systematic recreational swimming program resulted in statistically significant improvement in swimming performance of the 200m freestyle. Heart rate showed no statistically significant improvement. From the results of this research we can conclude that even if the recreational swimming program was oriented to improving the performance of 200m freestyle, can lead to positive changes. Greater rate of decline in maximal aerobic capacity with age in physically active vs. sedentary women. Journal of Applied Physiology 83:1947.

### HYPOXIC ENDURANCE TRAINING CAN REDUCE INSULIN RESISTANCE IN OBESE RATS

Zhang, L., Lu, Y.L., Xu, J.F., Feng, L.S.

*China Institute of Sport Science*

Abstract: Insulin resistance and high blood glucose level are common in obese people. We have found that hypoxic endurance training can help to reduce body fat and increase the catabolism of body fat. In this research we want to investigate further if it also can help to remedy glucose metabolic disturbance. 260 SD rats of 3 weeks age were fed by high fat diet, which contains 18-20% fat, for 12 weeks. 160 fatter rats, which were 20.7% heavier than the rest, were picked out and then underwent 2 weeks of adaptive training. 130 rats of similar performance were picked out with mean FBG  $8.68 \text{ mmol/L}$ , indicated obvious glucose metabolic disorder. The rats were divided into 13 groups, 1 is original status group, and the other 12 groups underwent normoxic training (NT) or simple hypoxia exposure (HE) or hypoxic training (HT) for 1, 2, 3 and 4 weeks, and all still fed by high fat diet. Treadmill were used to train the rats with speed of 26 m/min under normoxia and 21 m/min under hypoxia, which was 13.6%  $\text{O}_2$ , which simulated 3500m altitude. The training time was 1 hour/day and 6 days/week. Serum fasting blood glucose (FBG), insulin, glucagon, growth hormone, cortisone, adrenaline, free fat acid (FFA), leptin, adiponectin and GLUT4 gene mRNA in gastrocnemius muscle were tested. Main Results: After 4 weeks of training, (1) Body weight reduction: the Lee's Index declined significantly from 325.9 to 308.3(NT), 312.2(HE) and 302.7(HT). (2) FBG (mmol/L) reduction: the FBG declined significantly from 8.684 to 6.889(NT), 5.398(HE) and 6.513(HT). (3) Blood Insulin (mIU/L) reduction: the Insulin declined significantly from 4.117 to 2.798(NT), 3.109(HE) and 1.926(HT). At the same time, the other hormones like glucagon, growth hormone and adrenaline significantly increased significantly from 35%-200%. (4) Blood FFA ( $\mu\text{Ep/L}$ ) reduction: the FFA declined significantly from 476.9 to 404.0(NT), 432.8(HE) and 366.2(HT). (5) Blood Leptin (pg/ml) increase: the leptin increased significantly from 632.8 to 672.0(NT), 691.2(HE) and 729.4(HT). (6) Blood Adiponectin (ng/ml) increase: the adiponectin increased significantly from 0.441 to 0.643(NT), 0.594(HE) and 0.670(HT). (7) Muscle GLUT4 mRNA level reduction: the GLUT4 mRNA level declined significantly by 21.1%(NT), 21.2%(HE) and 34.2%(HT). Conclusion: Simple hypoxic exposure can reduce body weight, FBG and memory insulin resistance significantly. If add aerobic training to hypoxic exposure, the results will be better. The mechanisms may include the better effects in reducing blood FFA, and raising blood leptin and adiponectin, which were benefit for improving the insulin sensitivity.

### EFFECT OF L-ARGININE SUPPLEMENTATION ON NITRIC OXIDE SYNTHESIS, INSULIN AND GROWTH HORMONE RELEASE DURING HIGH-INTENSITY EXERCISE

Alvares, T., Marques, A., Conte-Junior, C., Silva, J., Paschoalin, V.

*Federal University of Rio de Janeiro*

Introduction L-arginine has been hypothesized to improve exercise performance by increasing nitric oxide synthesis and levels of insulin and growth hormone (GH). Changes of these parameters in response to L-arginine supplementation may clarify the mechanisms underlying its putative physiological effects on physical performance. Therefore, the aim of this study was to analyze changes on plasma nitrate plus nitrite ( $\text{NO}_x$ ), and serum insulin and GH levels in response to exercise after L-arginine supplementation. Methods 15 highly trained runners (4 females) were randomly divided in ARG (6 g of L-arginine) and PLA (6 g of corn starch) groups. At the first, the runners took the supplementation and rested for 20 min. Afterwards, the subjects performed two bouts of a 5 km time-trial running test with a 10-min rest period. Blood samples were drawn before supplementation (PRE), immediately after the first 5 km time-trial running test (IP-1), immediately after the second 5 km time-trial running test (IP-2) and after 20 min of rest (+20). Plasma  $\text{NO}_x$ , serum insulin and GH, and total running time (TRT) were evaluated. Results Significant increases in plasma  $\text{NO}_x$  from PRE ( $61.0 \pm 22.8$  vs.  $59.9 \pm 15.4 \mu\text{mol/L}$ ) to IP-2 ( $103.3 \pm 46.0$  vs.  $94.0 \pm 32.8 \mu\text{mol/L}$ ) and +20 ( $102.9 \pm 51.6$  vs.  $99.8 \pm 29.6 \mu\text{mol/L}$ ) and serum GH levels from PRE ( $3.28 \pm 0.95$  vs.  $3.21 \pm 0.5 \text{ ng/mL}$ ) to IP-1 ( $4.35 \pm 0.23$  vs.  $4.17 \pm 0.13 \text{ ng/mL}$ ), IP-2 ( $4.22 \pm 0.25$  vs.  $4.17 \pm 0.09 \text{ ng/mL}$ ) and +20 ( $4.14 \pm 0.28$  vs.  $4.13 \pm 0.18 \text{ ng/mL}$ ) were observed in both ARG and PLA with no significant differences between the groups. There were no significant differences in serum insulin at any sample times in both ARG and PLA groups. Furthermore, no significant difference between ARG and PLA was observed on TRT on the both running tests. Discussion In both ARG and PLA groups,  $\text{NO}_x$  and GH increased significantly in response to exercise. Furthermore, no significant difference in serum insulin and exercise performance was observed between the groups. Since we did not observe any significant effect L-arginine supplementation on increases on  $\text{NO}$ , insulin or GH concentrations, there was no expectation of improvement in exercise performance. Previous evidence (Alvares et al., 2012) has also shown no positive effect of L-arginine on  $\text{NO}$  synthesis and exercise performance as compared to placebo. L-arginine-based nutritional supplements may not be effective as a potential ergogenic aid to promote metabolic and hormonal changes in healthy and physically active individuals. References Alvares TS, Conte CA, Paschoalin VM, Silva JT, Meirelles CM, Bhambhani YN, Gomes PS. Appl Physiol Nutr Metab. 2012;37(1):115-26.

## VOLUNTARY RUNNING EXERCISE WITH NEW SUPPLEMENT INCREASE MUSCLE MASS VIA FOLLISTATIN ACTIVATION

Oishi, Y., Hashimoto, T.

*Ritsumeikan University*

**Introduction:** Satellite cells are important for myofibers repair, maintenance, and growth (Grand et al., 2007). The number of satellite cells increases by exercise (Charifi et al., 2003, Verdijk et al., 2009). In addition, the number of satellite cells was increased by creatine or estrogen administration (Deborah et al., 2007, Olsen et al., 2010). However, yet remarkably little is known about molecular mechanisms underlying augmented number of satellite cells induced by exercise training and supplements. We herein posit that follistatin is a potential mechanism as the important factor to regulate muscle mass by inhibiting myostatin (Gilson et al., 2009), which negatively regulating muscle mass (McCroskery et al., 2003). We found previously that an exercise-inducible metabolite increased mRNA levels of myogenin, which is a muscle-specific transcription factor involved in the skeletal muscle development and repair (Hashimoto et al., 2007). Therefore, in this study, we attempted to examine whether exercise training with new supplement, developed based on exercise-inducible metabolites, could increase muscle mass via increased expression of myogenin and/or follistatin. **Method:** Male Fisher 344 rats were divided into three groups: control group (CON) (n=6), exercise group (EX) (n=9), and exercise with the supplement group (SP) (n=9). The SP group undertook new supplement 3 times per week by oral administration. The SP and EX exercised voluntarily wheel running 3 times per week. After 5 weeks exercise and supplement administration, muscles (tibialis anterior (TA), extensor digitorum longus (EDL), soleus (SOL) and plantaris (PLA)) were removed and immunostained with total paired box homeotic gene 7 (Pax7), activated myogenic differentiation factor D (MyoD), and myonuclei. We also assessed Pax7, MyoD, myogenin and follistatin by western blotting. We also histochemically analyzed muscle cross sectional area (CSA). **Result:** TA, EDL and PLA weights per body weights in the SP and EX groups were significantly higher than those in the CON (P<0.01). SOL weights per body weights, however, were significantly higher only in the SP group than in the CON (P<0.01). Protein expressions of Pax7, MyoD, and myogenin did not change. The total number of Pax7, MyoD, and myonucleus did not change. The slow fiber and fast fiber CSA did not change. Follistatin level in SP were significantly higher than those in the CON (P<0.05) by western blotting. **Discussion:** In this study, the number of satellite cells did not increase in the EX and SP groups, probably due to the low intensity of voluntary running exercise. Actually in the previous study, the number of satellite cells was increased by high intensity (85-95% Vo2 peak) endurance training (Charifi et al., 2003). However, in the SP group, rats showed significant increase or tendency of increase in muscle weights per body weights, as compared to CON or EX, respectively. The result suggests that voluntary running exercise with new supplement might increase muscle weights through the increased expression of follistatin.

## IS SALIVARY TESTOSTERONE A VALID MARKER OF MATURATION IN ELITE YOUTH MALE ATHLETES?

Nikolovski, Z., Elgingo, M.I., Voss, S.C., Douglas, A.R., Cable, N.T., Johnson, A.

*ASPIRE Academy*

**Introduction** The assessment of biological maturity in elite youth athletes is important to establish, since there is large variability in somatic and biological growth between individuals of the same chronological age (CA), and quantification of maturational status is needed in order to apply correct training loads and reduce the risk of injury. At present markers of maturity include peak height velocity (PHV), skeletal age (X-ray) and assessment of secondary sexual characteristics (SSC). X-ray is costly and invasive, whilst SSC is not tolerated by adolescent boys, in Arabic cultures. This study investigated whether salivary testosterone can be used as a reliable and non-invasive assessment of biological age by correlating with established markers of maturation. **Methods** 140 elite male youth athletes (age 12 to 18) were consented and assessed as a part of their annual medical screening. After an overnight fast, anthropometric measures were taken for the determination of peak height velocity (Mirwald et al., (2002) and X-ray images were taken of the left and right wrist for the determination of skeletal age according to the methods of (Fels and TW3) as described in Malina (2001). A saliva sample was collected using oral swabs and testosterone determined with ELISA kit from Salimetrics LLC (State College, PA, USA). Differences in testosterone concentrations were examined using IBM SPSS 20.0 (Armonk, NY, USA). **Results** Mean peak height velocity for all subjects was 14.1 + 2.0 years CA. Mean skeletal age was greater than CA for both methods (14.26 + 3.7 years TW3 vs. 15.23 + 2.3 Fels). When mean salivary testosterone concentrations are expressed as relative to PHV (i.e. 1 year or more before PHV, around PHV, or more than 1 year after PHV) mean concentration (SD) of testosterone were 51.4 (17) pg/ml, 109.1 (46) pg/ml and 179.2 (62) pg/ml, respectively. These concentrations are significantly different (p<0.001). Furthermore, 60% of the variance in testosterone concentration is explained by CA (R<sup>2</sup> = 0.6026). **Discussion** These data suggest that there are differences in the quantification of maturation using PHV and skeletal age. The addition of salivary testosterone concentration allows the differentiation of maturation, since there are marked increases from before to after PHV. Such a non-invasive test may therefore be helpful in application of the correct training loads in these populations. **References:** Mirwald, R.L, et al. ## OXIDATIVE STRESS STATUS AFTER THE SOCCER GAME IN ELITE MALE PLAYERS

Djordjevic, B.1, Baralic, I.2, Andjelkovic, M.2, Dikic, N.2, Antic, T.2, Vukasinovic-Vesic, M.2, Kotur-Stevuljivic, J.1, Radojevic-Skodric, S.3

*1: Faculty of Pharmacy, University of Belgrade, 2: Sports Medicine Association of Serbia, 3: School of Medicine, University of Belgrade*

**Introduction** Exercise is a prone condition to enhanced oxidative stress and damage and the specific activity pattern of a soccer game may favor additional pro-oxidant redox alterations. The present investigation attempted to determine the responses of muscle damage markers, circulating levels of oxidative stress and antioxidant status markers after training game. **Methods** Forty soccer players, members of the young selection of soccer club "Partizan", were assigned to 4 different teams that competed against each other in 2 simultaneous training games. Plasma creatine kinase (CK), lactate dehydrogenase (LDH), malondialdehyde (MDA), advanced oxidation protein products (AOPP), superoxide anion (O<sub>2</sub><sup>•-</sup>), superoxide-dismutase (SOD), total antioxidant status (TAS), sulfhydryl (-SH) groups, total oxidant status (TOS) and redox balance were measured before and immediately after the training game. In addition, soccer players recorded their dietary intake during 3 consecutive days in order to estimate average energy and nutritional intake. **Results** A training game significantly elevated CK and LDH levels (p<0.05). The levels of oxidative stress markers (MDA, AOPP and O<sub>2</sub><sup>•-</sup>) remained unchanged. Soccer game induced an acute decrease (p< 0.05) in SOD and TAS. In parallel, the SH groups content and redox balance remained unchanged. TOS significantly decreased after the game (p<0.05). Multiple regression analysis revealed that O<sub>2</sub><sup>•-</sup>, TOS and AOPP are significant predictors of TAS both before and after the game. Also, SOD and SH were significantly correlated to O<sub>2</sub><sup>•-</sup> and TOS. Average dietary vitamin A and E intakes were below the recommended dietary allowances (RDA): 68% of the RDA for vitamin A and 42% of the RDA for vitamin E. **Discussion** The present data suggest that soccer training game increases the levels of muscle damage markers. Oxidative stress status

did not change immediately after the game, probably due to recruitment of endogenous antioxidants. Established connection between TAS and oxidative stress markers might indicate that plasma antioxidants are instantly utilized to eliminate free radicals. Our findings suggest that plasma antioxidant response following training game is modified by inadequate intake of antioxidants. Ascensão A, Rebelo A, Oliveira E, Marques F, Pereira L, Magalhães J. (2008). *Clin Biochem*, 41, 841-851.

### **SALIVARY SEX HORMONES RESPONSE IN RUGBY PLAYERS AFTER WHOLE BODY CRYOSTIMULATION**

Grasso, D.1, Lanteri, P.1, Di Bernardo, C.1, Mauri, C.1, Porcelli, S.2, Colombini, A.1, Zani, V.3, Bonomi, F.G.3,4, Melegati, G.1, Banfi, G.1,5, Lombardi, G.1

*I.R.C.C.S. Istituto Ortopedico Galeazzi*

1:IRCCS Istituto Ortopedico Galeazzi (Milano, Italy), 2:CNR (Segrate, Italy), 3:Polisambulatorio Bongi (Orzinuovi, Italy), 4:Humanitas Gavazzeni (Bergamo, Italy), 5:University of Milano (Milano, Italy) Introduction Saliva represents a low stress, noninvasive collection methodology that allows steroid hormone monitoring in athletes, reflecting type, duration and intensity of exercise (Papacosta et al., 2011; Crewther et al., 2013; Gatti and De Palo, 2011). Whole body cryotherapy (WBC) consists of short whole-body exposures to extremely cold air (-110° to -140°C): initially used to treat inflammatory diseases, is currently acquiring increasing popularity in sports medicine. Cryostimulation practice is widely accepted as an effective treatment to accelerate muscle recovery in rugby players (Banfi et al., 2010). Aim of this study was to investigate the changes in salivary levels of steroid hormones after 2 and 14 WBC sessions in rugby players, in order to investigate the effects of the treatment on the salivary hormonal status of these athletes. Methods Twenty five professional rugby players, belonging to the Italian National Team, underwent to a 7 days-long cryotherapy protocol consisting of 2 daily sessions. Saliva was sampled: the morning prior to the start of the WBC, after end of the second WBC, in the evening, and the morning of the day after the last WBC session. Saliva was analyzed for cortisol, DHEA, testosterone and estradiol using a competitive enzyme-linked immunosorbent assay. Results Cortisol and estradiol showed a reduction already after the 2 WBC sessions of the first day, often exceeding critical (CD) difference and circadian variations. After 14 consecutive WBC sessions cortisol, DHEA and estradiol levels decreased, testosterone increased as well as the testosterone to cortisol ratio. Even in this case, the majority of subjects showed variations exceeding the CD. Discussion Rugby training is known to induce cortisol increase and testosterone decrease (Elloumi et al., 2003), while no data about DHEA and estradiol exist. In the present study, WBC had acute effects on salivary steroid hormones profile already after a single twice-daily session; but the most significant variations were observed, in all the evaluated hormones, after one-week consecutive twice-daily sessions. Saliva represents a useful tool to monitor athlete's hormonal asset even concomitantly with WBC treatment. ### **THE EFFECTS OF IRON SUPPLEMENTATION ON COMPLETE BLOOD COUNT FOLLOWING AN ACUTE ECCENTRIC EXERCISE BOUT**

Deli, C.K., Paschalis, V., Georgakouli, K., Zalavras, A., Fatouros, I.G., Koutedakis, Y., Jamurtas, A.Z.

*University of Thessaly*

Purpose: the purpose of this study was to investigate the effect of iron supplementation on complete blood count after eccentric exercise in adults compared to children. Methodology: sixteen male adults (18 – 50 years old) and eleven boys (10 – 12 years old) participated in the study, which was conducted in two cycles in a double blind mode. At each cycle the participants were consumed either the iron supplement (37mg of elemental iron per day for three weeks before and one week after the eccentric exercise) or the placebo (flour) in a random order. After a 4 weeks period of wash out following the first cycle, the participants repeated the procedure at the second cycle. Results: Significant interaction between time (baseline, 24 and 72 hours post exercise) and condition (iron supplement or placebo), as well as main effect of age came up for Hb. Before exercise ( $M = 14.068$ ,  $SE = 0.28$ ), Hb was greater than 72 hours after exercise ( $M = 13.513$ ,  $SE = 0.23$ ), but only for the iron group, and adults ( $M = 14.687$ ,  $SE = 0.2$ ) had greater hemoglobin than children ( $M = 12.873$ ,  $SE = 0.237$ ) in all time points regardless of condition. Significant time-by-age interaction came up for Hct, and adults had greater levels than children at baseline, before and 72 hours after exercise. Main effect of time came up for red blood cells (RBC), with values at 72 hours being lower compared to baseline, while main effect of age existed on white blood cells (WBC) with adults showing greater values compared to children. Conclusion: Four weeks of iron supplementation affects in the same way most of the hematological parameters after eccentric exercise in both adults and children, without any significant changes except for Hb, Hct, RBC and WBC. Additionally, iron supplementation can lead to lower levels of Hb after eccentric exercise in both adults and children, and this needs special attention.

#### **PAST SPORTS ACTIVITIES DURING GROWTH INDUCES BONE MINERAL CONTENTS AND CHANGES IN BONE GEOMETRY IN YOUNG MEN AND WOMEN**

Kato, T., Yamashita, T., Matumoto, M., Takami, K., Honda, A., Umemura, Y.

*Suzuka University of Medical Science*

Introduction High-impact jump training not only increases bone mineral content (BMC), but also improves bone structure and strength in early-pubertal girls. Dual energy X-ray absorptiometry (DXA) measured BMC, areal bone mineral density (aBMD) and MRI determined bone geometric characteristics of the mid-femur in young men and women were analysed, and the effect of past sporting activity on each was determined. We also looked at whether the effect of estrogen function on bone geometry was affected by childhood exercise. Methods Sixty-three premenopausal young women ( $21.4 \pm 0.6$  years) and 79 young men ( $21.2 \pm 0.8$  years) were analysed. The average

age of menarche of the female subjects was  $12.7 \pm 1.5$  years old. Osteogenic index (OI) of previous sporting activity was calculated as follows; (times/week)  $\times$  years  $\times$  strain score of previous sports activity (Nilsson et al 2009). Subjects were classified into three groups, the first two based on age of commencement of sport participation, elementary school group (6-12 years), junior high school to college group (13-22 years) and a third group for those who only participated in low-impact non-weight-bearing sports such as swimming or had no sport participation (no-sport). Main outcome measures DXA was used to measure BMC and aBMD in the lumbar spine and proximal femur. MRI was used to determine bone geometric characteristics in the mid-femur such as femoral mid-diaphyseal cross-sectional area (CSA), periosteal perimeter, and maximum and minimum second moment of area. Results In women, OI was significantly correlated with all the MRI determined bone geometric parameters and DXA measured BMC and aBMD at the femoral neck. However, there was no significant correlation of OI with BMC and aBMD at the lumbar spine and total proximal femur. In men, OI was significantly correlated with all DXA and MRI determined bone parameters, except for the perimeter. In women, analysis of covariance revealed that the elementary school group showed significantly greater femoral mid-diaphyseal perimeter (vs no sport group), bone CSA (vs junior and no-sport) and max and min second moment of area (vs no-sport). However, no significant difference was found in muscle CSA among 3 groups of women. Conclusions During growth, past sporting activity has different effects on bone strength parameters under the effects of sexual dimorphism. Estrogen inhibits periosteal expansion, thus the effects of sporting activity before and in early puberty appears to have a positive effect on bone shape and geometry. References Nilsson M, Ohlsson C, Mellstrom D, Lorentzon M. (2009) *J Bone Miner Res*, 24:125-133.

### **LIFESTYLE MODIFICATION OF EXERCISE AND DIET IMPROVES SERUM TESTOSTERONE LEVEL AND AORTIC STIFFNESS IN OVERWEIGHT AND OBESE MEN**

Hiroshi, K., Miyaki, A., Higashino, R., Akazawa, N., Choi, Y., Ra, S.G., Matsubara, T., Tanahashi, K., Eto, M., Tanaka, K., Ajisaka, R., Maeda, S.

*University of Tsukuba*

Background: Serum Testosterone level is associated with arterial stiffness. In obese individuals, arterial stiffness is high and serum testosterone level is low as compared with age-matched normal weight counterparts. Several studies have shown that lifestyle modification (aerobic exercise or dietary modification) decreases arterial stiffness in obese individuals. However, it is unclear about the effect of such lifestyle modification on serum testosterone level in obese men. The purpose of this study was to examine whether a lifestyle modification of exercise and diet increases serum testosterone level in overweight and obese men, and if so, whether the increase in serum testosterone level correlates with the decrease in arterial stiffness. Methods: Eleven overweight and obese men (age:  $53 \pm 3$  yrs, BMI:  $30 \pm 1$  kg/m<sup>2</sup>) completed a 12-week lifestyle modification program (well-balanced 1680 kcal/day diet and brisk walking for 40-60 min/day, 3 days/week). Before and after the program, we measured aortic pulse-wave velocity (PWV), an index of aortic stiffness, and serum total testosterone level in the participants. To analyze the statistical differences between before and after the program, the students' t test for paired values was used. Relationship between the change in aortic PWV and that in serum testosterone level was analyzed using Pearson's correlation. Results: After the 12-week lifestyle modification program, a significant weight loss in the overweight and obese men ( $-11.9 \pm 1.3$  kg,  $P < 0.05$ ) was observed. After the program, aortic PWV decreased significantly and serum testosterone level increased significantly ( $P < 0.05$ ,  $P < 0.05$ , respectively). Moreover, there was a significant relationship between the change in aortic PWV and that in serum testosterone level ( $r = -0.67$ ,  $P < 0.05$ ). Conclusions: After the 12-week lifestyle modification, aortic PWV decreased significantly and serum testosterone level increased significantly in the overweight and obese men. We also demonstrated that there was a negative relationship between the change in aortic PWV and the change in serum testosterone level. These findings suggest that lifestyle modification of exercise and diet increases serum testosterone level and the increase in serum testosterone level may contribute to a decrease in arterial stiffness in overweight and obese men.

### **MINIMALLY INVASIVE MICROPERFUSION NEEDLE FOR CONTINUOUS LACTATE MONITORING DURING EXERCISE**

Tsuruoka, N., Ishii, K., Matsunaga, T., Nagatomi, R., Haga, Y.

*Tohoku University*

Introduction Lactate concentration during exercise is usually measured by hand-held blood lactate analysers (Tanner RK et al., 2010). However, it is difficult to collect blood continuously in the field exercise. Recently, we developed microperfusion needle and collected subepidermal tissue lactate (Tsuruoka et al., 2012). Lactate is collected and carried out of the body by perfusion fluid. The diameter of the needle is 250  $\mu$ m and the length of inserting area is about 1 mm. A thin needle around 250  $\mu$ m in diameter can be inserted in subepidermal tissue without pain. The purpose of this study was to confirm whether there is a correlation between collected lactate concentration and blood one during exercise. Methods Five male C57BL/6 mice were used in this experiment. After the mice were anesthetized with Sevoflurane, the needle was inserted into the skin of mice's back and fixed. Each mouse was run in a separate lane on the treadmill at 10 m/min initially. Running speed was gradually increased 5 m for every 5 min until the target speed and then fixed at target speed. Target speeds were 15, 20, and 25 m/min. Dialysate (saline) perfusion was started before running to prevent a plugging or a clotting. Two minutes after fixing a target running speed, perfused saline was collected into the syringe for 10 minutes. After the exercise, blood samples were collected and measured lactate concentration using simplified blood lactate test meter. Lactate concentration of perfused solutions was measured using fluorescent stain kit (L-Lactate Assay Kit, Cayman Chemical Company, USA). Person's correlation test was performed between lactate concentration of perfused solution and blood. Results Lactate concentration of perfused solution was significantly correlated with lactate concentration of blood ( $P < 0.01$ ). The recovery rate of lactate was about 0.57 %. There was no damage in fabricated needles after used for animal experiment. There were no bleed and infection on mice's back after the experiment. Discussion This result shows that bloodless lactate measurement is possible using this microperfusion needle. In addition, since this device use microperfusion, continuous monitoring of lactate is possible in combination with on-line sensor. There was no damage in microperfusion needle and mouse's back. This shows our device can be used in safety even under heavy exercise. This needle has a possibility of measuring regional lactate concentration since this needle is very thin and can collect lactate from subepidermal tissue around needle. References Tanner RK, Fuller KL, Ross ML. (2010). *Eur J Appl Physiol.*, 551-559. Tsuruoka N, Ishii K, Matsunaga T, Nagatomi R, Haga Y. (2012). *Proc. MEMS*, 941-944.

## EFFECTS OF YOGA BREATHING ON HEART RATE AND THE CARDIAC PARASYMPATHETIC NERVE SYSTEM

Orita, M.1, Hayasi, S.1, Saito, T.1, Wada, T.1, Murata, M.1, Onodera, S.2

1:GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE 2:KAWASAKI UNIVERSITY OF MEDICAL WELFARE

**Introduction:** Yoga breathing is comprised of diaphragmatic breathing and thoracic breathing. The purpose of this study was to compare the heart rate and parasympathetic nerve system on Yoga breathing with a spontaneous breathing trial. **Methods:** Twelve healthy Japanese males participated in this study (age  $26 \pm 1$  year, height  $175.0 \pm 4.9$  cm, weight  $70.5 \pm 0.4$  kg). All subjects were fully informed about the details of the study and provided written informed consent. The measurement conditions were the spontaneous breathing condition and the yoga breathing condition. Before breath control, all subjects kept resting in a supine posture for 10-min (baseline). Then, each subject did controlled breathing (spontaneous breathing or yoga breathing) while sitting for 10-min. After breath control, all subjects continued to rest in a supine posture for 25-min as recovery period. The breathing during baseline and recovery period was unified into spontaneous breathing. Heart rate and the cardiac parasympathetic nerve system were measured from baseline to the end of the recovery period. In order to except the influence of breathing-rate change at the time of baseline and recovery period, breathing rate was adjusted so that it became one time to every 4 seconds (2 second inhalation and 2 second expiration). The variation of HF to baseline was calculated. **Results and discussion:** The heart rate of both conditions in recovery period was significantly lower than that of controlled breathing ( $P < 0.05$ ). The heart rate in yoga breathing ( $70 \pm 11$  bpm) was significantly higher than baseline ( $62 \pm 7$  bpm) ( $P < 0.05$ ). The cardiac parasympathetic nervous system (HF) in yoga breathing was significantly lower than baseline ( $P < 0.05$ ). The cardiac parasympathetic nervous system (HF) during yoga breathing in recovery period ( $113.5 \pm 30.7$ ) was significantly higher than immediately after the end of controlled breathing ( $99.5 \pm 9.9$ ) ( $P < 0.05$ ). Yoga breathing needs assistance of the abdominal muscles, intercostal muscle and diaphragm activity. It is considered that heart rate was raised by yoga breathing, and the cardiac parasympathetic nervous system (HF) was suppressed by yoga breathing. However, it is considered that the yoga breathing exasperated the cardiac parasympathetic nervous system (HF) in the recovery period.

## ARE OPTIMISTIC PERCEPTIONS OF PERSONAL PHYSICAL ACTIVITY BEHAVIOUR A PROBLEM IN PHYSICAL ACTIVITY PROMOTION? RESULTS FROM A NATIONAL SURVEY.

Knox, E., Esliger, D.W., Biddle, S.J., Sherar, L.S.

*Loughborough University; The NIHR Leicester-Loughborough Diet, Lifestyle and Physical Activity Biomedical Research Unit*

The 2007 and 2008 wave of the Health Survey for England (HSE) included questions surrounding perceptions of personal physical activity (PA) behaviour (i.e. do I feel that my PA level is good?). Such questions have been used in previous research to assess perceptions of personal PA behaviour and awareness of PA (Vandelanotte et al, 2011). This research suggests that individuals who do not meet PA guidelines, need to perceive themselves as inactive, and be aware that their behaviour is inadequate, before they will be motivated to change (van Sluijs et al, 2007). Method Data from the 2007 and 2008 waves of the HSE were examined. Mann-Whitney U-tests were used to investigate demographic differences between the two waves of the survey, and between self-reported PA and awareness of PA in HSE 2007. Correlational analysis was conducted to examine whether an individual's perception of engaging in sufficient PA is related to their intention to engage in more PA. Results The samples answering: 'Do you think you do enough PA to keep fit?' ( $N=4,471$ ); 'How active do you think you are relative to others?' ( $N=2,510$ ); and those with self-reported PA ( $N=3,666$ ) had homogenous demographic distributions (e.g. ethnic group [ $p=.2$ ], geographic location [ $p=.21$ ], socio-economic group [ $p=.81$ ], household income [ $p=.97$ ] and social class [ $p=.72$ ]). There was no significant difference in household income [ $p=.29$ ], employment status [ $p=.1$ ], marital status [ $p=.63$ ], BMI [ $p=.29$ ] and age [ $p=.9$ ] between HSE 2007 ( $N=14,385$ ) and HSE 2008 ( $N=22,623$ ). Perceptions of personal PA were optimistic relative to actual measurements of PA. 35% believed they did enough PA to achieve fitness and 87.3% stated they were very or quite active relative to others. In contrast, self-reported PA suggested that only 29% achieved PA guidelines (150 minutes/week moderate-vigorous PA). The perception that one already does enough PA for fitness was negatively correlated with the intention to do more PA ( $r=-.38$ ;  $p<.001$ ). Correlations remained significant after controlling for demographic factors. The data suggests a discrepancy between personal perceptions of PA behaviour and actual PA behaviour. In addition, when accelerometers were introduced to HSE 2008, only ~5% met PA guidelines (NHS, 2009). Although PA levels are low, these individuals did not judge themselves as having inadequate PA levels. This is likely to be motivationally maladaptive as such misperceptions prevent intentions to improve behaviour from being formed. Appropriate educational interventions are needed. ## ASSESSING CARDIORESPIRATORY FITNESS WITHOUT PERFORMING EXERCISE TESTING IN KOREAN ADULT MEN.

Jeon, Y.J.1, Im, J.H.1, Lee, B.K.2, Kim, C.H.3, Kim, B.W.3

1) KAIST(Daejeon, S Korea) 2) SangMyung University(Cheonan, S Korea) 3) Daejeon University(Daejeon, S Korea)

**Introduction** The purpose of this study is to assess cardiorespiratory fitness with non-exercise variables such as body index and resting heart rate. The prediction of  $VO_{2max}$  using non-exercise data is necessary when measurement equipment cannot be prepared. In addition, safe and low-cost measurement is possible without active motivation by subjects, complex test devices, or a skilled examiner. **Method** The subjects are consisted of 533 male aging from 17 to 65 and we separated them into two groups randomly; 385 for a sample, 148 for a cross-validation group. They went through maximal exercise testing with Bruce protocol, and we measured the metabolic responses in the end of the first(3 minute) and second stage(6 minute). To predict  $VO_{2max}$ , we applied multiple regression analysis to the sample with stepwise method. **Results** Model 1's variables are weight, height, resting heart rate, age( $R=0.46$ ,  $SEE=6.07$ ,  $SEE\%=15.21$ ,  $p<.01$ ), and the equation is  $VO_{2max}=2.401-0.311(\text{Weight})+0.254(\text{Height})-0.130(\text{HRrest})-0.095(\text{Age})$ . Model 2's variables are weight, height, resting heart rate( $R=0.43$ ,  $SEE=6.16$ ,  $SEE\%=15.44$ ,  $p<.01$ ), and the equation is  $VO_{2max}=10.173-0.357(\text{Weight})+0.374(\text{Height})-0.111(\text{HRrest})$ . Model 3's variables are weight, height( $R=0.39$ ,  $SEE=6.16$ ,  $SEE\%=15.44$ ,  $p<.01$ ), and the equation is  $VO_{2max}=9.981-0.327(\text{Weight})+0.305(\text{Height})$ . Model 4's variables are weight( $R=0.31$ ,  $SEE=6.48$ ,  $SEE\%=16.24$ ,  $p<.01$ ), and the equation is  $VO_{2max}=56.334-0.240(\text{Weight})$ . The result showed that moderate  $R^2$  and low SEE value and all the prediction variables did not show multi-collinearity. When we conducted cross-validation of these models with 385 men, measured  $VO_{2max}$  and estimated  $VO_{2max}$  had statistical significance with correlation  $r=0.34 \sim 0.52$ ,  $P<.01$ . **Discussion & Conclusion** The prediction equations developed in this study were founded to predict  $VO_{2max}$  of health Korean men in a very accurate manner( $R=0.31 \sim 0.46$ ,  $SEE=6.07 \sim 6.48$ ,  $SEE\%=15.21 \sim 16.24$ ). The

models suggested in this study used the prediction variables that can be measured easily and showed the accuracy that is similar to or higher than those of other studies. Bland-Altman plotting confirmed that the estimation models are reliable and have low systematic error. Although all models are functional with validity considering their simplicity and utility, Model 1 has the best accuracy. Reference Nes, B. M., Janszky, I., Vatten, L. J., Nilsen, T. I. ### PREDICTION OF MAXIMAL OXYGEN UPTAKE USING METABOLICAL VARIABLES IN SUB-MAXIMAL EXERCISE.

Im, J.H.1, Jeon, Y.J.1, Lee, B.K.2, Kim, C.H.3, Kim, B.W.3

1) KAIST(Daejeon, S Korea) 2) SangMyung University(Cheonan, S Korea) 3) DaeJeon University(Daejeon, S Korea)

**Introduction** The purpose of this study is to develop and validate statistical models for predicting VO<sub>2</sub>max using body index and sub-maximal metabolic variables. The indirect prediction of VO<sub>2</sub>max using together body index, respiratory variables, and heart rate during sub-maximal exercise identified at the time of maximal exercise stress testing offers many advantages un many aspects such as accuracy and on-site utilization. **Method** The subjects are consisted of 714 people aging from 18 to 63, and we separated them into two groups randomly; prediction group(n=474) and cross-validation group(n=220). They went through maximal exercise testing with Bruce protocol, and we measured the metabolic responses in the end of the first(3 minute) and second stage(6 minute). To predict VO<sub>2</sub>max, we applied multiple regression analysis to the prediction group with stepwise method. **Results** Prediction variables for model 1~4 are gender, weight, age, height, time to reach 150 HR, 6 minute HR, 6 minute VO<sub>2</sub>, and VCO<sub>2</sub>. The result showed that R is 0.73~0.76(p<.01), R<sup>2</sup> is 0.54~0.58, SEE=4.75~4.96, and SEE% is 12.87%~13.51% with high R<sup>2</sup> and low SEE value. Based on cross-validation results, the measured VO<sub>2</sub>max and estimated VO<sub>2</sub>max had large correlation with statistical significance(r=0.524~0.783, P<.01). Model 1's equation is VO<sub>2</sub>max(ml/kg/min)= 56.638-5.863(Gender)-0.261(Weight)-0.079(Age)+0.099(Height)-0.122(6minHR)+0.013(6minVO<sub>2</sub>)-0.008(6minVCO<sub>2</sub>). Model 2's equation is VO<sub>2</sub>max(ml/kg/min)=74.020-6.711(Gender)-0.235(Weight)-0.097(Age)-0.125(6minHR)+0.013(6minVO<sub>2</sub>)-0.008(6minVCO<sub>2</sub>). **Discussion & Conclusion** This study developed prediction equations, targeting a relatively large number of healthy Korean males and females. According to a survey of previous studies by Malek et(2004), Cooper and Storer(2001) developed a prediction equation, targeting a prediction group of 522 subjects(male 328, female 194). Furthermore, the models having low prediction error were identified(%TE=4.67~6.36). Bland-Altman plotting confirmed that the estimation models are reliable and have low systematic error. Therefore, predicting VO<sub>2</sub>max using body index and submaximal metabolic variables has high accuracy and will be useful in fields. Reference Malek, M. H., Housh, T. J., Berger, D. ### WHEELCHAIR DANCE "SKILL" AND EXERCISE INTENSITY DURING DANCE IN BEDRIDDEN INDIVIDUALS WITH SEVERE CEREBRAL PALSY

Terada, K.1, Satonaka, A.2,3, Terada, Y.4, Suzuki, N.2,3

1: Nagoya College (Toyoake), 2: Nagoya U. (Nagoya), 3: IDR (Kasugai), 4: NKU- JC (Inuyama)

**Introduction** It is extremely difficult for the bedridden individuals to participate in physical activity. We had wheelchair dance custom-made for the bedridden individuals with severe cerebral palsy in this study. The aim of this study was to examine the relationship between wheelchair dance "skill" and the exercise intensity during the waltz and the jive performance. **Methods** We recruited 6 individuals with severe athetospastic cerebral palsy (50.7±8.9 years) from a welfare facility. Their intelligence was not impaired. They were instructed to dance with an instructor as a standing partner. As no participants could manipulate their wheelchair by themselves and deformities of limbs and trunks differed among them, we had the waltz and the jive custom-made for each participant. We measured oxygen uptake (VO<sub>2</sub>) and heart rate during the waltz and the jive. Each participant's skill of the waltz and the jive was also evaluated. The evaluation consisted of 10 items, with each rated on a 3 step scale as either 0 (can't do it at all), 1 (can do it a little bit), or 2 (can do it without problems). A perfect score was 20 points. **Results** (A) 2 participants experienced greater VO<sub>2</sub> and heart rate increase during the waltz session than during the jive, (B) 2 participants experienced roughly equivalent increases in VO<sub>2</sub> and a slight heart rate increase during both types of sessions, and (C) 2 participants showed very little change in either VO<sub>2</sub> or heart rate. The (A) group participants had especially high scores in the waltz performance evaluation, 19 points and 18 points, whereas the (B) and (C) group participants had low scores in both the waltz and the jive (an average 12 of and 8 points, respectively). **Discussion** The jive, a dance performed to more of an up tempo rhythm, is considered one of the more challenging within the difficult Latin style. In the participants with a significantly higher performance score on the waltz than the jive, linking arms with their standing partners enabled greater control of the related exercise, and preservation of a stable posture. Accordingly, even for these individuals with severe cerebral palsy, if dancing posture can be maintained, exercise intensity improves, and patients' fitness levels can be expected to as well (Terada, et al., 2011). Exercise programs can therefore be prescribed by using severe cerebral palsy patients' ability to hold the posture necessary for the waltz as one standard, and then determining whether or not dances which make maximal use of these postures can be performed. **References** Terada K, Satonaka A, Terada Y, Suzuki N. **Introduction** It has been suggested that exercising in contact with nature may provide health benefits beyond exercising elsewhere, but evidence of the effects of 'green exercise' on physical health is still scarce (Thompson Coon et al., 2011). Recent studies indicate possible effects of viewing images of nature on heart rate variability (HRV) (Gladwell et al., 2012). HRV reflects the status in the autonomic nervous system and is related to cardiovascular health. As a pilot study, we have investigated HRV and blood pressure (BP) after a standardized

exercise program in two different environmental settings: indoors (gym hall) vs. outdoors in a natural setting. Methods Healthy adults, 7 males and 7 females (age 48.5 $\pm$ 7.3 yr; BMI 25.4 $\pm$ 2.45; VO<sub>2</sub>max 39.8 $\pm$ 7.7 ml/min/kg), undertook two exercise sessions within 1-week, each consisting in 25-min biking (60.1 $\pm$ 7.9 %HRR) followed by 20-min circuit strength training with rubber bands (49.7 $\pm$ 9.6 %HRR). The subjects exercised at 15:30, randomized to the indoor or the outdoor group. After both sessions, beat-to-beat intervals were recorded overnight with HR-monitor belt and BP was measured the following morning. A 5-minute sequence during the first slow wave sleep (Brandenberger et al. 2005) was isolated for the HRV frequency analyses. Outputs were analyzed using a linear mixed model, with individuals' value collected in baseline conditions (no exercise for 48-hours) set as a covariate. Results Diastolic BP was significantly lower ( $p=0.018$ ) the morning following the outdoor exercise sessions. A tendency to lower values was observed also for the systolic BP, although significance was not achieved. A poor quality of the overnight beat-to-beat monitoring did not allow including all the subjects in the analysis: only 8 subjects had a complete set of monitoring (baseline and post exercise). No significant differences across groups were found in HRV parameters. Discussion The data suggest that green exercise may positively impact the cardiovascular modulation, with possible health benefits in the long term, such as lower BP values. Though, studies on larger samples and longer interventions are recommended. References Gladwell, V. F., Brown, D. K., Barton, J. L., Tarvainen, M. P., Kuoppa, P., Pretty, J., et al. ### REGULAR MOIST SNUFF DIPPING DOES NOT AFFECT ENDURANCE EXERCISE PERFORMANCE.

Mattsson, C.M., Björkman, F., Edin, F., Larsen, F., Ekblom, B.

*Åstrand Laboratory of Work Physiology, The Swedish School of Sport and Health Sciences*

Physiological and medical effects of snuff have previously been obtained either in cross-sectional studies or after snuff administration to non-tobacco users, but the effects of snuff cessation (SC) after several years of daily use on individual level are unknown. 24 participants with >2 years of daily snuff-use were tested before and after >6 weeks SC (SCG), together with a control group (CO) of 11 snuff users who kept their normal habits. Resting heart rate (HR) was significantly lower in SCG after SC. Body mass in SCG group increased by 1.4  $\pm$  1.7 kg and blood pressure (BP) were reduced, but without significant differences between groups. Total cholesterol increased from 4.12  $\pm$  0.54 (95% CI 3.89–4.35) to 4.46  $\pm$  0.70 (95% CI 4.16–4.75) mM/L in SCG, due to increased LDL, and this change was significantly different from CO. Resting values of HDL, C-reactive protein, and free fatty acids (FFA) remained unchanged in both groups. During a four-stage incremental (from 50 to 80% of VO<sub>2</sub>max) and a prolonged (60 min at 50% of VO<sub>2</sub>max) cycling test HR and BP were reduced in SCG, while oxygen uptake (VO<sub>2</sub>), respiratory exchange ratio, blood lactate (bLa) and blood glucose (bGlu) concentration, and rate of perceived exertion were unchanged. All measurements were unchanged in CO. During the prolonged exercise FFA was reduced but there was no significant difference between groups. During the maximal treadmill running test peak values of VO<sub>2</sub>, pulmonary ventilation (VE), time to exhaustion and bLa were unchanged in both groups. In conclusion, endurance exercise performance (VO<sub>2</sub>max and maximal endurance time) does not seem to be affected by prolonged snuff use, while effects on cardiovascular risk factors are contradictory.

### 10 YEAR CARDIOVASCULAR RISK ASSESSMENT IN UNIVERSITY STUDENTS

Uvacsek, M.1, Kneffel, Z.1, Tóth, M.1, Johnson, A.W.2, Vehrs, P.2

*1.Semmelweis University, Budapest 2.Brigham Young University, Provo, USA*

Introduction Cardiovascular disease (CVD) causes more than half of all deaths in the European region, and according to WHO, 80% of premature heart disease and stroke is preventable. Healthy lifestyles, such as eating a healthy diet, regular physical activity, and not smoking are the most important preventive measures. Use of CVD risk assessment tools in a young population provides necessary information about risk for CVD which can be used to develop health promotion initiatives for youth. Methods The aim of the study was to compare, BMI, percent body fat (%BF), blood pressure, total cholesterol (TC) and high density lipoprotein cholesterol (HDL C), family history, activity behaviors, and the 10 year risk of having a heart attack between 166 students (21.62 $\pm$ 2.59 yrs.) from Utah, USA and 198 students (22.11 $\pm$ 2.51 yrs.) from Hungary. The body dimensions were measured according to ISAC methods (Norton et al.1996) the %BF was measured with Omron BF 306 and the 10 year CVD risk was calculated online (<http://hp2010.nhlbihin.net/atpiiii/calculator>). Results According to the results, 92% of the Hungarian students and 100% of the Utah students had an estimated 10 year risk of 1% or less, however 8% of the Hungarians had moderate risk. The high prevalence of low risk was due to the young age of subjects, healthy body composition and non smoking behavior. The Hungarians who had higher risk of heart attack had significantly higher waist hip ratio (WHR), TC, diastolic blood pressure (DBP) and were smokers compared to the Hungarians with low risk. Four percent of the Utah students and 3% of the Hungarian students had positive cardiovascular family history. Based on self-reported levels of physical activity, 19% of Utah women and 14% of Utah men were sedentary compared to 50% of Hungarian women and 46% of Hungarian men. Conclusion Age is one of the primary risk factors for CVD. Young men and women who participated in this study were, for the most part healthy and had a low risk for CVD. Nevertheless, our data shows that even young men and women who are sedentary, smoke, and have high WHR, TC, and DBP have increased risk of CVD. Although, symptoms of CVD may not be manifest until later in life, health promotion efforts should also be targeted to young men and women. ### NATIONAL PHYSICAL FITNESS TESTS DATA IN GREEK CHILDREN AGED 7 TO 10-Y-OLD AND THE IMPORTANCE OF THEIR INTER-RELATIONSHIP.

Tambalis, K., Papoutsakis, S., Sidossis, L.

*Harokopio University*

Introduction: Physical fitness of children is connected to a clustering of risk factors such as hypertension, hyperlipidemia, and obesity (Anderssen et al., 2007, Tambalis et al., 2011). In order to create preventive strategies, it is important to incorporate national physical fitness levels in children. Therefore, the purpose of the current study was to evaluate the distribution of age- and gender- specific physical fitness tests measurements in 7- to 10-year-old Greek children and to determine their relation to body mass index. Methods: Population-based data derived from a health survey in approximately 85% of all Greek schools. Anthropometric measurements (i.e., height and weight) and physical fitness tests (i.e., multi-stage shuttle run, vertical jump, standing long jump, small ball throw and 30-meter sprint)

from 141,169 children (boys: 51 %) were evaluated. The results of each fitness test performance with quartiles by age and sex were also calculated. Children were classified as having a score in the lower-poor (1st), middle-good (2nd-3rd), and upper-excellent (4th) quartiles of the distribution. Results: This study provides age- and gender-specific normative values for physical fitness tests in Greek children aged 7 to 10 years old, using the LMS statistical method. The correlation coefficients between BMI and performances in speed, explosive power and aerobic fitness tests were negative and significant (all  $P$ -values $<0.01$ ), for both genders. Among physical fitness tests, the strongest correlations were observed between anaerobic speed (30m sprint) and all the other tests, for both genders ( $r$  varied 0.42 - 0.46, all  $P$ 's $<0.001$ ). Moreover, approximately 3.5% of children pass the upper quartile in all tests. Discussion: The presented population-based data for physical fitness tests in almost all Greek children aged 7 to 10 years old revealed that only a small percentile of children pass the upper quartile in all tests. Moreover, there is a clear interaction between children's performance and BMI, also confirmed by other relative studies (Nevill et al., 2009). We provide evidence that the 30 meter sprint test is a physical test easy to use in all school contexts in order to measure physical performance and also an effortless way to monitor possible modifications towards the promotion of physical activity and healthy lifestyle. #### ALTERED GLYCOGEN METABOLISM IN ALPHA-ACTININ-3 DEFICIENT INDIVIDUALS

Norman, B., Esbjörnsson, A., Glenmark, B., Lindholm, M., Jansson, E.

*Laboratory Medicin*

Introduction Alpha-actinin-3 deficiency is caused by a stop codon polymorphism in the ACTN3 gene (R577X), and homozygotes for the mutation (XX-genotype) lack  $\alpha$ -actinin-3 in their type II fibers where the protein is normally expressed. The deficiency has been shown to be associated with athletic performance and athletes with XX-genotype have in numerous studies been shown to have inferior sprint and power performance compared to RR/RX. Recent findings in ACTN3 knock-out mice have shown that several enzymes in glycolytic metabolism are upregulated, glycogen phosphorylase (GPh) activity is markedly reduced and muscle glycogen content is increased in association with  $\alpha$ -actinin-3 deficiency (1). These findings suggest that alteration in glycogen metabolism may provide a mechanistic link for the observed differences between the ACTN3-genotypes. Methods In the present investigation glycogen content at rest, glycogen utilization during sprint exercise in separate pools of type I and type II fibers and effects of three months of endurance training on resting glycogen levels were measured in skeletal muscle biopsies from human subjects with different ACTN3 genotypes. Results At rest no differences in glycogen content between the three ACTN3 genotypes were found. However, the decrease in glycogen content during sprint exercise was significantly lower in XX than in RR/RX but only in the type II fibers. In addition the increase in resting glycogen levels with endurance training was significantly larger in XX. Discussion These results are in line with the findings in knock-out mice and endorse the proposal that  $\alpha$ -actinin-3 may be involved in the regulation of glycogen metabolism. References 1. Quinlan, K. G., J. T. Seto, et al. 2010 *Hum Mol Genet* 19(7): 1335-1346

#### COLOCALISATION OF PAXILLIN WITH FOCAL ADHESION KINASE IN HUMAN SKELETAL MUSCLE AND ITS ASSOCIATED MICROVASCULATURE

Wilson, O.J.1, Bradley, H.1, Shaw, C.S.2, Aldred, S.1, Wagenmakers, A.J.M.1,3

*1University of Birmingham, Birmingham, UK; 2Victoria University, Melbourne, Australia; 3Liverpool John Moores University, Liverpool, UK*

Introduction Focal adhesion complexes regulate the conversion of mechanical stimuli into intracellular signalling. Within these sites are growth factor- and mechano-sensitive signalling proteins such as focal adhesion kinase (FAK) and paxillin, and their activation is associated with angiogenesis and skeletal muscle hypertrophy. We have previously visualised FAK in human skeletal muscle tissue (Wilson et al. 2012), but little is known about paxillin's localisation and spatial correlation with FAK. This study aimed to generate the first microscopic images of paxillin and its colocalisation with FAK to test the hypothesis that these two proteins closely interact in human skeletal muscle and its associated microvasculature, and to confirm previous observations in cell lines. Methods Percutaneous muscle biopsies were collected from the resting m. vastus lateralis of 7 healthy fasted males (mean $\pm$ SD; age 22 $\pm$ 4 y; BMI 23.6 $\pm$ 0.9 kg/m<sup>2</sup>). Cryosections (5 $\mu$ m) were stained with antibodies against paxillin and coincubated with anti-dystrophin to identify the sarcolemma, anti-myosin heavy chain type I for fibre-type differentiation, lectin UEA-I to identify the endothelium of capillaries and anti-alpha-smooth muscle actin to identify larger blood vessels. Colocalisation analysis was performed using confocal microscopy. Fluorescence intensity and colocalisation (Pearson's correlation coefficient) was determined using Image Pro 5.1. Results Paxillin was primarily localised to sarcolemmal regions in transversely orientated muscle fibres, forming a continuous distribution along the sarcolemma with partial colocalisation with dystrophin ( $r=0.414\pm0.026$ ). Paxillin immunoreactivity was ~2.4 fold higher at the sarcolemma compared with sarcoplasmic regions ( $P<0.001$ ) and sarcoplasmic paxillin immunoreactivity was slightly higher (~10%) in type I than type II fibres ( $P<0.01$ ). Colocalisation analysis suggests FAK and paxillin partially colocalised at sarcolemmal and microvascular regions ( $r=0.367\pm0.036$ ). Within the endothelium and smooth muscle, paxillin was distributed heterogeneously. Conclusion Paxillin is primarily localised to sarcolemmal and microvascular regions in human skeletal muscle and mirrors the localisation and distribution of FAK. Their spatial correlation in these distinct regions confirms our hypothesis that these proteins closely interact and supports their suggested role in the regulation and coordination of growth factor- and mechano-sensitive signalling. Wilson, O.J., Shaw, C.S., Sherlock, M., Stewart, P.M., and Wagenmakers, A.J. (2012). **ANGIOTENSIN CONVERTING ENZYME EXERTS SYSTEM CONTROL OVER FUEL HANDLING IN SKELETAL MUSCLE**

Brogioli, M.1,2, Vaughan, D.1, Meier, T.1,2, White, A.3, Waldron, S.1, Rittweger, J.1,4, Flück, M.1,5

*1 Manchester Metropolitan University (UK), 2 ETH Zurich (CH), 3 Race Director Chester Marathon (UK), 4 German Aerospace Center (D), 5 Balgrist University Hospital (CH)*

1 Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, Manchester, United Kingdom  
 2 Institute of Human Movement Sciences and Sport, ETH Zurich  
 3 Race Director, Chester Marathon Introduction: A silencer region (I-allele) within intron 16 of the gene for the major regulator of vascular perfusion, angiotensin converting enzyme (ACE), is implicated in phenotypic variation of aerobic fitness in humans. Using a genetical metabolomics approach we set out to expose whether metabolic processes in locomotor muscle at rest and during exercise underlie the reported differences in aerobic performance between genotypes with the ACE I-allele versus those without the I-allele, i.e. ACE-II / ACE-ID vs. ACE-DD. Methods: Not-specifically trained white British men (n=51) were recruited from the Northwest of England. Anthropometry, maximal oxygen uptake (VO<sub>2</sub>max), respiration exchange ratio (RER) and serum metabolites were assessed at rest and during a lab-based test which consisted of 30 minutes exhaustive, single-leg aerobic bicycle exercise at 60% of single leg aerobic power output (n=29). Another subset of subjects completed a field test consisting of the Chester Marathon (n=23). Muscle biopsies were collected at rest and 30 minutes after the lab-based test; and used to assess muscle capillarity and muscle metabolites using mass spectrometry. Differences between subjects with and without the ACE I-allele were assessed with a two-tailed T-test. Pre vs. post differences were assessed using an ANOVA with post hoc test of Fisher. Statistical significance was called at p<0.05. Results: Subjects without the silencer region demonstrated a reduced RER and showed elevated serum glucose concentration during the single-leg exercise. Elevated serum glucose in the subjects without compared to those with the ACE I-allele was confirmed by measures immediately after the Marathon (7.7 vs. 4.3 mM) which only subjects with the ACE I-allele did complete under 3 hours. Subjects lacking the ACE I-allele demonstrated a lower capillary-to-fibre ratio in vastus lateralis muscle (-24%) and showed a selective depletion of metabolites in the non-polar phase after the single leg exercise (p = 0.01). Conclusions: The observations imply a genetically modulated role for angiotensin converting enzyme in control of glucose import and substrate combustion in working human skeletal muscle.

**AICAR STIMULATION INCREASED MITOCHONDRIAL CD36 PRESENCE IN C2C12 CELLS**

Niita, S., Ishizawa, R., Yamada, T., Hamidie, R.D.R., Masuda, K.

*Kanazawa University*

Introduction In skeletal muscles, the fatty acid (FA) transport protein CD36 facilitates the cellular uptake of long-chain FA on the plasma membrane. The transporter is also suggested to localize on the mitochondrial outer membrane, where its quantity correlates with FA oxidation rate. Therefore, mitochondrial CD36 could regulate FA oxidation capacity and may play an important role in fatty acid metabolism. Previous study reported that exercise-training increase not only the total CD36 content, but also its content on plasma membrane and in mitochondria. Moreover, acute or repeated adenosine monophosphate- (AMP) activated protein kinase (AMPK) activation also increases CD36 content in rat cardiac myocytes and rat skeletal muscle cell line L6. However, factors for translocation/expression CD36 to/on the mitochondria remains unknown. The purpose of the present study was to determine whether the mitochondrial CD36 protein content was increased or not. We performed the repeated treatment with 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR) or caffeine on the mouse skeletal muscle cell to activate AMPK and Ca<sup>2+</sup> signaling pathway. Methods Mouse skeletal muscle cells (C2C12) were cultured in 10% fetal bovine serum (FBS) and subsequently differentiated in 2% donor bovine serum (DBS). After differentiation, cells were incubated (5 h; 5 consecutive days) with or without 1 mM AICAR or 3 mM caffeine, containing 10% FBS and 1% penicillin-streptomycin. Nineteen hours after the last day of treatment, the cells were harvested. Then the cells were homogenized and centrifuged to obtain a mitochondrial and cytosolic fraction. The two fractions and whole cell preparation were compared for CD36, phospho-AMPK and voltage dependent anion channel (VDAC) protein levels using immunoblotting. Results The AICAR treatment induced an increase in CD36 protein content in the mitochondrial fraction (p < 0.05), without affecting cytosolic or whole cell contents. In contrast, caffeine treatment did not upregulate the CD36 protein content in the mitochondrial and cytosolic fractions, or on the whole cell preparation. The VDAC content was not changed in whole preparation by AICAR and caffeine treatment. AICAR and caffeine caused an acute increase in the phospho-AMPK within 1 h (p < 0.05). But AMPK phosphorylation was not stimulated when the cells were harvested (19h after the last AICAR treatment). Conclusion Repeated and long-term treatment (5 h x 5 consecutive days) with AICAR and caffeine will cause a temporal but repeated increase in AMPK phosphorylation. The repeated exposure to AICAR, but not caffeine, selectively raised the mitochondrial CD36 protein content in C2C12 cells, without affecting total content of CD36 within the myocyte.

**ASSESSMENT OF S6K1 ACTIVITY IN HUMAN SKELETAL MUSCLE USING THE QUANTITATIVE RADIOLABELED TECHNIQUE**

Apro, W., Hamilton, D.L., Blomstrand, E.

*The Swedish School of Sport and Health Sciences*

Introduction Skeletal muscle growth is to a large extent regulated by the mechanistic target of rapamycin complex 1 (mTORC1) pathway (Goodman et al., 2011). It has been well demonstrated that the activity of this complex is enhanced by mechanical load as well as amino acids. The ribosomal protein S6 kinase 1 (S6K1) is one of the most well characterized substrates of mTORC1 and upon phosphorylation of S6K1 at Thr389 by this complex, the activity of S6K1 increases. As such, the phosphorylation status of S6K1 at this site has been used as functional readout of mTORC1 activity in human and animal tissue (Baar & Esser, 1999; Terzis et al., 2008). However, the western blot method generally used to measure S6K1 phosphorylation is only semi-quantitative which may provide less accurate results. In this study, we have assessed S6K1 activity using the quantitative radiolabeled technique. Methods Resistance trained men performed heavy resistance exercise and were supplemented with essential amino acids before, during and after exercise. Biopsies were taken in the vastus lateralis muscle before and 1 h after exercise. Muscle samples were homogenized in ice cold Chaps buffer and S6K1 was immunoprecipitated (IP) using a total S6K1 antibody and Protein G coated magnetic beads. Following IP, the beads with the protein-antibody complex were washed in appropriate buffers after which each sample was divided into triplicates and washed once with kinase buffer. The kinase reaction was run in the appropriate kinase buffer with radiolabeled ATP for 45 min at 30 °C with constant shaking. Two of the triplicates contained S6K substrate and the last triplicate served as a blank without substrate. The reaction was terminated by spotting the reaction mixture on phosphocellulose paper that was immersed in phosphoric acid. Radioactivity was then measured in a scintillation counter. Results The exercise and amino acid intervention resulted in an approximately eight fold increase in S6K1 activity.

Discussion In this study we show that it is possible to measure S6K1 kinase activity in human skeletal muscle following an intervention that is known to increase skeletal muscle protein synthesis and mTORC1 signalling. The use of a quantitative kinase assay will allow for more accurate study of the this signalling pathway in human muscle. References Baar K & Esser K. (1999). ## MARKERS OF MITOCHONDRIAL BIOGENESIS ARE AFFECTED BY AGING AND EXERCISE TRAINING IN RAT SKELETAL MUSCLE

Koltai, E., Hart, N., Taylor, A.W., Goto, S., Ngo, J.K., Davieas, K.J.A., Radak, Z.

*Semmelweis University*

Introduction Impairments of the mitochondrial reticulum or network, and its function have often been associated with aging. A decline in mitochondrial biogenesis and mitochondrial protein quality control in skeletal muscle, directly contributes to this problem, but exercise training has been suggested as a possible cure. PURPOSE: In this report, we tested the effects of moderate intensity exercise training on young and old rats, and assessed mitochondrial biogenesis and mitochondrial protein quality control. Methods Twelve young (three mo) and twelve old (26 mo) male Wistar rats were used in the study and grouped into young control (YC), young exercised (YE), old control (OC) and old exercised (OE). The investigation was carried out according to the requirements of The Guiding Principles for Care and Use of Animals, EU. Exercised rats were trained on treadmill for 6 weeks, 5 times per week, where the running speed and duration of the exercise were gradually increased. We examined in this study the gastrocnemius muscle by Western blot and fluorometric assays. Statistical significance was assessed by one-way ANOVA, followed by Tukey's post hoc test. Results Exercise training prevented or attenuated significant age-associated (detrimental) declines in SIRT1 activity ( $437 \pm 174$  v.  $1166 \pm 109$  rel. act.  $p < 0.05$ ), AMPK ( $0.21 \pm 0.11$  v.  $1.05 \pm 0.29$  rel.dens.  $p < 0.01$ ), peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1 $\alpha$ ) ( $0.35 \pm 0.04$  v.  $0.87 \pm 0.08$  rel.dens.  $p < 0.01$ ) and the Lon protease, in the gastrocnemius muscle of rats. Exercise training also prevented the age-related (detrimental) increases in NRF1 ( $1.11 \pm 0.17$  v.  $0.67 \pm 0.1$  rel.dens.  $p < 0.01$ ), TFAM, Mfn1 ( $0.98 \pm 0.31$  v.  $0.48 \pm 0.16$  rel.dens.  $p < 0.01$ ), Fis1 and polynucleotide phosphorylase (PNPase) ( $1.52 \pm 0.42$  v.  $1.05 \pm 0.25$  rel.dens.  $p < 0.01$ ) levels. Conclusion Our data suggest that regular exercise training can help minimize detrimental skeletal muscle aging deficits stimulating mitochondrial biogenesis through the PGC-1 $\alpha$  system, a rejuvenating the mitochondrial network via fission and fusion, and improving quality control of mitochondrial proteins by the Lon protease. All of these properties, working in conjunction with one another, would improve the overall functionality of mitochondria in aged cells. K.J.A.D. and J.N. were supported by grant #RO1-ES003598, and by ARRA Supplement 3RO1-ES 003598-22S2, both from the NIH/NIEHS to KJAD.

## ASSOCIATION OF TYPE XI COLLAGEN GENES WITH CHRONIC ACHILLES TENDINOPATHY IN TWO INDEPENDENT POPULATIONS.

Hay, M.1, September, A.V.1, Posthumus, M.1, Collins, M.2,1

1: *University of Cape Town (Cape Town, South Africa)*, 2: *Medical Research Council (Cape Town, South Africa)*

Introduction Injury to the mid-substance of the Achilles tendon is multifactorial, resulting from interactions of extrinsic and intrinsic factors. Several genes, including COL5A1, have recently been identified as important intrinsic risk factors. COL5A1 encodes the  $\alpha 1$  chain of type V collagen, which plays an important role in collagen fibril assembly. Type XI collagen, which is also expressed in tendons, shares structural and functional homology with type V collagen. Type XI collagen is encoded by the COL11A1, COL11A2 and COL2A1 genes. Mutations in these genes cause severe disorders, while polymorphisms, such as COL11A1 rs3753841 (T/C), COL11A1 rs1676486 (C/T) and COL11A2 rs1799907 (A/T), have been associated with connective tissue disorders. The aim was to investigate the association of these three SNPs with Achilles tendinopathy (AT) in South African (SA) and Australian (AUS) cohorts and whether these SNPs interact with COL5A1 to modulate the risk of AT. Methods A total of 182 participants diagnosed with chronic Achilles tendinopathy (AT, 104 SA, 78 AUS) and 336 appropriately matched asymptomatic controls (CON, 160 SA, 176 AUS) and were genotyped for the three SNPs. Results Although there were no independent associations with any of the COL11A1 (rs3753841 and rs1676486) and COL11A2 (rs1799907) SNPs with AT, gene-gene interactions between the COL11A1 and COL11A2 genes were associated with AT. Specifically, the T and C alleles of the COL11A1 rs3753841 and rs1676486 SNPs, respectively, as well as the T allele of the COL11A2 rs1799907 SNP, were associated with increased risk of AT. The functional AGGG allele (rs17146744) within the COL5A1 3'-UTR also interacted with these type XI collagen SNPs to increase the risk of AT. Due to the allele interactions between COL11A1, COL11A2 and COL5A1, a genotype risk score was calculated for the AT and CON participants. The "at risk" genotypes for AT at each variant contributed 2 points (COL5A1 AGGG/AGGG; COL11A1 rs3753841 TT; COL11A1 rs1676486 CC and COL11A2 TT) towards the genotype risk scores while the low-risk genotypes contributed 0 points. When the scores for rs1676486, rs1799907 and rs17146744 were calculated, the minimum risk score of 0 was significantly under-represented in the AT group ( $p = 0.015$ , OR = 5.4, 95% CI = 1.2-23.8), while the maximum score of 6 was significantly over-represented in the AT group ( $p = 0.022$ , OR = 2.4, 95% CI = 1.2 to 5.0). Discussion In summary, this study provides evidence that genes that encode for the structurally and functionally related type XI (COL11A1 and COL11A2) and type V (COL5A1) collagen interact with one another to modulate the risk for Achilles tendinopathy.

## MOLECULAR BIOGESESIS IN RATS SELECTED BY RUNNING CAPACITY

Torma, F., Sárka, L., Hart, N., Britton, S., Koch, L., Radák, Zs.

*Semmelweis University*

Introduction Recently the positive physiological effect of the daily sport activity is quite well known. Studies observing different genetical groups are limited. Wisloff et al.\* showed that disadvantageous genetical background not only effect the running distance but the circulatory-, endothel functions, and blood sugar homeostasis so. Methods We worked with rats selected by their running capacity (26th generation). The first genetical unit represents the "high running capacity" (HRC) rats the other the "low running capacity" (LRC) ones. Three groups were formed in each genetical unit one were trained five days per week (at 70% VO<sub>2</sub>max), another exposed to calorie restriction. Physiological parameters were measure like maximal relative oxygen uptake, body weight, and some cognitive tests were preformed. As

a marker of performance we register the running distance during the oxygen uptake measurement. For the molecular background we used western blot diagnostic method. Our interest was dedicated to examine the parts of mitochondrial biogenesis therefore biochemical markers from gastrocnemius muscles were measured. We were curious about the PGC-1, Sirt1 and the MFN-1 pathways. Results We observed improved running distance in both genetic groups in the case of training. The LRC trained group distance data was similar to the HRC untrained groups. Some other remarkable physiological changes were evincible in both treated group. In the field of biochemistry similar adaptational pattern can be seen in the PGC-1 and the Sirt-1 levels in the treated groups. The Mfn-1 results can be explained by the better mitochondrial functions of trained animals. Discussion Our recent finding suggests that the physical activity reduce physiological problems connected to the genetic disadvantages due to the better functional status of the mitochondria. This results can help to draw attention to the importance of regular physical activity especially in less favored population. ### GENOMIC COPY NUMBER VARIATION WITHIN THE TNC AND ADAM8 GENES AS POSSIBLE PREDISPOSING RISK FACTORS FOR ACHILLES TENDON PATHOLOGY

Rickaby, R., Raleigh, S., Posthumus, M., Collins, M.

*University of Northampton, UK, UCT/ MRC Research Unit for Exercise Science and Sports Medicine, South Africa, and South African Medical Research Council, South Africa*

**INTRODUCTION** Achilles tendon pathology (ATP) is a multifactorial disorder which predominantly affects athletic populations. A variety of risk factors are known to predispose to ATP and recent work has identified that genetics has a prominent role. However, to date, studies into the genetic basis of ATP have largely focused on small scale DNA variants such as SNPs. The influence of larger scale (>1kb) copy number variation (CNV) on the risk of ATP has not been addressed. **METHODS** We decided to investigate whether genomic CNV within two genes that might have important roles in the pathogenesis of ATP, through diverse mechanisms, were additional risk factors in a South African case (N=103)-control (N=89) Caucasian cohort. It has previously been shown that a GT repeat variant within the tenascin C (TNC) gene is associated with ATP and ADAM8 expression levels have been shown to be high in ruptured Achilles tendon compared to controls. For our analysis of TNC we used a Taqman CNV probe (Hs06903309) to determine the CN status for a region of the TNC gene located within intron 15. For ADAM8 we used the Hs02429708 probe that detects CNV variation within exon 23 of the gene. CN status at each candidate locus was determined using a multiplex PCR reaction on a StepOne Plus (Applied Biosystems) real time instrument running CopyCaller (version 2.0) software. CN signals were normalised against a reference probe for RNase P. A t-test was used to detect significant (P<0.05) differences between ATP cases and controls. **RESULTS AND DISCUSSION** For the TNC Hs06903309 probe we found no significant difference (P=0.953) between mean CN in ATP cases and controls. Likewise, for the ADAM8 Hs02429708 probe we found no evidence of mean CN difference (P=0.346) between ATP cases and controls. In summary, our preliminary findings suggest that CNV at the two loci investigated do not predispose individuals to Achilles tendon pathology. Our work is now extending to investigate the role of CNVs as risk factors for ATP in additional candidate genes in larger population cohorts.

### MONITORING ADAPTATION TO HEAT STRESS: CAN HSP72 EXPRESSION IN LEUKOCYTES BE A SURROGATE MEASURE FOR CHANGES IN SKELETAL MUSCLE?

Tuttle, J.A.1, Barrington, J.H.1, Pearce, O.2, Castle, P.C.1, Lewis, M.P.3, Taylor, L.1

*University of Bedfordshire, Bedford, UK.*

**Introduction** HSP 72 is a protein known to be upregulated when the human body is exposed to external stressors particularly excessive heat. The protein acts to prevent other proteins from denaturing under external stressors and so has a major role in human adaptation to activity in extreme environments. Measurement of the transcriptional levels of HSP72 (Hsp72) could therefore, act as an effective monitor for successful adaptation to such environments, however, it is levels in skeletal muscle that are seen as most relevant. Clearly, constant muscle biopsies are not viable for monitoring levels therefore this study was designed to investigate whether Hsp72 levels in leukocytes (much more easily obtained) can act as a "surrogate" for the changes occurring in skeletal muscle. **Methods** Our group have previously defined an exercise protocol (30 min downhill run (-10% gradient; 30°C, 50% RH) at LT) that maximises Hsp72 expression in leukocytes. 5 additional participants were enrolled onto the protocol with a muscle biopsy step (Vastus lateralis; VL) added to the blood-harvesting step. Hsp72 expression was determined in both leukocytes and skeletal muscle by quantitative PCR and compared. Relevant physiological measures (Rectal temperature (Tre) measured continuously during exercise, quadriceps tenderness (QT) and visual analog scale of pain (VAS) measured before exercise, and immediately, 3 hrs, 24 hrs and 48 hrs post) were made to confirm and quantify the physiological strain caused by the protocol. Results VL Hsp72 increased immediately post exercise (95% CI = 1.3 ± 0.5 to 5.8 ± 2.5 fold, p < 0.001) but leukocyte Hsp72 (95% CI = 0.7 ± 0.3 to 2.3 ± 0.6 fold, p = 0.105) did not. Additionally, the changes seen in VL were of a greater magnitude than those seen in leukocytes (F = 24.0, p < 0.001). Tre increased at 30 min (95% CI 37.3 ± 0.3 to 39.3 ± 0.4 p < 0.001) compared to 0 min while VAS was increased at 24 hrs post exercise (95% CI 0.0 ± 0.0 to 3.8 ± 3.8 p = 0.001) compared to basal. QT did not change from basal. **Conclusion** Increases in Hsp72 demonstrated in VL are not mirrored in leukocytes. This suggests that leukocyte Hsp72 may not be a reasonable surrogate tissue. Further work utilising increased participant numbers and HSP72 protein expression are required to fully elucidate whether leukocytes can be utilised as a surrogate tissue.

### THE AGTR2 GENE POLYMORPHISM IS ASSOCIATED WITH MUSCLE FIBRE COMPOSITION AND ENDURANCE ATHLETE STATUS

Mustafina, L.J.1,2, Mustafina, M.M.2, Lyubaeva, E.V.3, Nasibulina, E.S.2, Glotov, A.S.4, Vinogradova, O.L.3, Ahmetov, I.I.1,2  
1; Volga Region State Academy of Physical Culture, Sport and Tourism; 2; Kazan State Medical University; 3; Institute for Biomedical Problems; 4; St Petersburg State University

**Introduction** The ability to perform aerobic or anaerobic exercise widely varies among individuals, partially depending on their muscle fibre composition. The renin-angiotensin system is supposed to be one of the regulators of skeletal muscle growth and differentiation (Zhang et al. 2003; Johnston et al. 2011; Ahmetov et al. 2012). The angiotensin II type 2 receptor (encoded by AGTR2 gene in the X chromosome) by mediating the effect of the angiotensin II play an important role in developmental biology and pathophysiology. The C3123A (rs11091046) polymorphism of the AGTR2 gene located within the 3'-untranslated region of exon 3 have been reported to be associated with several cardiovascular phenotypes. In the present study, we examined the impact of the C3123A polymorphism of the AGTR2 gene on muscle fibre type composition and elite athlete status. **Methods** One hundred and fifteen Russian athletes (34 females and 81 males)

from different sporting disciplines (duration of event: 45 s – 2 hrs) were involved in the study. AGTR2 genotype and allele frequencies were compared to 148 controls (84 females and 74 males). To examine the association between AGTR2 gene variant and fibre type composition, muscle biopsies from m. vastus lateralis were obtained and analyzed in 55 young healthy men. Results Muscle fiber typing showed significant correlation between AGTR2 polymorphism and muscle fiber specification. The AGTR2 C allele carriers had significantly ( $P=0.003$ ) higher percentages of slow-twitch fibers ( $54.2 \pm 11.1$  vs  $45.2 \pm 10.2\%$ ) than A allele carriers. Furthermore, we found that the frequency of the AGTR2 C allele was significantly higher in endurance-oriented male athletes compared to controls ( $61.7$  vs  $43.2\%$ ;  $P=0.0014$ ). When considering individual sporting disciplines, the frequency of AGTR2 C allele was significantly higher in male 800 m - 10 km runners ( $P=0.027$ ) and kettlebell lifters ( $P=0.001$ ) compared to controls. Similarly, the frequency of the AGTR2 C allele was significantly higher in female cross-country skiers compared to female controls ( $83.3$  vs  $50.6\%$ ;  $P = 0.036$ ). Conclusion In conclusion, we have shown for the first time that variation in the AGTR2 gene is associated with muscle fibre type composition and elite endurance athlete status. #### PP-PM67 Training and Testing [TT] 2

##### VALIDATION OF A GAME BASED PERFORMANCE TEST IN TEAM HANDBALL

Wagner, H., Orwat, M., Hinz, M., von Duvillard, S.P., Müller, E.

*University of Salzburg*

Team-handball is a fast pace game of defensive and offensive actions that includes specific movements consisting of passing and catching a ball, throwing, jumping, screening, blocking, fast accelerations including stops, direction changes and frequent changes with low intensity movements as in standing, walking and jogging. The aim of the study was to develop and validate a game based performance test in team-handball. 20 experienced team-handball players performed two game based tests with one-week separation between each test, an incremental treadmill-running test, and a team-handball test game. The game based test consisted of 8 heats (separated by 40-60s rest between every heat) including team-handball specific actions and intensities similar to those observed in game analyses (Michalsik et al., 2012). We measured peak oxygen uptake ( $VO_{2peak}$ ), utilizing portable metabolic system (Cosmed K4B2), blood lactate concentration (LA) (EKF, Biosen C), heart rate (HR) (Polar, Kempele, Finland), sprinting time, and offensive and defensive time actions as well as running intensities (Inmotion LPM-system, Abatec, Austria), ball velocity and jump height (PeakMotus, Vicon Peak, UK). Reliability and validity of the tests were calculated utilizing ICCs, PM-correlations and independent t-tests. For the test-retest reliability, we found an ICC of  $>.80$  for the maximal LA and HR and the mean offense and defense time, ball velocity and jump height that yielded an ICC of  $>.90$  for the  $VO_{2peak}$  in the game based test. Significant differences between experienced and elite players (construct validity) were found for the HR, defensive time and ball velocity as well as a high correlation ( $r = .88$ ) between the game based test and the test game that resulted in the maximal LA and low correlation of ( $r = .58$ ) between the game based test and the incremental treadmill-running test for  $VO_{2peak}$ . We found also similar percentage for walking and standing (73%), low (18%) and high (9%) intensity running in the game based performance test compared to those found in game analyses by Michalsik et al. (2012). In conclusion, we found that the game based performance test is a valid test to assess performance in team-handball that is similar to those used in actual game. However, a high cardiorespiratory fitness measured during the incremental treadmill-running test is not an essential component to play team-handball on a high level during the entire game (team-handball specific endurance). References Michalsik LB, Aagard P, Madsen K. (2012). Int J Sports Med (published online)

##### ACUTE WBV DOES NOT AFFECT THE TORQUE-LENGTH PROFILE OF THE QUADRICEPS MUSCLE-TENDON UNIT.

Rieder, F.1, Kösters, A.1, Müller, E.1, Seynnes, O.R.2

*1: PLUS (Salzburg, Austria), 2: NIH (Oslo, Norway)*

Introduction Besides possible increases in force and power output after one bout of whole body vibration (WBV), recent publications indicated acute changes in the length-tension relationship of the plantarflexor muscle-tendon unit (MTU). In addition, shifts of peak torque towards longer muscle lengths were attributed to an increased compliance of the MTU (Kemertis et al., 2008; Pelligrini et al., 2010). This hypothesis is consistent with similar changes in the force-length relationship of the medial gastrocnemius MTU when a stretched-induced-decrease in tendon stiffness occurs (Kubo et al, 2001). Hence, the aim of this study was to investigate acute effects of WBV on the quadriceps torque-angle relationship and on the patellar tendon stiffness. Methods 24 subjects were randomly assigned to a WBV or to a control group. The WBV group did 7 x 1-minute bouts static squatting on a NEMES BOSCO vibration plate (frequency=20Hz, amplitude=2mm) whereas the control group performed the same squats without vibration. Patellar tendon stiffness and isometric knee extension torque-angle relationship were measured 24 hours before, immediately after and 24 hours after the intervention. Outcomes were assessed with a two way ANOVA for repeated measures. Results The optimal angle of torque production did not shift and maximal torque remained unchanged in all tested angles after vibration. There was no significant change in patellar tendon stiffness immediately after ( $+10.9\% \pm 16.5\%$ ) or 24 hours after ( $-3.5\% \pm 10.5\%$ ) vibration. No significant change was observed in any variables measured in the control group. Discussion Using the present protocol, WBV has no acute effects on quadriceps maximal torque production. Unlike previous report on the plantarflexors, the knee extensors torque-length profile was unaffected by vibration. In line with these results, the unchanged tendon stiffness suggests that this configuration of WBV does not affect the mechanical properties of tendinous tissue acutely. Differences in passive tensile loading, inherent to the squatting position of the WBV plate, may explain the discrepancy between the present findings and results obtained on the plantarflexors (Kemertis et al., 2008; Pelligrini et al., 2010). ## ACTIVITY PROFILES OF FOUR DIFFERENT FOOTBALL SMALL-SIDED GAMES

Aguiar, M.1, Botelho, G.2, Gonçalves, B.1, Sampaio, J.1

1: UTAD (Vila Real, Portugal), 2: ESAC/CERNAS/IPC (Coimbra, Portugal)

**Introduction** Small-sided games are widely used by football coaches at all levels of the game to develop technical, tactical abilities and physical conditioning of players. Research suggests that physiological, perceptual and technical responses can be modified during small-sided games in football by modifying game constraints such as the number of players, the size of the pitch, the rules of the game, or coach encouragement (Hill-Haas et al., 2008). The aim of this study was to identify the physiological and activity profiles of 4 football small-sided games formats. **Methods** 10 professional football players participated in 4 variations of small-sided games (2-, 3-, 4- and 5-a-side) with an intermittent regime involving 3×6 min bouts with 1 min of passive planned rest. Relative pitch size per player remained constant across the 4 small-sided games at around 150m<sup>2</sup>. Player's activity, rating of perceived exertion and heart rate profiles during the small-sided games was measured using portable GPS units at 5 Hz. ANOVA was used to compare the variables across the small-sided games format, Bonferroni Post hoc test was used to identify pairwise comparisons. Results Statistically significant differences among small-sided games format in the %HRmax ( $p=0.001$ ) were found, as well as, between small-sided games format in all times spent in heart rate zones, exception made in time spent at 75-84 %HRmax. Moreover, statistically significant differences ( $p<0.001$ ) between rating of perceived exertion values in the small-sided games format were found. Statistically significant differences among small-sided games format to total distance performed ( $p<0.001$ ) and between the number of sprints performed in each small-sided game ( $p<0.001$ ) were found. Statistically significant differences were found across small-sided games in the total body load. The 4-a-side presented the highest and the 5-a-side the lowest values ( $95.18 \pm 17.54$  and  $86.43 \pm 14.47$ , respectively). The body load per minute declined each 2 minutes of play. **Discussion** The results showed that smaller game formats elicit higher mean heart rate, rating of perceived exertion, and that players spent more time in higher %HR zones. By this, smaller formats are more appropriate to increase physiological stress, while larger formats can be used to improve match-specific demands. The body load results may suggest that small-sided games duration can be programmed in 2 min blocks interspersed with very short periods of rest, in order to allow for a quick recovery and maintenance of the workload characteristics. These concerns are particularly important when using 5-a-side games because at the end of the game period the body load has substantially decreased. **References** Hill-Haas S, Coutts A, Rowsell G, Dawson B (2008). *J Sci Med Sport*, 11, 487-490.

## ANALYSIS OF TRACK RUNNING PERFORMANCE USING GLOBAL POSITIONING SYSTEMS AND ACCELEROMETER BASED DATA

Niessen, M., Hartmann, U.

*University Leipzig - Faculty of Sport Science*

**Introduction** The continuous tracking of speed (vrun) and position during running events is often limited by the characteristics of study locations, including the complexity of the terrain and other conditions that influence the accuracy, continuity and availability of captured information. Nowadays light weight portable global positioning systems (GPS) with embedded tri-axial accelerometers (ACC) have been developed to obtain time spent moving, record distance covered, monitor vrun and measure ACC forces. Aim is to focus on pros and cons of GPS and ACC as well as their reliability and validity under track running conditions. **Methods** Within the present study the physical performance during altered track running (20-400 m; range vrun: 2.2-9.3 m/s) of a group of competitive athletes ( $n=10$  men (S1):  $25 \pm 3$  yrs,  $182 \pm 6$  cm,  $81 \pm 6$  kg;  $n=10$  women (S2):  $20 \pm 5$  yrs,  $162 \pm 5$  cm,  $59 \pm 6$  kg) was captured and analysed. A vest containing the GPS and ACC sensor was tightly fitted and placed between the scapulae to ensure a non-restricted range of movement. The ACC operated with 100 Hz, the GPS collected the position data with 5 Hz, reaching  $9.0 \pm 1.1$  satellites concurrent. Additionally a single light beam system (SLB) and a digital measuring wheel were used as gold standard for completed distance and time. Descriptive and group-specific parametric statistics were applied. Validity and reliability were assessed using 95% limits of agreement and coefficient of variation (CV) for all variables. Results Mean GPS results in S1 showed distance deviances for short sprint runs (<50 m, vrun:  $7.5 \pm 0.6$  m/s) of  $-0.7 \pm 2.2\%$  ( $n=20$ ), for sprints 50-100 m (vrun:  $8.4 \pm 0.4$  m/s) of  $-0.2 \pm 1.0\%$  ( $n=19$ ) and for runs  $\geq 100$  m until 300 m (vrun:  $8.3 \pm 0.5$  m/s) of  $-0.1 \pm 0.6\%$  ( $n=23$ ). The mean running distance divergence in S2 against the reference constant value of e.g. 70 m was  $67.8 \pm 2.1$  m ( $-3.1\%$ ;  $p \leq 0.001$ ), the reliability was good (CV: 3.1%;  $p \leq 0.483$ ). Over splits and 400 m in S2 the underestimation of GPS grows up to 3.5 % ( $-14.8$  m). Peak total ACC, defined as largest positive sum of the dynamic acceleration in the three directions, showed a range of 7.7-12.2g and individual profiles. **Discussion/Conclusion** The GPS and ACC sensors are a valid and reliable method of measuring distance and simultaneous movement in the three perpendicular axes at various running intensities. In accordance with previous studies, the current results demonstrate the systematic underestimation of GPS measurements compared with measured distances and SLB-calculations of speed at all measured intervals. By coupling ACC with GPS, movements can be determined accurately, and position applied to track physical performance. Both can assist field research in exercise science more or less sensitive, even at higher movement intensities.

## EFFECT OF LOW-VOLUME HIGH-INTENSITY TRAINING ON PERFORMANCE IN MASTER SWIMMERS

Porcellini, S.1,2, Bellistri, G.1, Pugliese, L.3, Bonato, M.3, La Torre, A.3, Maggioni, M.A.3, Massoni, M.3, Marzorati, M.1

*National Research Council*

1IBFM, National Research Council, Italy. 2DSBT, University of Udine, Italy. 3DBS, University of Milan, Italy **INTRODUCTION** Training programs for swimmers are usually characterized by high-volume sessions, approximately 20–30 h/wk depending on the period of the season and the level of the athletes (Sharp, 2000). Moreover, a great part of the weekly training volume is usually performed at low intensity. Recently the benefits on performance and physiological responses of low-volume high-intensity training has been reported in several athletes (Laursen et al, 2002). As for high-intensity training in swimming, few studies mainly focused on young are available (Sperlich et al, 2010). The aim of the present study was to evaluate in high-level master swimmers the effect of low-volume high-intensity training on performance and physiological factors. **METHODS** Twelve male master swimmers ( $32 \pm 5$  yrs) performed two different 6-week training periods separated by 3 weeks of tapering. The first period of training (HV-LI) was characterized by high volume and low intensity sessions (swimming about 14 km/wk), whereas the other (LV-HI) by low volume and high intensity sessions (swimming about 7 km/wk). All swimmers were tested before (PRE) and after each training period. In laboratory, they performed an incremental arm exercise test until exhaustion in order to obtain peak cardiovascular and metabolic values. In 25-m swimming pool, the best performance time was assessed in 100m, 400m and 2000m swims. A 7 x 200m protocol was also performed for individual anaerobic threshold (Vant) assessment. **RESULTS** In relation to PRE, after HV-LI: 1)  $VO_{2peak}$  significantly increased (+9%); 2) performance time on 2000m and on 400m significantly

improved (+4.2 % and +4.0 % respectively). In relation to HV-LI, after LV-HI: 1) VO<sub>2</sub>peak did not change; 2) time performance on 2000m and on 400m did not change; 3) Vant improved, resulting significantly higher than PRE (1.07 ± 0.2 vs. 1.27 ± 0.1 m/s, respectively PRE and after LV-HI); 4) time performance on 100m significantly improved (+2%). DISCUSSION HV-LI training improved maximal aerobic power, time performance on 2000m and 400m. LV-HI did not negative influenced effect of HV-LI on maximal aerobic power, 2000m and 400m. Additionally, LV-HI training also improved 100m time performance and velocity at anaerobic threshold. Despite a consistent reduction (about 50%) of training volume, high-intensity training preserves the aerobic swimming performance improvements of traditional high-volume training and it is more effective on short-distances performance time. ### EFFECT OF A SOCCER MATCH SIMULATION ON THE FUNCTIONAL HAMSTRING-TO-QUADRICEPS RATIO

Coratella, G., Schena, F., Bellin, G., Pacifici, A., Visentin, G., Beato, M., Impellizzeri, F.M.

*University of Verona*

**Introduction** Functional hamstring-to-quadriceps ratio (H/Q: ratio between eccentric hamstring to concentric quadriceps torque) is gaining popularity in soccer as potential predictor of injury risk. It has been shown that after fatiguing exercise tasks, H/Q is reduced, and this may increase the injury risk(Rahnama,2003). The aim of this study was to examine the effect of fatigue on H/Q ratio after a soccer match simulation and to examine whether it is influenced by sport-specific experience (i.e. sport-specific adaptations). **Methods** For this cross-sectional study, 22 amateur soccer players and 18 control (sport science students practicing different sports like swimming, running, etc.) completed the Loughborough Intermittent Shuttle Test (LIST). During fatiguing exercise, RPE and heart rate was monitored. Pre and post LIST, participants performed 1) isokinetic strength test at 60°/s, 180°/s and 300°/s on dominant (D) and non dominant (ND) limb, 2) Squat Jump (SJ) and Counter Movement Jump (CMJ). Dependent variables were analysed using a mixed 3-way ANOVA. Results No three-way interaction we found. After LIST, D showed a significant reduction in H/Q at 180°/s (CI 95% -0.150 to -0.055) and 300°/s (-0.149 to -0.044), and there was a trend at 60°/s (-0.065 to 0.002, p=0.065). In ND limb, significant reduction in H/Q occurred only at 60°/s (-0.080 to -0.011). Eccentric peak torque flexion angle resulted significantly increased in D at 60°/s (7.3° to 14.2°), 180°/s (3.6° to 13.5°) and 300°/s (1.8° to 9.4°) and in ND at 60°/s (5.3° to 12.1°), 180°/s (8.5° to 19.1°) and 300°/s (2.4° to 9.8°). In both limbs concentric peak torque angle during extension did not change. Two way interaction was found for RPE (p<0,01) and heart rate were significantly lower in soccer players. Both SJ and CMJ showed decrement in all subjects, but it was significantly greater in control. **Discussion** Functional H/Q ratio was significantly altered by exercise-induced fatigue, especially in dominant limb, confirming A previous study(Delextrat,2010). A novel finding was that the peak angle during eccentric knee flexion was left shifted indicating an alteration of torque-length relationship. This latter result may be an additional factor influencing the injury risk that warrants further studies. However, it is not different between groups, suggesting that this mechanism is not influenced by sport background. Delextrat, A et al. (2010). The use of the functional H:Q ratio to assess fatigue in soccer. Int. J of sports med., 31(3), 192–7. Rahnama, N. et al. (2003). ### AN IDEAL WAITING TIME FOR VERTICAL JUMPING PERFORMANCE AFTER THE WARM UP PROGRAMME CONSIST OF STATIC STRETCHING

Meric Bingul, B.1, Bulgan, C.2, Son, M.1, Aydın, M.1, Cinel, Y.1

*1:KOU(Kocaeli, Turkey), 2:HU (Istanbul, Turkey)*

**Introduction:** Football is one of the most popular team sports in the world. During the match and training, there is a lot of movement spent for running, jumping etc. A good warm up session cannot only improve performance but also prevent injuries due to strenuous moves during training and/or tournaments (Bishop, 2003; Holcomb, 2000; Gelen et al, 2012). According to the literature, dynamic stretching exercises increase strength performance during warm up session (Chattang et al 2010; Perrier et al 2011), and static stretching exercises decrease strength performance (Nelson et al 2005; Kistler et al 2010). It is recommended to give some waiting time for eliminate to this negative effect after the static stretching exercises (Torres, 2008). The aim of this study was to determine an ideal waiting time for vertical jump performance after the warm up exercises which was consisted of static stretching. **Methods:** 24 football players from Kocaelispor A2 Team in Turkey participated to this study. All subjects had previous competitive match experience at national tournaments. They have also training experience. Five different warm-up protocols were applied to players in each of 48 hours randomly. First protocol was 5 minute jogging, second protocols 5 minute jogging with static stretching. The other protocols 5 minute jogging with static stretching+ 5 minutes, 10 minutes and 15 minutes interval time respectively. In static stretching protocol, 4 different movements were worked out with two sets in 30 seconds for each muscle group. Following each warm-up session, subjects were tested vertical jump. Descriptive statistics (mean ± SD) formulated for the variables age, height, body weight data were analysed. Repeated measures of variance in SPSS program were used to compare the data obtained from 5 protocols. **Results:** As a result of this study, the warming up session that was consisted of static stretching exercises had effected negatively on vertical jumping performance. However, this negative effect was disappeared after the five minutes waiting time (p<0.05). **Discussion:** In previous studies showed that the negative and the positive effects of static stretching and the other stretching types. Chaouachi et al. (2010) studied the effect of warm-ups involving static or dynamic stretching on agility, sprinting, and jumping performance in trained individuals. They applied static stretching, an adequate warm-up and dynamic sport-specific activities to trained individuals with at least 5 or more minutes of recovery before their sport activity. Also, Torres et al. (2008) indicated that negative effects of static stretching leave the body after 5 minutes or longer period. This study and the literature showed that some relationships among warm-up, performance and interval time exist. It is recommended not to choose static stretching exercises in performances that requires explosive power such as vertical jump. If it is to be preferred, it should be given at least 5 minutes waiting time before performance to loose its negative effects.

### EFFECT OF FITNESS LEVEL ON TRAINING LOAD DURING SMALL-SIDED GAMES IN SOCCER PLAYERS

Al Haddad, H., Simpson, B., Buchheit, M., Gregson, W., Di Salvo, V., Mendez-Villanueva, A.

*Aspire, Doha*

**Introduction** Small-sided games (SSG) are very popular training drills in soccer. SSG appear to replicate to a certain extent the physical intensity, movement patterns and the technical requirements of competitive match play (Hill-Haas et al., 2011). Therefore, from an integrated and soccer-specific physical training perspective, SSG are commonly used to develop physiological adaptations to the game. However, whether players' fitness levels can impact the acute training load responses during SSG and therefore the development of a

certain physical quality remains unknown (Mendez-Villanueva et al., 2013). Therefore, in this study we investigated whether the training load arising from SSG would differ between players with substantially different levels of aerobic fitness. Methods Fifteen professional soccer players first performed an incremental running test to estimate their maximal aerobic speed. Players were then divided in two groups: high aerobic speed (HAS) and low aerobic speed (LAS), based on a moderate effect size (ES) difference (i.e., 0.5 x between-group SD) from the group average. Finally, eight players were eligible and were included in this study (i.e., 4 in HAS and 4 in LAS). During 3 different training sessions a 5-a-side SSG was performed and a total of 35 data sets of 7-min 5-a-side SSG (50x40m) (17 for HAS and 15 for LAS) were compared. Total distance covered, high-speed running distance >14.4 km.h<sup>-1</sup> and the number of accelerations >3 m.s<sup>-2</sup> were measured with GPS (GPSports, 15Hz). Heart rate (HR) related-indices were also collected (mean HR as % of HRmax, time spent at >90% of HRmax expressed as % of total playing time). Results Average estimated maximal aerobic speed was 18.4±0.7 km.h<sup>-1</sup> for HAS and 15.4±0.3 km.h<sup>-1</sup> for LAS. No clear differences between HAS and LAS for total distance covered (679±238 vs. 634±221m, ES=0.20, 90% confident limits [-0.19;0.59]), high speed running distance (103±42 vs. 90±60 m, 0.25 [-0.14;0.64]) were observed. LAS players presented greater number of accelerations (4.5±3.9 vs. 2.2±1.7, 0.85 [0.46;1.24]) compared with HAS. Average HR (86±2% vs. 81±3%, 1.28 [0.89;1.67]) and total time spent >90% of HR max (43±24% vs. 14±18%, 1.36 [0.97;1.75]) were greater in LAS compared with HAS. Discussion Superior aerobic fitness was unlikely to affect the distance covered during a 5-a-side SSG but was associated with a reduced external (i.e., accelerations) and internal (i.e., HR) training load. These results may indicate the need for more individualized training prescription based on player's fitness level and/or game specific requirements. Hill-Haas, S. V., Dawson B., Impellizzeri F. ### EFFECTS OF DIFFERENT ISOKINETICS KNEE EXTENSION WARM-UP ON MUSCLE PERFORMANCE IN YOUNG SUBJECTS

Vieira, C.A.1,2, Ferreira-Júnior, J.B.1,3, Soares, S.1, Rocha-Júnior, V.A.1, Magalhaes, I.E.J.1, Vieira, A.1, Bottaro, M.1

1:UnB (Brasília, Brazil), 2:UFG (Goiânia, Brazil), 3:IFTM (Paracatu, Brazil)

**Introduction** The assessment of muscular strength is essential for understanding the neuromuscular performance capacity of an individual or athlete. Thus, these subjects typically perform a warm-up to prepare to engage in neuromuscular tests. Studies utilizing isokinetic strength testing generally require subjects to perform different velocities warm-up protocols. Further examination of isokinetic testing protocols revealed that the warm-up velocities range from 30 to 300°s<sup>-1</sup>, and in many cases investigators fail to report warm-up protocols. Thus, the optimal warm-up protocol for isokinetic strength performance assessment enhancement remains unclear. Therefore, the purpose of this study was to analyze the effects of different warm-up routines on strength in young adults. **Methods** Fifteen healthy young men (24.8 ± 3.5 years) were exposed to five knee extensors warm-up randomized protocol before an isokinetic strength test (at 60°s<sup>-1</sup>). The warm-up protocols were: 1) submaximal (SUB), 10 submaximal consecutive repetitions (about 50% of maximum effort) at 60°s<sup>-1</sup>; 2) intermittent (INT), 10 maximal intermittent repetitions (30 seconds between reps) at 60°s<sup>-1</sup>; 3) 180, 10 maximal consecutive repetitions at 180°s<sup>-1</sup>; 4) 300, 10 maximal consecutive repetitions at 300°s<sup>-1</sup> and 5) control (CON) session (no warm-up). **Results** PT was significantly (p<0.05) higher after the INT (295.27±53.21 N.m) when compared to 300 (267.50±47.35 N.m) and 180 (275.21±48.61 N.m) warm-up protocols. Also, PT was significantly (p<0.05) higher in the no warm-up CON (285.41±48.70 N.m) protocol when compared to 300. **Discussion** One of the main findings of the present study was that the warm-ups protocols were not more efficient than no warm-up. These results are in agreement to Altamirano et al. (2012). They reported that warm-up did not affect PT. Another finding was that no warm-up and INT protocols were superior when compared to higher velocities warm-ups protocols (180 and 300). Some individuals reported mental and physiological benefits after a warm-up (Sweet; Hagerman, 2001). Thus, for those individuals the INT protocol could be an interesting warm-up strategy. Also, Batista et al. (2007) reported that the INT protocol seems to be an effective way to produce postactivation potentiation. Finally, according to our results subject should avoid warm-up using velocities higher than the testing velocity. **References** Altamirano KM, Coburn JW, Brown LE, Judelson DA. ### ACCELEROMETER MEASURED DAILY PHYSICAL ACTIVITY AND SEDENTARY PURSUITS - COMPARISON BETWEEN TWO MODELS OF THE ACTIGRAPH

Tanha, T., Tornberg, Å., Dencker, M., Wollmer, P.

*Clinical Sciences*

**Abstract Background:** Physical activity is and will continue to be a very important factor for cardiovascular health. There are numerous studies on physical activity and in recent years accelerometry is accepted as an objective measurement method. New generation accelerometers are on the market and are used frequently and data and cut-off points from the old generation accelerometers are often used interchangeably. However, there is very few validation studies performed between different generations of the commonly used Actigraph accelerometers. **Methods:** We compared daily physical activity data generated from the old generation Actigraph model 7164 with the new generation Actigraph GT1M accelerometer in 15 randomly selected young females for eight consecutive days. Minutes per day of light, moderate and vigorous physical activity (LMVPA), moderate and vigorous physical activity (MVPA), vigorous physical activity (VPA) and very vigorous physical activity (VVPA) were calculated. Moreover, minutes of sedentary pursuits per day was calculated. **Findings:** There were significant (P<0.05) differences between the Actigraph 7164 and the GT1M concerning LMVPA (237±49 vs. 225±37 min/day), MVPA (61±17 vs. 56±14 min/day), VPA (15±7 vs. 9±4 min/day) and VVPA (4±3 vs. 1±1 min/day). No significance was observed in data from mean minutes of sedentary pursuits between the two different models. **Conclusions:** Data from the old generation Actigraph 7164 and the new generation Actigraph GT1M accelerometers differ, where the Actigraph GT1M generates lower values for free living physical activity. Mean minutes sedentary time per day is not dependent accelerometer model. These results need to be taken into consideration when using these devices.

**KINEMATIC MEASURES OF TRAMPOLINE ATHLETES WITH RESPECT TO DOWNWARD TRAMPOLINE BED DEFLECTION: A PILOT STUDY**

Rupf, R., Chapman, C.

*University of Toronto, Canadian Sport Institute Ontario*

Introduction Jump height is an important scoring criterion in the sport of trampoline. The mechanisms that contribute to jump height in this sport however, are not well understood. Measuring the downward deflection (DD) may provide more insight into some variables such as vertical stiffness, which may aid jump height on elastic surfaces (Moritz, 2004). The purpose of this pilot study is to measure joint kinematics of trampoline athletes during the DD of the bed throughout the jump cycle. Methods A vision based system with a camera along the length and width of the trampoline bed were set to monitor DD. Goniometers (Mega Electronics) were placed at the hip (H) and knee (K) with information fed into the ME6000 data logger. Athletes (N=4) performed a straight bounce jump routine with the 3-6 consecutive jumps taken for data analysis when they reached their maximum height. Joint angle data for the hip (H) and knee (K) were synchronized with DD over the jump cycle, and average values were obtained. Correlates for jump height were determined and stepwise linear regression was performed to investigate potential factors for jump height. Significance was set to  $p < 0.05$ . Results Average time of flight for national and recreational athletes was 1.3 s (0.3), with an average jumping frequency of 0.6 Hz (0.1). Two major inflection points were observed in both H and K which occurred at 35.0% and 70.4% of the jump cycle at the H and 41.1% and 74.8% of the cycle for the K. In relation to the DD an inflection point occurred on the way down, and the other on the way up for both H and K (80.1% and 80.7% on way down respectively and 64.8% and 63.4% on way up respectively). No differences were seen between the H and K deflection points for both time and DD. Early stepwise models show that minimizing the entry and exit knee angle during the jump cycle time and the timing of the first knee extension in relation to the bottom of the bed may be important predictors for jump height ( $r^2 = 0.945$ ). Discussion Looking at the DD deflection of the bed in combination with the jump cycle time, would suggest that there are three distinct phases in the trampoline bed; one for landing, one for pushing off, and one during the take-off. Pushing off closer to the maximum DD of the bed may result in greater trampoline jump height. Greater leg extension is seen from all athletes; however, less leg extension may have positive contributions to jump height. The results of this study suggest that stiffness may be an important muscular criterion to jump height in trampoline athletes. References Moritz C, Farley T. (2004). *Jrnl Exp Bio* 208, 939-949.

**DOES THE RECENT INTERNAL LOAD ON PLAYERS AFFECT MATCH OUTCOMES IN ELITE AUSTRALIAN FOOTBALL?**

Aughey, R.1,2, Flyger, N.1, Sweeting, A.J.1, Inness, M.W.H.1,2, Elias, G.P.1, Gallaher, E.L.1, Walker, E.1,2

*Victoria University / Western Bulldogs FC*

Introduction Elite football clubs allocate significant resources to monitoring the internal load on athletes during a competitive season (Borrenson & Lambert, 2009). Despite this investment, little is known on the effect of team internal load on match outcomes in elite football. Methods Internal load was quantified from the session RPE method (Foster et al 2001) for elite individual players from one team in 141 professional Australian football matches over 6 seasons, then averaged for players that competed for the team each week. Average weekly internal load (WL) and strain (load x monotony or sameness of load; WS) was compared to Average monthly load (ML) and strain (four-week rolling average; MS) for each player against the match outcome, with covariates for relative position of teams in the competition and days between matches. Differences were assessed with effect size (ES) and magnitude based inferences. Results Average weekly load on players was likely 10% higher for match wins ( $ES\ 0.38 \pm 0.28$ ), but when days between matches was used as a covariate this was reversed and was very likely 17% lower for wins ( $-0.82 \pm 0.56$ ). When relative ladder position was considered, there was no clear difference in total load between wins and losses ( $-0.31 \pm 0.56$ ). There was no clear effect in the percentage difference between WL and ML for wins ( $-0.32 \pm 0.40$ ). Weekly strain was not clearly different for wins ( $0.10 \pm 0.31$ ), but a likely 76% higher in WS vs. MS ( $0.59 \pm 0.44$ ) that was possibly reversed when days between matches was used as a covariate ( $-34\%$ ,  $-0.44 \pm 0.90$ ), with no clear difference when relative ladder position was a covariate ( $0.26 \pm 1.42$ ). Discussion The interactions between weekly individual athlete load and strain, recent load and strain and wins and losses of teams are complex. In order to best prepare teams for competition the difference between weekly and recent strain seems the most important variable to consider, with a larger deficit between weekly strain and 4-wk average strain more conducive for success. Understandably, the importance of this manipulation of strain is ablated when the relative technical proficiency of teams is considered. References Borresen, J and Lambert, M. (2009). *Sports Med*, 39, 779-795. Foster, C. et al. *J Strength Cond Res*, 2001. 15(1): p. 109-15.

**THE INFLUENCE OF ADDITIONAL SODIUM IN A BEVERAGE ON REPEATED SPRINT ABILITY IN PROFESSIONAL SOCCER PLAYERS**

O'Reilly, J., Sun, B., Wong, H.S.S.

*The Chinese University of Hong Kong*

Introduction In soccer, players lose variable amounts of electrolytes, of which sodium ( $Na^+$ ) is the most important (Shirreffs et al., 1997). Sprinting is of great importance for performance in elite soccer, as it clearly distinguishes between top-class and high-level elite players (Mohr et al., 2008). Field-based repeated sprint tests have been significantly correlated with both running and sprinting distance during actual match play (Rampinini et al., 2007). Therefore, it was the aim of this study to examine whether the addition of  $Na^+$  to a beverage is related to the ability to perform repeated sprints. Methods 15 healthy, male professional soccer players from the Hong Kong football league (mean  $\pm$  SD: age  $24.1 \pm 3.5$  years, height  $1.78 \pm 0.07$  m, body mass (BM)  $72.6 \pm 12.1$  kg) took part in two soccer-specific, in-season training sessions of similar intensity (T1 & T2), while drinking either a beverage with 22 mmol/L  $Na^+$  (S) or 0 mmol/L  $Na^+$  (NS). Environmental conditions (Temp: 35 °C, RH: 90%, Wind speed: 1.03 - 1.20 m/sec) were similar on both occasions. Players commenced exercise in a euhydrated condition. Players were randomly assigned either S or NS beverage in T1 and consumed the other beverage in T2. Ad libitum

drinking was permitted in T1 and drinking in T2 was pre-determined to match consumption volume in T1. Each participant was assessed to establish their pre- and post-training hydration status by urine specific gravity (USG). A repeated sprint ability (RSA) test (Rampinini et al., 2007) was conducted immediately after both training sessions. Results RSA time was significantly decreased in the S trial (S vs NS:  $7.07 \pm 0.28$  s vs  $7.20 \pm 0.28$  s,  $p < 0.05$ ). Mean percentage BM losses were within recommended ranges (i.e.  $< 2\%$ ) on both days. There were no significant differences observed in USG between training sessions ( $p < 0.05$ ). Discussion The consumption of a beverage containing Na<sup>+</sup> had a positive effect on the sprint performance of soccer players, when compared to the ingestion of a sodium-free beverage. Similar to previous research, our study highlighted mild dehydration amongst the players (Owen et al., 2013), which was most likely due to the ad libitum fluid consumption. However, individual data showed that many players were dehydrated to a level where performance decrements can be expected (i.e.  $> 2\%$  BM). Furthermore, the inclusion of Na<sup>+</sup> in the beverage did not significantly alter USG in the professional soccer players. Mohr M, Krstrup P, Andersson H, Kirkendall D and Bangsbo J. (2008). INTRODUCTION Physiological responses to Brazilian Jiu-Jitsu (BJJ) practice have been investigated during simulated combats (ANDREATO et al, 2012; BORGES et al, 2012), but limited information exists regarding common used training sessions (SILVA et al, 2011). Therefore, the aim of this study was to analyze heart rate (HR) behavior during an ordinary BJJ training session involving both technical and combat exercises. METHODS Twelve male BJJ athletes ( $23.0 \pm 4.1$  yrs;  $75.7 \pm 11.0$  kg and  $176 \pm 4$  cm) volunteered to this study and carried out a training session of ~ 1 h. A general warm-up (WUP) was followed by technical exercises (TEC) involving guard pass and sweeps, and combats (COM) consisting in BJJ simulated matches. HR was continuously monitored during the session (POLAR® S810, Finland), being expressed in both absolute (bpm) and relative (% HRmax) values. Comparisons between specific phases regarding average and peak HR were performed by one-way ANOVA for repeated measures followed by Tukey's post hoc test with  $P < 0.05$ . RESULTS Session duration was  $62.2 \pm 2.5$  min, with average HR of  $134 \pm 12$  bpm or  $68.7 \pm 6.8\%$  HRmax. WUP, TEC and COM lasted  $11.8 \pm 1.2$ ,  $21.4 \pm 1.6$  and  $28.7 \pm 0.8$  min. Average HR in WUP and TEC were  $119 \pm 17$  and  $119 \pm 14$  bpm, corresponding to  $63 \pm 8$  and  $63 \pm 5\%$  HRmax. These values were significantly lower ( $P < 0.05$ ) than those observed in COM ( $151 \pm 12$  bpm or  $81 \pm 3\%$  HRmax). Peak HR in WUP and TEC were  $156.7 \pm 16$  and  $149.4 \pm 14.4$  bpm, or  $79.6 \pm 8.4$  and  $75.8 \pm 7.0\%$  HRmax. Peak HR values in COM ( $189 \pm 9$  bpm or  $95.9 \pm 5.1\%$  HRmax) were also significantly different from those in other phases ( $P < 0.05$ ). DISCUSSION From average HR values the BJJ training session could be considered moderate for the studied subjects. Peak HR in COM was similar those reported by Borges et al. (2012) and Andreato et al. (2012) in BJJ simulations combats. This phase demanded the highest effort of the athletes during the training session, leading to peak values that indicate high intensity exertion. ## FINGER FLEXOR STRENGTH MEASUREMENT WITH DIFFERENT ARM POSITIONS IN SPORT CLIMBERS

Balas, J., Kodejska, J.

Faculty of Physical Education and Sport

Introduction Different arm positions have been used to assess specific finger flexor strength in sport climbers (Grant, Hynes, Whittaker, & Aitchison, 1996; Watts, Martin, & Durtschi, 1993). The aim of the study was to evaluate the validity and reliability of 4 different arm positions for finger flexor strength measurement in sport climbers. Methods Twenty two male climbers of various climbing abilities volunteered to the study. All measurements were undertaken in a sitting position with the same position of finger on the measurement device in a randomly assigned order. Three attempts for left and right hand for each arm position were performed with a 2 minute rest: 1) grip strength with the thumb in opposition, arm extended near the body; 2) arm on a table in the horizontal position (90 degrees between trunk and arm) flexed in elbow (90 degrees); 3) arm partially extended (120 degrees between trunk and arm); 4) arm fully extended (180 degrees between trunk and arm). The measured strength was related to body mass. The intra-class correlation coefficient ICC 2,1 (Shrout & Fleiss, 1979) was used to assess the intra-session reliability of the measurements. The criterion validity was expressed by the relationship between the test results and the climbing ability. Results A high ICC 2,1 was found for all tests 1) 0.90 2) 0.85 3) 0.94 4) 0.86. The highest relationship to the climbing ability was found for the test with fully extended arms ( $r = 0.77$ ). The grip strength, the test with 90 degrees and 120 degrees arm flexion correlated moderately with the climbing ability (0.55, 0.52, and 0.55). Discussion All finger flexor tests demonstrated a high reliability similar to the handgrip dynamometry. Watts et al. (1993) and Macleod et al. (2007) found the grip strength related to body mass as a good indicator of climbing ability although the test lacks specificity with most hand positions required during sport climbing. According to our results, the test with flexed arms proposed by Grant et al. (1996) provided similar results as hand dynamometry. The test with fully extended arms appeared most suitable to assess finger flexor strength in climbers. References Grant, S., Hynes, V., Whittaker, A., & Aitchison, T. (1996). ## THE TEST-RETEST RELIABILITY AND MINIMAL DETECTABLE CHANGE OF THE BALANCE ERROR SCORING SYSTEM

Amin, D., Coleman, J., Herrington, L.

University Centre Doncaster

Introduction Balance is an important aspect of sports performance, which can be impaired following minor head injury (MHI; Vieira et al., 2009). The balance error scoring system (BESS) is a clinical tool commonly used for assessment of post-MHI recovery (Riemann & Guskiewicz, 2000). In order for a clinical tool to be accepted in practice, it must be robust from a psychometric perspective, in terms of reliability and sensitivity. This study aimed to ascertain test-retest reliability and, the previously unknown, minimal detectable change (MDC) of the BESS in order to ensure it was appropriate for use in the clinical setting. Methodology N = 36 (25 female; 11 male) academy-

level athletes (19 trampolinists, 11 soccer players, 6 dancers) were assessed using the BESS on two separate testing sessions, 1 week apart. The BESS comprises 6 testing conditions based on modified rhomburg stances and is scored according to "error points" (Valovich McLeod et al., 2006). Results Strong test-retest reliability of the total BESS score was identified (ICC = 0.784) with a MDC of 6-10 error points, dependent on confidence interval used. Discussion and clinical implications The strong reliability score and the relatively low MDC when using conservative measures would recommend the use of BESS in post-MHI assessment of young academy-level athletes. The results from this investigation favour comparably to previous literature (Broglia et al., 2009; Valovich et al., 2006) and further advocate the need to ascertain a mean total error score as a basis for assessment (Bell et al., 2011). However, more is required to further determine BESS MDC in this and other subject groups and whether the use of post-hoc video analysis would enhance reliability of the tool (Padua et al., 2011). ### **BIODENSITY STRENGTH TRAINING: HIGH-INTENSITY LOW-VOLUME TRAINING IN 550 YOUNG AND OLDER MALES AND FEMALES**

Smith, D.1, Skinner, J.2, Rockey, S.1, Conviser, J.

*University of Wyoming (1) and Indiana University (2)*

Introduction bioDensity strength training is a high-intensity (maximal-voluntary contraction) and low volume approach to resistance training (RT) that has been commercially available since 2009 (Jaquish, J. et al. 2012). Four multi-joint and multi-muscle group maximal-voluntary contractions are performed for 5 seconds once per week. To date, the strength gains associated with this limited-range static mode of RT have not been reported. This retrospective study reports strength changes in young to older males and females across 24-weeks of training. Methods 550 males and females completed 24 weekly bioDensity RT sessions. Changes in Chest Press (CP), Leg Press (LP), Core Pull (Core) and Vertical Lift (VL) strength were determined (RMANOVA) at 8, 12, and 24 weeks. The effect of age on strength gains was determined by a median-age split in males (> or < 57.0 years; N=174) and females (> or < 60.5 years; N=376). Results bioDensity RT resulted in significant strength gains for CP, LP, Core, and VL at 8-weeks in men and women. Age-specific results show similar strength increases at 8-weeks with the exception of CP in younger men and Core in older men, although significant increases were observed for Core in older men at 12-weeks (12.7%; P<0.05). For all but Core strength gains at 12-weeks in older men, there were no additional increases in strength between 12- and 24-weeks for any of the exercises in males or females in any age group. Discussion These findings demonstrate significant and functional increases in strength across a wide age range of males and females with 1 session per week of high-intensity bioDensity RT. However, the 5-second maximal-voluntary contraction 1-time per week was not a sufficient intensity and volume combination to elicit further strength gains at 24-weeks. These findings are aligned with those of others demonstrating the efficacy (de Vos et al. 2008), feasibility, and safety (Littbrand et al. 2011) of high-intensity strength training even in older adults. Introduction. Fencing is an Olympic combat sport during which athletes perform a one to one action using bladed weapons. The combat consists in 3 x 3 minutes fighting, with 1 minute rest between each combat. There are few studies investigating on oxygen uptake and energetic demand during Fencing competition, thus the energetic expenditure (EE) and requests in this sport remain speculative. This study was performed to obtain an understanding of the physiological capacities underlying fencing performance. Methods. The aerobic energy expenditure and the recruitment of lactic anaerobic metabolism were determined in 15 athletes (2 females and 13 males) during a simulation of fencing by using a portable gas analyser (MedGraphics VO2000), able to provide data of oxygen uptake (V'O<sub>2</sub>), carbon dioxide production (V'CO<sub>2</sub>) and heart rate (HR). The excess of CO<sub>2</sub> production (CO<sub>2</sub>excess) was also measured in order to obtain an index of anaerobic glycolysis. Blood lactate (Bla) was assessed by means of a portable lactate analyzer (Lactate Pro, Arkray Inc., Kyoto, Japan). Results. During the match group EE was on average (mean ± standard deviation) 10.5±2.8 kcalxmin<sup>-1</sup>, corresponding to 9.1±2.3 metabolic equivalents. V'O<sub>2</sub> and HR were always above the level of the anaerobic threshold previously assessed in a preliminary incremental test. CO<sub>2</sub>excess showed an abrupt increase in the first recovery after the first fight and reached a value of 339.1±240.1 mLxmin<sup>-1</sup>. Blood lactate concentration at peak was 6.8±2.4 mmolxL<sup>-1</sup>. Discussion. These data suggest that Fencing is a physically demanding sport activity with great involvement of both the aerobic metabolism and anaerobic glycolysis. Coaches should consider these facts when building training programs able to improve the specific adaptations required by Fencing. References. Crisafulli A et al. ## THE RELATIONSHIP BETWEEN BODY COMPOSITION AND THE AEROBIC CAPACITY OF AMPUTEE SOCCER PLAYERS

Ozcan, R.1, Kayihan, G.2, Ozkan, A.3, Erol, A.E.1

1: Gazi University 2: Sakarya University 3: Barın University (Turkey)

**Introduction** Soccer which includes various explosive movements like jumping, shooting, forward and backward shuffles, challenges, turns, dribbles, sprints, controlling the ball under pressure, running at different intensities, speeds, and sliding tackles, is an aerobic-based anaerobic sport (Köklü et al. 2011). In amputee soccer, short bursts of high intensity power production and aerobic capacity play a major role in performance (Özkan et al., 2012; Yazıcıoğlu K., 2007). The physiological demands of soccer require players to be competent in several aspects of fitness (Reilly & Doran, 2003). Moreover, body structure has generally been found to have a significant relationship to physical and aerobic performance (Docherty & Gaul, 1991). Therefore, the purpose of the present study was to investigate the relationship between body composition and aerobic capacity of amputee soccer players. **Methods** Thirteen amputee soccer players participated in this study voluntarily. Subjects' height, body weight, body mass index, skinfold thicknesses and body fat percentage (Jackson and Pollock formula) were determined. Aerobic capacities of 13 players were evaluated by the 1-Mile Run Test (1-MRT) and the Cooper Test (CT). The subjects' VO<sub>2</sub>max was estimated by the prediction equations developed Cureton et al. (1995) for the 1-MRT and Cooper et al. (1968) for the CT. **Results** The results of the Pearson Product Moment correlation analysis indicated that estimated aerobic capacity by 1-MRT was significantly correlated with body weight, body mass index and biceps, triceps, pectoral, midaxillar, suprailiac, subscapula, abdominal, thigh skinfold thicknesses ( $r = -0.588$  to  $-0.759$ ,  $p < 0.05$ ). Significant correlations were found between estimated aerobic capacity by 1-CT and body weight ( $r = -0.766$ ,  $p < 0.05$ ), body mass index ( $r = -0.801$ ,  $p < 0.05$ ) biceps, pectoral, midaxillar, suprailiac, subscapula, abdominal and calf skinfold thicknesses ( $p < 0.05$ ); whereas, in contrast, there is no significant correlations between 1-CTVO<sub>2</sub>Max and thigh, triceps skinfold thicknesses ( $p > 0.05$ ). **Discussion** In adults, body size, as reflected by height and weight, is significantly related to aerobic performance or physical working capacity (Docherty & Gaul, 1991). Similarly, in conclusion, the findings of the present study indicated that body composition was described as an essential factor in aerobic performance in amputee football players. **References** Cooper K. ## THE EFFECTS OF CAFFEINATED CHEWING GUM ON SIMULATED RACE PERFORMANCE IN COMPETITIVE FEMALE CYCLISTS

Costa, V.P., Guglielmo, L.G.A., Paton, C.D.

Federal University of Santa Catarina

**Introduction** Numerous studies have investigated the effects of caffeine supplementation on endurance and sprint performance with both trained and untrained subjects (Doherty, et al. 2004; Astorino & Robertson, 2010). Therefore, the aim of this study was to determine the effects of caffeine on simulated race performance in competitive female cyclists. **Methodology** Ten well-trained female cyclists ( $25 \pm 7$  yrs;  $58.3 \pm 5.4$  ml.kg<sup>-1</sup>.min<sup>-1</sup>; PPO =  $334 \pm 46$  W) completed a series of three test over ~21 days. The cyclists completed an incremental ramp test followed by a maximal effort performance test on the first day. The performance test consisted of three laps of a 10km race circuit (30km total); in the final 200 meters of each lap subjects were required to complete a maximal sprint. Following the familiarization the cyclists completed two further performance trails with either caffeine (200mg) or a matched placebo chewing gum in a randomised counter balanced design. The cyclists chewed the gum for a set period after completing the first 10km circuit. Physiological and perceptual measures were taken at set intervals in both trials. Differences between trials were determined using magnitude based inferential statistics and are reported as mean differences with 90% confidence intervals. **Results** Mean power outputs over the first and second 10km laps of the trial were not substantially different between caffeine and placebo ( $1.1 \pm 4.0\%$ ;  $0.0 \pm 2.0\%$  respectively). However mean power output over the final 10-km was substantially higher ( $4.1 \pm 4.1\%$ ) with caffeine. Differences in mean power in the three 200 meter sprints were trivial but trended to a small increase in power following caffeine consumption ( $-1.7 \pm 3.5\%$ ,  $1.4 \pm 4.5\%$  and  $1.9 \pm 5.3\%$  for each respective sprint). There were no substantial differences in VO<sub>2</sub>, RPE, [La] or HR between trials over the first 20km, however there were small increases in VO<sub>2</sub>, [La] and HR but not RPE during the final 10km. **Discussion/Conclusion** The acute ingestion of caffeine via chewing gum provides a small but potentially worthwhile increase in performance during the final 10km of a 30km performance trial in female cyclists. In addition while caffeine did not lead to any clear enhancement in sprint performance there was a trend for an enhancement during the latter sprint trials. The improvements in performance were associated with small changes in measured physiological responses and no substantial changes in RPE. **References** Astorino TA, Roberson DW. Efficacy of acute caffeine ingestion for short-term high intensity exercise performance: a systematic review. J Strength Cond Res 24:257–265, 2010. Doherty M, et al. Caffeine lowers perceptual response and increases power output during high-intensity cycling. J Sports Sci 22:637-643, 2004.

## AN EVALUATION OF METABOLIC RESPONSES BY TIME CONSTANT VALUE OF REGRESSION ANALYSIS

Sasaki, T., Tsunoda, K., Hoshino, H., Takeda, H.

Hokusei Gakuen University

**Introduction** The oxygen consumption returns to resting level earlier than the change of HR after exercise. VO<sub>2</sub> and HR can be described by respective exponential curve fitting. Exponential equations had shown different time constants after the exercise. Those functions represent different physiological responses in the individual athlete. The purpose of this study is to clarify physiological characteristics by using the time constants after the exercise test. **Methodology** Twenty three volunteer athletes cooperated to perform incremental metabolic test in this study. The test is made up following conditions: 3 min sitting rest, step load tread mill running and at least 5 min sitting rest after exercise. Exercise tests are started at 3 km/h and increased by 0.5km/h every minute until exhaustion. The function for the VO<sub>2</sub> estimation can be described as the function of HR. **Result** All the metabolic data are standardized for comparing each metabolic parameter. The relationship between measured value and regression data shows significant similarity for the 23 athletes ( $r$  : over 0.8) . Therefore, this regression analysis can be used in order to represent individual athlete metabolic response after exercise. Mean values of time constants in each parameters after the exercise are make up following: VO<sub>2</sub> = 65.1sec, VCO<sub>2</sub> = 101.9sec, VE = 109.7sec, and HR = 102.3sec. Time constant of the HR has low correlation to the time constant of the VE ( $r=0.31$ ), the VO<sub>2</sub> ( $r=0.4$ ), and the VCO<sub>2</sub> ( $r=0.47$ ). These parameters show low correlation coefficient below the 0.5. On the other hand, time constant of the VO<sub>2</sub> has high correlation to the

time constant of the VE ( $r=0.84$ ) and the VCO<sub>2</sub> ( $r=0.77$ ). These parameters show high correlation coefficient over the 0.7. Discussion There is the difference of time constant for each metabolic parameter in exponential regression. It is necessary to solve for energy calculation and to describe the VO<sub>2</sub> and the HR after the exercise. However, it could not be estimating energy expenditure during human activities until some years ago. Now, energy estimation is possible by use the method (Sasaki and Tsunoda (2006)). Thus, it has become important for precise calculation that the metabolic parameter after the exercise is obtained. In this study, it can be considered that the difference in time constants of the VO<sub>2</sub> and the HR depend on individual metabolic capacity. In fact, SD is indicated large value in both parameters in VO<sub>2</sub> (20sec) and in HR (30sec). Therefore, large difference of the time constants reflects individual metabolic characteristic. #### PP-PM78 Training and Testing [TT] 13

##### CASE-STUDY: CURVILINEAR RELATIONSHIP BETWEEN SALIVARY TESTOSTERONE AND TRAINING LOAD IN A FEMALE OLYMPIC HAMMER THROWER.

Fudge, B.W., Pringle, J.S.M., Ingham, S.A.

*English Institute of Sport*

Testosterone might have a role in the adaptive response to training by regulating long-term muscle performance and/or short-term expression of neuromuscular performance; potentially a result of a dose-response relationship with training load, particularly in elite athletes (Crewther et al., *Sports Med*: 41, 2011). PURPOSE: To investigate a possible dose-response relationship between salivary testosterone of an elite power athlete relative to training load in a period leading up to major competition. METHODS: A female hammer thrower (personal best: 71.98 m; age: 21 y; body mass: 72.4 kg; height 1.71 m) agreed to participate in the present case-study that tracked training load and salivary testosterone during an 83-day period leading up to the London Olympic Games, 2012. Saliva collection was completed in accordance with recognized procedures for sample handling and storage (Dabbs, *Physiol Behavior*: 1, 1991) on 39 occasions during the 83 day-period and subsequently analyzed using a Salimetrics® high sensitivity salivary testosterone enzyme immunoassay kit. Training load was calculated as a moving exponential average using the number of throws completed each day with a decay constant of 42-days (Busso et al., *Eur J Appl Physiol Occup Physiol*: 69, 1994). Investigation of the relationship between salivary testosterone and training load was completed using a hierarchical regression approach. RESULTS: There is an observable relationship between training load (range: 11.0-15.6 average throws/day) and salivary testosterone (range: 34.0-255.9 pmol/L) that has a greater ( $p = 0.036$ ) predictive power when described by a curvilinear (inverted U-shaped) model ( $r = 0.470$ ,  $r^2 = 0.220$ ,  $F(2,38) = 5.091$ ,  $p = 0.011$ ) compared to a linear model ( $r = 0.343$ ,  $r^2 = 0.118$ ,  $F(1,38) = 4.945$ ,  $p = 0.032$ ). CONCLUSIONS: The relationship between training load and salivary testosterone appears to follow a dose-response pattern in an elite female hammer thrower. Although yet to be tested in an athlete support setting, the construction of an individual athlete's dose-response relationship between testosterone and training load could potentially allow optimisation of hormonal response that might underpin muscle and neuromuscular performance in the long and short term, respectively.

##### SOCIAL MEDIA SERVICE PROMOTES PHYSICAL ACTIVITY IN YOUNG RECRUITS

Santtila, M., Pihlainen, K., Kyröläinen, H.

*Finnish Defence*

Introduction It is generally well known that the physical fitness of army recruits has decreased and body weight has increased during the last decades (e.g. Dyrstad et. 2005, Santtila et al. 2006). The negative phenomena have partly been explained by increased physical inactivity among children and adolescents. Therefore, the purpose of present study was to investigate how promotion service of physical activity in social media (MarsMars.fi, HeiaHeia.com, Helsinki, Finland) affects physical activity and physical fitness in the Finnish call-up aged male recruits. Methods Subject group consisted of 802 voluntary male recruits (19.3±1.2 yrs, 1.80±0.07m, 75.5±13.9 kg). The promotion information and password of social media service were sent by mail to subjects three months before the compulsory military service. Body mass, aerobic capacity and physical activity information were self-reported by a structured questionnaire, which was replied during the first military service week. During the second week of military service, body mass was measured and maximal aerobic capacity was evaluated by 12 min running tests (Cooper 1968). Thereafter, the self-reported data were compared to the measured outcomes. Results 112 of 802 persons utilized the service. Aerobic capacity of the service utilizers ( $n=112$ ) did not change significantly (2353±397 vs. 2409±351 m,  $p=0.082$ ). Neither change was recorded in body weight. 60.4% of the service utilizers reported that their physical activity increased. The whole subject group ( $n=802$ ) reported that the best way to promote physical activity before the military service was exercises and training programmes offered by local civilian sport clubs (38.5%). A main reason for not using the present service was lack of need for the offered service (37.0%). Discussion Only 14.0 % of the study group took social media physical activity service in use. Physical activity of those subjects increased significantly due to the social media service. However, it did not lead to changes in body mass or aerobic capacity. According to present results, the promotion of physical activity in social media is very challenging. In conclusion, it will be very important to have a proper marketing campaign to get more adolescents interested in this kind of services, and there is still a need for development of new and more attractive physical activity services even outside of the internet. ## RELATIONSHIP OF BODY COMPOSITION ON PERFORMANCE IN ADOLESCENT SWIMMERS

Gómez-Bruton, A.1,2, González-Agüero, A.1,3, Gómez-Cabello, A.1,2, Matute-Llorente, A.1,2, Julián-Almárcegui, C.1, Casajús, J.A.1,2, Vicente-Rodríguez, G.1,2

1. *GENUD, Research group, Universidad de Zaragoza*, 2. *Universidad de Zaragoza, Spain*, 3. *Aberystwyth University, Ceredigion*

**Introduction:** Body composition, particularly lean mass, is associated to performance in many adult elite sports. Adolescence is an optimal period to detect talent; we aimed therefore to elucidate the role of lean and fat mass in swimming performance during adolescence. **Methods:** A total of 82 adolescent swimmers (47 males) with a mean age of  $14.5 \pm 2.1$  years participated in this study. Participants were divided into two age-groups: younger (YG) and older (OG) than 14.5 years. Mean values of upper limbs and mean values of lower limbs lean and fat masses were evaluated using 2 methods: dual-energy X-ray absorptiometry (DXA) and bioimpedance. Two methods were used in order to view differences between method results and Personal best times (PBT) correlations. PBT were obtained from a freestyle 50 m maximum course registered in a 25 m swimming pool by a trained rater. Tanner-controlled partial correlations between body composition parameters and PBT were conducted. **Results:** In the male group, lean mass of both limbs was negatively correlated to PBT (the higher lean the better time), while in the female group arm fat mass was positively correlated to PBT (the higher fat the worse time), independently of the method of evaluation (all  $p \leq 0.05$ ). However, separately by age-groups, male YG showed no correlations for any variable, while female YG showed positive correlations between all fat measurements and PBT ( $r$ =from 0.56 to 0.803, all  $p \leq 0.05$ ). Male OG swimmers showed negative correlations for most lean mass measurements and positive correlations for fat mass evaluated by DXA, while female OG showed positive correlations between PBT and fat evaluated with DXA and bioimpedance (all  $p \leq 0.05$ ). Upper limbs fat was the body composition parameter that correlated most often and with higher correlation values ( $r=0.8$ ) with PBT independently of the method used in both groups. DXA and bioimpedance showed similar correlations independently of sex and age. **Conclusion:** It seems that performance is related to body composition in different ways depending on gender and age. Lean mass seems to be crucial for PBT in older adolescent males. However, no correlations were found in females for lean mass, while fat mass positively correlated with PBT independently of the age group. This could be due to the fact that females present lower values of lean mass, which is key to propulsion and higher values of fat mass than boys that may act as ballast and therefore be the most determinant body composition variable for this group regarding PBT.

## INTENSITY PARAMETERS CORRESPONDING TO FIXED LACTATE CONCENTRATIONS DETERMINED BY PERCEIVED EXERCITION.

Doria, C., Dantas, J.L., Rossi, H., Rosa, G., Pietrangelo, T., Fano'-Illic, G.

*University*

Blood lactate concentration (LAC) and rating of perceived exertion (RPE) have been shown as good markers of metabolic demand and LAC is widely used to determine intensity parameters (e.g., heart rate (HR) or speed) for runners in order to prescribe and to control training workload. If RPE is strongly correlated with LAC, the former could predict intensity parameters as well as LAC. Thus, the aim of this study was to determine the agreement between intensity parameters predicted by LAC and RPE in amateur runners. **Methods** Ninety-five amateur runners performed a test on a treadmill (Technogym RunRace, Italy) to determine intensity parameters at 2 mmol (LAC2) and 4 mmol (LAC4) as tested levels (stages duration= 4 min; pauses=1 min to measure LAC; speed increment=1.5 km.h<sup>-1</sup>/stage). The test started with an initial speed corresponding to the 70% of the average speed attained during the last competition, while criterion to stop was the achievement of a LAC  $\geq 4$  mmol. LAC, HR, speed and RPE were recorded in every stage. Individual RPE (RPEI) corresponding to LAC2 (RPEI2) and LAC4 (RPEI4) were predicted for each volunteers through the equation obtained from linear regression between LAC (independent) and RPE (dependent) values. Subsequently, HR (bpm) and speed (km.h<sup>-1</sup>) were predicted through the equation obtained from linear regression using fixed LAC and RPEI values as independent variables. Coefficient of determination (R<sup>2</sup>) was used to verify the fit of regressions. Bland & Altman plot was used to verify the agreement of the predicted values. Data are showed as mean  $\pm$ SD. **Results** The individual regressions between LAC and RPE showed high R<sup>2</sup> ( $0.94 \pm 0.065$ ). Thus, RPEI2 ( $4.2 \pm 1.0$  a.u.) and RPEI4 ( $6.8 \pm 1.1$  a.u.) could be adequate predicted by the linear regression. The Bland & Altman showed that HR predicted by LAC2 and RPEI2 (bias=  $-0.07 \pm 0.34$  bpm; CL 95%=  $\pm 0.7$  bpm), as well as by LAC4 and RPEI4 (bias=  $-0.5 \pm 2.0$  bpm; CL 95%=  $\pm 3.9$  bpm) showed excellent agreement. In the same way, speed predicted by LAC2 and RPEI2 (bias=  $-0.01 \pm 0.04$  km.h<sup>-1</sup>; CL 95%=  $\pm 0.08$  km.h<sup>-1</sup>), as well as by LAC4 and RPEI4 (bias=  $-0.05 \pm 0.35$  km.h<sup>-1</sup>; CL 95%=  $\pm 0.69$  km.h<sup>-1</sup>) also showed excellent agreement. **Conclusion** RPEI showed equal accuracy in relation to its correspondent LAC to predict intensity parameters (HR and speed). This is significant evidence since RPE correspondent to fixed LAC do not change after training period. Reference 1. Boutcher SH, et al. The effects of specificity of training on rating of perceived exertion at the lactate threshold. *Eur J Appl Physiol Occup Physiol.* 1989;59(5):365-9. ere

## EXPERT YOUTH COACHES' VIEW ON LONG TERM TECHNIQUE TRAINING

Voigt, L., Hohmann, A.

*University of Bayreuth - Institute of Sport Science*

**Introduction** Previous research on long term performance development highlighted the significance of technical training at a younger age (Hohmann et al., in press). However, most research in this area focused on explaining general motor skill acquisition and on the conditions that athletes practice under. What appears to remain unaddressed from a practical point of view is the question of how to correctly design the process of technique training in youth sports on the long run. The purpose of this paper was to analyse expert youth sports coaches' understanding of their training practice and to identify basic principles for long term technique development. **Methods** 68 expert youth-coaches (age:  $48.7 \pm 7.4$  years; coaching experience:  $23.7 \pm 7.1$  years) from different sports were selected purposefully to fit a number of similar criteria. The coaches were classified as expert coaches based on specified criteria related to multiple success in coaching. Specifically, expert coaches were defined by the number of successfully coached athletes who reached international competitions in the sport-specific high performance age. Following a qualitative research methodology, data were collected from qualitative, semi-structured interviews. An interview guide was developed to allow for the optimal comparability of the data and to ensure that each interview addressed the required topics. Data were analyzed by using coding procedures and inductive categorization methods inspired by grounded theory principles (Glaser and Strauss, 1967) in order to identify core categories and themes. **Results and Discussion** The evaluation of the data focused on reconstructing an general strategy for a long term design of technique training. Analysis of the transcribed interviews led to a chronological sequence of four main categories: (1) "feeling for technique", (2) "technique-inventory", (3) "technique-precision" and (4) "technique-stability". The findings suggest that successful youth coaches use these categories as an explanatory

framework to structure their knowledge on long term technique training. From a practical point of view it can be assumed that this framework relates the underlying theories and required methods of technique training to the specific stages of youth training. Further research is needed to test this framework against existing principles of technique training (e.g. Williams & Hodges, 2006) and whether it works to explain the process of technique training in other contexts and sports. ### EXERCISE TOLERANCE ABOVE CRITICAL POWER DOES DEPEND ON THE RATE OF UTILISATION OF $W'$ WHEN MANIPULATED TO THE EXTREMES WITHIN THE SEVERE INTENSITY DOMAIN

Greco, C.1, Souza, K.M.2, Dekerle, J.3, Denadai, B.S.1

1: UNESP (Rio Claro, Brazil), 2: UFSC (Florianopolis, Brazil), 3: UB (Eastbourne, United Kingdom)

**Introduction** Critical Power (CP) can be derived from the modelling of the power-time relationship and has been shown to be sustainable for 20-40 minutes. Any constant or slightly varied power output above CP can be maintained as long as  $W'$  (i.e., the curvature of the power-time relationship) is not fully depleted. Indeed,  $W'$  determines exercise tolerance when exercising above CP. Therefore, the purpose of this study was to determine the effect of high vs. low rate of utilization of  $W'$  on exercise tolerance within the severe intensity domain. **Methods** Eight active participants (age =  $25.4 \pm 3.5$  yr; body mass =  $75.2 \pm 9.9$  kg;  $VO_{2max}$  =  $57.5 \pm 10.4$  ml/kg/min) performed an incremental test for lactate threshold and  $VO_{2max}$  determinations, four maximal constant-workload tests to estimate CP and  $W'$ , and finally two varied-workload tests performed in randomized order (depletion of 70% of  $W'$  in either 3 or 10 minutes followed by a time to exhaustion at CP + 10W, respectively tlim3 and tlim10). All tests were performed to exhaustion. The three equivalents of the 2-parameter model ( $P=(W'/tlim)+CP$ ;  $tlim = W'/(P-CP)$ ;  $W=CP \cdot tlim + W'$ ) were used to fit the data and estimate CP and  $W'$ . The CP and  $W'$  estimates from the 3 equations were compared to select the best fit using the model associated with the lowest standard error for CP (SEE). **Results** CP and  $W'$  were  $231.9 \pm 61.1$  W (SEE =  $2.9 \pm 1.1$  W) and  $22.0 \pm 6.2$  kJ (SEE =  $1.0 \pm 0.2$  kJ), respectively. The tlim3 ( $15.8 \pm 6.5$  min) was significantly ( $p = 0.03$ ) longer than tlim10 ( $11.8 \pm 8.3$  min). **Discussion** The main finding of this study was that the tolerance to severe intensity exercise was increased when 70% of  $W'$  was depleted at a faster rate, early in the test. The severe intensity domain encompasses work rates above CP in which  $VO_{2max}$  can be elicited. While the same value of  $VO_2$  (i.e.,  $VO_{2max}$ ) is achieved regardless of exercise intensity within this domain, the time to achieve  $VO_{2max}$  is inversely related to exercise intensity (Caputo and Denadai, 2008). The increased rate of oxidative energy turnover (tlim3 condition) within the first part of the exercise is likely to reduce the depletion of the finite anaerobic energy reserves (i.e.,  $W'$ ), thus improving exercise tolerance. In conclusion, faster rate of utilization of the  $W'$  can improve the tolerance during exercise at severe intensity domain. This has previously been demonstrated when exercising maximally for 3-4 minutes (Bailey et al., 2011). **References** Caputo F, Denadai BS. (2008). Eur J Appl Physiol, 103, 47-57. ### EFFECTS OF HIGH AND MODERATE INTENSITY SEMI-SUPERVISED AEROBIC TRAINING PROGRAM IN ELDERLY

Riani Costa, L.A., Alcântara, C.P.A., Júlio, R.A.C., Junior, N.D.S., Kanegusuku, H., Queiroz, A.C.C., Murad Neto, A., Freire, F., Duarte, M., Forjaz, C.L.M.

University of São Paulo (USP), Diagnósticos da América (DASA)

**Introduction** High intensity supervised aerobic training is recommended to improve cardiovascular fitness in elderly. However, restricted social mobility limits the engagement in supervised training, and musculoskeletal abnormalities may difficult the prescription of high intensity exercise, enhancing the semi-supervised moderate exercise as an alternative option. This study was designed to test the hypothesis that moderate and high intensity semi-supervised aerobic training produces significant and similar benefits in elderly. **Methods** Forty seven sedentary subjects (>60 years) performed a maximal cardiopulmonary exercise test before and after 6 months of training. Forty subjects were eligible to start the program, and were randomly divided into 2 groups: high intensity aerobic training (HIT) or moderate intensity aerobic training (MIT). Each training program was composed by 3 sessions/week (2 home-based + 1 clinic-based). In each session, subjects walked or run during 40 min at a pre-determinate heart rate (HR) which was self-monitored. HR was established at the anaerobic threshold (AT) for the first 3 months for both groups and, afterwards, intensity was increased to the respiratory compensation point (RCP) only in the HIT. Twenty-four subjects completed the 6-month program (13 HIT/ 11 MIT). **Results** were compared by 2-way ANOVA (Newman-Keuls post-hoc test,  $P < 0.05$ ). **Results**  $VO_{2max}$  did not change after training in either of the groups, but total time of exercise and maximal work rate increased similarly in MIT and HIT (20 vs. 25 and 29 vs. 35%, respectively).  $VO_2$ , HR and ventilation at AT also increased similarly in both groups (7 vs. 24%, 8 vs. 3 and 12 vs. 32%, respectively). Moreover, HR and ventilation in RCP increased similarly too (3 vs. 1 and 13 vs. 18%, respectively). However,  $VO_2$  at RCP increased (14%) and resting HR decreased (9%) only in the HIT. Additionally, all the groups presented similar reductions in systolic and diastolic resting blood pressures (3 vs. 6 and 7 vs. 9%, respectively). **Discussion** Six months of moderate and high intensity semi-supervised aerobic training similarly improved exercise capacity, cardiovascular health and respiratory efficiency, while only HIT increased high intensity exercise tolerance and improved resting autonomic balance.

### EFFECTS OF DIFFERENT MOTIONS ON TIMING ERROR IN A COINCIDENT TIMING TASK

Tomoyuki, I., Kazuki, K., Chihiro, E., Masayuki, K.

Kurashiki University of Science and The Arts

**Introduction** Improvement in timing skills is an important factor in improving performance. Therefore, many studies have been carried out to measure and estimate timing skills. The standard method used to measure timing skill is the button-press method. However, in sports, there are few simple motions similar to the button-press task. Therefore, the purpose of this study is to examine the influences of different motions on timing error in a coincident timing task. **Methods** Twenty-four healthy young men ( $20.6 \pm 2.0$  yrs,  $171.0 \pm 6.6$  cm,  $67.1 \pm 11.3$  kg) and fourteen healthy young women ( $18.7 \pm 1.2$  yrs,  $160.3 \pm 6.8$  cm,  $50.6 \pm 6.8$  kg) volunteered for this study. Questionnaire surveys were carried out to investigate past sports experience. The results of the questionnaire were used to categorize subjects into 3 groups: open-skill sports group (O-group), closed-skill sports group (C-group), and the no sports group (N-Group). Timing skills were measured using 2 motion conditions that coincided with the arrival of a moving target running on a circular trackway on display. The 2 motion conditions evaluated were the button and landing conditions. In the button condition, the task was to manually press a button coinciding with the arrival of a moving target. In the landing condition, the task was to landing from a 35-cm high table coinciding with the arrival of a moving target. The timing error of each task was calculated. **Results and Discussion** In the button condition, the timing error was  $0.025 \pm$

0.015 sec in the N-group,  $0.019 \pm 0.005$  sec in the C-group, and  $0.030 \pm 0.022$  sec in the O-group. No significant differences were observed in the timing error in the button condition between the 3 groups. The timing error in the case of the landing condition was  $0.108 \pm 0.039$  sec in the N-group,  $0.071 \pm 0.025$  sec in the C-group, and  $0.077 \pm 0.016$  sec in the O-group. The timing error in the C-group and O-group was significantly lesser than that in the N-group ( $P < 0.05$ ). In addition, the timing error of the button condition was not correlated with that of the landing condition. This result showed that an increase in the motion time influences timing error. Furthermore, simple motion in a coincident timing task, such as a button-press task, cannot be used to evaluate timing skill. Therefore, we concluded that a task with a slightly greater motion time, such as a landing condition, is required to measure timing skill. ### RELIABILITY OF ISOMETRIC PEAK TORQUE AND RATE OF TORQUE DEVELOPMENT OF INTERNAL SHOULDERS ROTATORS MUSCLES IN SWIMMERS

Greco, C.C., Bassan, N.M., Moreira, N.C., Cesar, T.E.A.S.C., Lima, L.C.R., Oliveira, F.B.D., Denadai, B.S.

*Human Performance Laboratory*

Introduction Peak torque (PT) and the rate of torque development (RTD) have been considered important neuromuscular parameters for the evaluation of athletes. In swimming, the internal rotators of the shoulders (ISR) have been considered important during the propulsive phase in front crawl (Pink et al., 1991). However, the information regarding the reliability of these parameters (i.e., PT and RTD) in the literature is lacking. The reliability is essential for experimental conditions such as training and rehabilitation programs. Therefore, the objective of this study was to analyze the reliability of the isometric and isokinetic PT and the RTD of ISR in swimmers. Methods Eight short- and middle-distance swimmers performed the following procedures, in different days, in a dynamometer: 1) Familiarization session; 2) Two identical experimental sessions consisting of two 5-s maximal isometric contractions to determine isometric peak torque (PTI), five maximal concentric contractions at  $60^\circ/\text{s}$  (PTC60) and five maximal concentric contractions at  $180^\circ/\text{s}$  (PTC180) to determine peak isokinetic torque. The RTD was determined during isometric contractions. The reliability of data was analyzed using Student *t* test, intraclass correlation coefficient (ICC) and typical error (TE). The reliability was classified in accordance with ICC values, as poor ( $<0.4$ ), moderate (0.4-0.75) or excellent ( $>0.75$ ) (Fleiss et al., 2003). Results PT values were similar between trials (PTI =  $48.9 \pm 11.0$  Nm and  $47.8 \pm 9.5$  Nm; PTC60 =  $55.5 \pm 10.1$  Nm and  $51.9 \pm 11.3$  Nm; PTC180 =  $55.1 \pm 7.1$  Nm and  $55.7 \pm 10.3$  Nm) ( $p > 0.05$ ). Moderate reliability was found for PT (PTI = 0.71; PTC60 = 0.62 and PTC180 = 0.71), and the TE for PTI, PTC60 and PTC180 ranged between 10.4-14.5%. RTD values were similar between trials ( $177.2 \pm 67.6$  Nm.s<sup>-1</sup> and  $186.1 \pm 85.4$  Nm.s<sup>-1</sup>) ( $p > 0.05$ ). Excellent reliability was found for the RTD (0.94) and the TE was 12.4%. Discussion The main finding of this study was that the isometric and isokinetic PT and RTD of the ISR presented moderate to excellent reliability in trained swimmers. Low to high reliability was reported for concentric PT of ISR (ICC = 0.53-0.98), due to factors such as the degrees of freedom, the subject's position and posture (Edouard et al., 2011). Therefore, caution might be necessary when using PT of ISR data as the basis for individual athlete-related decisions. ### CORRELATES OF WHOLE BODY AND MUSCLE OXYGEN ON KINETICS, PHYSIOLOGICAL VARIABLES AND PERFORMANCE IN SPRINT KAYAK

Oliveira Borges, T.1,2,3, Dascombe, B.J.4, Bullock, N.2,3, Coufts, A.J.1

1. UTS, AUSTRALIA, 2. AIS, AUSTRALIA, 3. AUSTRALIAN CANOEING 4. UNIVERSITY OF NEWCASTLE, AUSTRALIA

Introduction The purposes of the present investigation were to determine the relationships between whole body and muscle oxygen kinetics, physiological variables and performance in 200-m and 1000-m and whether well trained junior sprint kayak athletes with higher maximum aerobic power (MAP) were superior than their lower counterparts ( $n=20$ ,  $17 \pm 1.2$  y). Methods The National Sprint Kayak Incremental step test was performed on a kayak ergometer in the laboratory to determine  $\text{VO}_2\text{max}$ , MAP, power:weight ratio and  $\text{VO}_2\text{peak}$  at lactate threshold ( $\text{VO}_2\text{LT}$ ). A series of square wave tests determined whole body and muscle on kinetics. On-water time trials were completed over 200-m and 1000-m. MAP scores from the laboratory test were used to separate the highest eight (HG) and lowest eight (LG) scores. Results There were large to nearly perfect correlations between performance over 200-m and 1000-m and MAP,  $\text{VO}_2\text{max}$  power:weight and  $\text{VO}_2\text{LT}$ . Moderate correlations were found between the muscle O<sub>2</sub> kinetics at the heavy domain ( $\Delta 50\%$ ) and performance over 200-m and 1000-m. All physiological and performance variables were superior for the HG (100%, certain chance) compared to LG. The O<sub>2</sub> uptake kinetics in the moderate domain (77%, likely) and the muscle O<sub>2</sub> kinetics in the heavy domain (97%, very likely) presented to be superior for the HG. Discussion Our findings demonstrate the importance of the aerobic fitness to sprint kayak performance in both 200-m and 1000-m events. Specifically, the power:weight ratio, MAP and muscle O<sub>2</sub> kinetics in the heavy domain underlie sprint kayak performance in well trained paddlers. The strongest relationship observed with MAP compared all other physiological and performance variables, suggests these characteristics should be developed through specific training. Moreover, the faster muscle O<sub>2</sub> kinetics in the HG, and its moderate relationship with kayak performance in the whole group, suggest that interventions that speed muscle O<sub>2</sub> uptake kinetics are important for developing kayak athletes. Further studies are required to better explore optimal methods for speeding O<sub>2</sub> kinetics and performance in sprint kayak athletes.

### COMPARISON OF BIA AND SKINFOLD PREDICTION OF BODY FATNESS WITH UNDERWATER WEIGHING DENSITOMETRY IN A LONGITUDINAL STUDY ON ADOLESCENT SPRINT ATHLETES

Aerenhouts, D., Van der Aa, E., Deliëns, T., Van Gheluwe, B., Clarys, P.

*Vrije Universiteit Brussel*

Introduction Estimation of body fatness is an important tool in athletic coaching. Sprint athletes are recognized as strength athletes who need to achieve a high power to weight ratio by maximizing muscle mass and maintaining low body fat. During adolescent growth, fat and fat free mass are known to evolve in a sex specific manner. The most accurate estimations of body fatness are achieved with laboratory techniques. However, less accurate but user friendly field methods offer a valuable alternative for follow-up of body fatness by athletics coaches (Norgan, 2005). It was the aim of this longitudinal study to compare field methods (BIA and skinfold based) with underwater densitometry in adolescent sprint athletes. Methods Adolescent sprint athletes (14 girls, 12 boys) were measured every 6 months during 3 years (age at start =  $15.0 \pm 1.1$  yrs in girls and  $15.1 \pm 1.3$  yrs in boys). On all 6 occasions, body fatness was estimated in 3 different ways. Anthropometric data were collected according ISAK guidelines (Marfell-Jones et al., 2006), used to estimate body fatness with the formu-

la of Slaughter et al. (1988). Secondly, BIA body fatness was estimated with the TANITA TBF 410. Finally, as the standard method, body density was measured through underwater weighing and body fatness was calculated with the formula of Siri (1956). Data were analysed with a Repeated Measures MANOVA. Pearson correlations were calculated between the different methods at each occasion. Significance level was set at 5%. Results No gender over time effect was observed during this study ( $P=0.181$ ). In both genders, mean values of body fatness according the skinfold formula and BIA evolved differently from the underwater weighing method ( $P=.012$  and  $P=.021$ , respectively). In girls, the skinfold formula and BIA correlated comparably with the underwater weighing method, with  $r$  ranging between .30 (non-significant) to .77 ( $P<.001$ ). In boys, the skinfold formula showed the strongest correlations with the underwater weighing method with  $r$  ranging between .32 (non-significant) to .64 ( $P<.001$ ). Discussion In both genders the field methods showed a different evolution of body fatness with the underwater weighing method which was considered as the standard. Moreover, low to moderately high correlations indicate important differences with the underwater weighing method at the individual level, especially in boys for the BIA method. Therefore, when using field methods to assess body fatness in adolescent sprint athletes, it is advised to additionally perform a laboratory measurement on a regular basis, which can be considered as a reference. ### EFFECT OF ISCHEMIC PRECONDITIONING ON LAND BASED SPRINTING IN TEAM SPORT ATHLETES.

Gibson, N.

*heriot-watt university*

**Introduction** The study aimed to assess whether exposure to ischemic preconditioning (IPC) in a trained population would affect land based maximal sprinting performance over 30 m. **Methods** Twenty five well trained participants regularly involved in invasion type team sport events were recruited to take part in a randomised crossover study design. Participants underwent both an IPC and placebo treatment involving three periods of 5 min occlusion applied unilaterally (3 x 5min occlusion to each leg) at either 220 mmHg or 50 mmHg respectively. Each period of occlusion was followed by 5 min reperfusion. Following treatment three maximal sprints over a distance of 30 m were undertaken from a standing start interspersed with one minute recovery. Split times were recorded at 10, 20 and 30 m. Results No significant effects of the IPC treatment were observed on sprint speed ( $P<0.05$ ) at any of the split timings. Additional calculated effect sizes of the treatment were found to be small ( $ES<0.2$ ). **Discussion** Results from the present study suggest there to be no benefit to team sport players in utilising IPC as a means of enhancing sprint performance over a distance of 30 m. Whilst IPC has been shown to be beneficial to sprint activities in other sports such as swimming, further research is required to elucidate whether this is the case over distances associated with land based events in track and field and/or in events reliant on repeated sprint ability.

### SPORTS-SPECIFIC FEATURES OF SOCCER PLAYERS' HEART

Olm, T., Baskin, K., Herde, K.

*Tallinn University*

**Introduction** Physical training induces adaptations which affect all of the heart. Sports-specific adaptive cardiac structural changes are still under debate. The aim of this study is to determine the effect of intermittent high intensity exercise of moderate duration on the heart. **Methods** The subjects were 209 professional soccer players. In the first group ( $n=127$ ) the average age was  $19.2\pm 1.2$  and in the second group ( $n=82$ )  $24.6\pm 2.9$  years. As a part of the routine testing the echocardiography was performed using GE Vivid E/9. The t-test and correlation coefficients were calculated. Results Only 3 averages in the two groups – age, body mass and training age – differ with statistical significance. However, we can observe some tendencies of differences. All mean indices in the older group were greater: AO by 2.8%, LA size by 2.1%, LVIDd by 3.8%, IVSd by 3.4%, LVPW by 3.0% and SV by 8.3%. Older athletes had more measures similar to or higher than the substandards: LA $\geq 3.6$  cm (in 7.3% of the members of the group); LVIDd $\geq 6.0$  cm (6.1%; vs. 3.2% of the younger players); IVSd $\geq 1.5$  cm (4.9%; vs 3.9%); LVPW $\geq 1.5$  cm (3.7%; vs. 1.6%). **Discussion** Comparing the echocardiographic means of the two groups we confirmed that AO and LA were greater in the adult group. High endurance sports requiring rapid accelerations, such as soccer, result in increases in LA dimension. But considerable LA enlargement ( $>4.5$  cm) was rare ( $<2\%$ ). Our athletes' largest LA size was 3.8 cm. The most frequent cause of the exercise-related cardiac arrest in young athletes is HCM. Large-sample studies have shown that a significant proportion of endurance athletes exceed the 'normal upper limit' (5.5 cm) for LV. Among high level athletes from different sports, the LV diameter was measured to be 6.0 to 7.0 cm. This kind of eccentric hypertrophy exists in 6% of endurance athletes (Whyte et al., 2004). We have the same percentage in the older group but the greatest measure was 6.1 cm. Concentric type myocardial hypertrophy, common to strength/power sports, is characterized as an increase in LV mass with an augmented relative wall thickness ( $RWT>0.42$ ). Our biggest RWT value in the younger group was 0.40. SV was significantly greater in older athletes, as a testimony of a better functional state. **Conclusion** We can conclude that soccer's sports-specific influence on the heart produces 'symmetric remodelling', an adaptation where both the dilatation and the wall thickening of the chamber occur moderately. Rapid heart development ends by 21 years, the most changeable part of the heart in older soccer players is the left ventricle. **REPEATED SPRINT ABILITY AND STRIDE KINEMATICS ARE ALTERED FOLLOWING AN OFFICIAL MATCH IN NATIONAL-LEVEL BASKETBALL PLAYERS**

Delextrat, A.

*Oxford brookes university*

Recent studies have shown evidence that fatigue may occur during basketball match-play. It is well documented in other sports that fatigue alters biomechanical parameters and stride kinematics during sprinting, which could negatively affect performance and possibly predispose the athlete to injury in the latter stages of a competition. Therefore, the purpose of the present study is to investigate the effects of fatigue induced by playing an official national-level basketball match on repeated sprint ability (RSA) and stride kinematics. Nine male starting basketball players (22.8±2.2 years old, 191.3±5.8 cm, 88.0±10.3 kg, 12.3±4.6% of body fat) volunteered to take part. Six repetitions of maximal 4-s sprints were performed on a non-motorised treadmill, separated by 21-s of passive recovery, before and immediately after playing an official match. Fluid loss, playing time, and the frequencies of the main match activities were recorded. The peak, mean, and performance decrement for average and maximal speed, acceleration, power, vertical and horizontal forces, and stride parameters were calculated over the six sprints. Differences between pre- and post-match were assessed by student t-tests. Significant differences between pre- and post-tests were observed in mean speed (-3.3%), peak and mean horizontal forces (-4.3% and -17.4%), peak and mean vertical forces (-3.4% and -3.7%), contact time (+7.3%), stride duration (+4.6%) and stride frequency (-4.0%), ( $P < 0.05$ ). In addition, the variation in several RSA parameters, such as peak and mean speed, peak and mean acceleration, mean power, and peak and mean vertical force were significantly correlated to fluid loss and sprint, jump and shuffle frequencies ( $P < 0.05$ ). These results highlight that the impairment in repeated sprint ability depends on the specific activities performed, and that replacing fluid loss through sweating during a match is crucial. **ECCENTRIC OVERLOAD BY INERTIAL RESISTANCE TRAINING: EFFECTS ON PATELLAR TENDINOPATHY AND MUSCLE POWER IN JUMPING SPORTS**

Gual, G., Fort-Vanmeerhaeghe, A., Romero-Rodriguez, D., Tesch, P., Costa, L.

*Universitat de les Illes Balears*

Introduction Patellar tendinopathy has an elevated prevalence in jumping sports such as volleyball and basketball (Lian et al, 2005; Swerver et al, 2011). Given the scientific evidence provided during the last decades concerning the therapeutic benefits of eccentric training (Larsson et al, 2012) and the scarcity of research focused on the prevention of this injury, we aimed to investigate the effects of a weekly eccentric training program by inertial resistance in the prevention of patellar tendinopathy and lower limbs muscle power. Methods Four male and four female basketball and volleyball teams participated in this study, and were randomly assigned to either the intervention group (IG) or the control group (CG). IG and CG performed during the whole session their planned sport program, while we added a weekly session of eccentric overload by inertial resistance to the IG. Data from patellar tendinopathy questionnaire (VISA-p), vertical counter-movement jump (CMJ) test and squat power test were recorded during three assessment times (T1, T2 and T3). Results Results showed no differences between groups neither in terms of patellar tendinopathy injury incidence nor VISA-p questionnaire. Female IG improved both the CMJ test (T1 vs T2 and T1 vs T3,  $p < 0.05$ ) and the squat power test (T1 vs T3,  $p < 0.05$ ). Male IG improved the squat power test either in T1 vs T2 and T1 vs T3 ( $p < 0.05$ ), while male CG improved the CMJ test only in the T2 vs T3 comparison ( $p < 0.05$ ). Discussion On the basis of this experimental study we conclude that a weekly eccentric overload squat training improves lower limbs muscle power in jumping sports. This training program does not worsen patellar tendon pain and/or function, but non-positive effects have been registered on injury prevention when comparing to a CG. Besides this, it is also important to mention that the improvements derived from this training program seem to be larger in women when comparing to men athletes. **THE EFFECT OF HEAVY VS. MODERATE-LOAD TRAINING ON STRENGTH, JUMP HEIGHT AND ACCELERATION PERFORMANCE.**

Mora Custodio, R., Yáñez-García, J.M., Rodríguez-Rosell, D., Pareja-Blanco, F., González-Badillo, J.J.

*Universidad Pablo de Olavide*

Introduction From the various training variables, it appears that training intensity is the most important variable to consider when designing a resistance training (RT) program [1]. It is not clear which intensity produces greater neuromuscular performance improvement [2]. Therefore, the aim of this study was to analyze the effect of two type of RT with different intensities and equal volume on muscular strength, jump height and sprint performance. Methods Thirty-two physically active women (age: 21.3±1.7yr, height: 1.65±0.07m, body mass: 61.2±9.7kg) were randomly assigned in three experimental groups: high load group (HLG; n=10), moderate load group (MLG; n=14) and control group (CG; n=8). Training involved two sessions per week for 12wk in which subjects performed full squats (SQ) with 65-80%RM (HLG) or 40-60%RM (MLG) with 4-6rep/set. Both groups performed the same volume. The variables measured were counter-movement jump (CMJ), 1RM\_SQ and acceleration capacity in 10 and 20m (T10, T20, T10-20). A related-samples t-test was used to analyze

within-group pre-post changes. The differences between groups were assessed using an analysis of covariance (ANCOVA) with the contrast F of Bonferroni. Significance was accepted at  $P \leq 0.05$ . Effect sizes (ES) were calculated using Hedge's *g*. Results Significant improvements were found in all variables for MLG whereas HLG obtained significant enhancement only in T10 and RM\_SQ. Any variable showed changes for CG. Although only the RM\_SQ showed significant differences between training groups, ES indicates that the magnitude of change in each measured variable was higher for MLG than HLG. MLG showed significantly greater improvements than CG in T20, T10-20 and RM\_SQ, whereas HLG obtained higher increases than CG only in RM\_SQ. Discussion The main finding of this study was that MLG achieved higher improvements in performance than HLG. Other works have analyzed the effects of different intensities but they have used different volume [2] or exercise [3]. Therefore, in our study, when RT was performed with the same volume produces greater performance improvement with moderate intensities (40-60%RM) than high intensities (65-80%RM) in women physically active. ### ANTHROPOMETRIC PROFILE OF GERMAN ELITE ATHLETES

Araújo, M.C.1, Mießen, K.A.M.1, Baumgart, C.1, Freiwald, J.1

1: Research Center for Performance Diagnostics and Training Advice - FLT (University of Wuppertal, Germany)

**Introduction** An association between competitive success and physique attributes has been observed in many sports [1], further the anthropometric profile differs between athletes of different sports [2;3]. Reference data of elite athletes may contribute to a better understanding of the specific demands of a sport as well as to monitoring training regimens. Therefore, the aim of this study was to provide a comparative profile of German elite athletes of four distinct sports. **Methods** Seventy-five athletes participated in the study, composing the following groups: Soccer First League (A), Soccer Fourth League (B), Handball First League (C), German National Teams of Beach Soccer (D) and Roller Hockey - Quad (E). After measurement of stature (S) and total body mass (TBM), tetrapolar bioelectric impedance analysis (BIA) was performed (Bodystat QuadScan 4000, version 2/02, GB) in a supine position within 10 min rest. Body mass index (BMI), percent body fat (%F) and total body water (%TBW) as well as body cell mass (BCM) were then determined. Differences between groups were calculated using ANOVA, with Bonferroni post-hoc test. Statistical significance was set at  $p \leq 0.05$ . **Results** Results are presented as mean for each group. A:  $n=18$ ,  $S=1.82$  m,  $TBM=79.5$  kg,  $BMI=24.0$ ,  $\%F=10.3$ ,  $\%TBW=63.4$ ,  $BCM=40.4$  kg. B:  $n=22$ ,  $S=1.82$  m,  $TBM=76.8$  kg,  $BMI=23.1$ ,  $\%F=10.6$ ,  $\%TBW=62.7$ ,  $BCM=38.2$  kg. C:  $n=16$ ,  $S=1.90$  m,  $TBM=93.9$  kg,  $BMI=26.0$ ,  $\%F=13.1$ ,  $\%TBW=60.6$ ,  $BCM=46.3$  kg. D:  $n=7$ ,  $S=1.79$  m,  $TBM=76.2$  kg,  $BMI=23.7$ ,  $\%F=12.2$ ,  $\%TBW=61.3$ ,  $BCM=38.2$  kg. E:  $n=12$ ,  $S=1.79$  m,  $TBM=78.1$  kg,  $BMI=24.4$ ,  $\%F=12.2$ ,  $\%TBW=61.5$ ,  $BCM=39.3$  kg. Compared to all other groups C has significantly higher values for TBM ( $p<0.001$ ), S ( $p\leq 0.004$ ), BMI ( $p\leq 0.038$ ) and BCM ( $p\leq 0.001$ ), as well as for %F only in comparison to group A ( $p<0.045$ ). There are no significant differences between other groups. **Discussion** Although there seems to exist a determined profile for elite athletes, anthropometric and body composition characteristics may be more specific to certain sports such as handball in this case. Further research should investigate whether these differences are also reflected in distinct strength, power or endurance performances parameters. Moreover, the variables studied here were not able to differentiate competitive levels in German soccer, in contrast to results for Italian soccer players [2]. **References** [1] Tanner, R. **Introduction** The best-suited protocols for preparatory exercises aimed to improve performance in competitive situations are not well described in the literature. Thus, the aims of this study were: I) to evaluate the effect of 4 different preparatory exercises (PEs) on vertical countermovement jump (VCMJ) performance; and II) to verify the effect of participation in a volleyball game on the performance of 4 blocking-specific jumps. **Methods** The study was divided into two phases. The first phase included 9 female volleyball athletes ( $15.4 \pm 0.5$  yrs) and examined the effect of the athletes carrying out 4 PEs (stretching [ST] leg cycloergometer [Bike], leg-press resistance exercise [RE], and specific vertical jump [VJ]; in a random order) for 5 days on their subsequent VCMJ performance (contact carpet). The second phase included 12 female professional volleyball athletes ( $23.1 \pm 3.2$  yrs) who were tested before and after a friendly game to determine the effect of the game on their performance of 4 different blocking-specific jumps (stopped blocking [SB], cross-blocking [CB], last blocking without jump [LB], and last blocking with jump [LBJ]). **Results** Among the PEs assessed (first phase), VJ led to the best VCMJ performance. The second phase showed that, while SB and LB were not changed after the game, CB and LBJ performance was increased. The specific PE (VJ) led to better VCMJ performance than did the non-specific PEs. Volleyball game increased performance only for the blocks with stretch-shortening cycle [SSC] movements. **Discussion** Specific pre jumping exercises appear to be effective producing enhancement during training and games, but other methods of preparation may also be applied as a complementary manner. Using ST as a PE did not impair the height of VJ. The height of VJ was increased after athletes performed 3 sets of RE. In addition, after performing VJ, the VCMJ performance was improved. Strojnik and Komi (1998) reported potentiation effects after SCC jumps, showing increased explosive power. It may suggest that this type of PE is useful before competitions to improve the performance. We showed that among PE used, VJ is the best for improving VCMJ performance and, only block jumps with SSC are improved after the game. **References** Strojnik, V., Komi, P. V. (1998) Neuromuscular fatigue after maximal stretch-shortening cycle exercise. *Journal Appl Physiol* 84, 344-350.

### AGE-RELATED DIFFERENCES IN PHYSIOLOGICAL CHARACTERISTICS OF FEMALE GYMNASTS AGED 5-13 YEARS OLD.

Theos, A., Ioannidi, V., Giannopoulos, A., Moustogiannis, A., Savvadi, A., Maridaki, M.

University of Athens

**Introduction** Anthropometric and physiological characteristics influence sport performance especially in children (Focke et al. 2013, Nedeljkovic et al., 2007). The aim of the present study was to investigate differences in physiological characteristics of female gymnasts of a large age range. **Methods** One hundred sixty eight female gymnasts were separated in four groups according to their age. Group 1

(G1) consisted of 41 girls (age:  $6.7 \pm 0.4$  yrs, height:  $119.9 \pm 8.4$  cm, weight:  $24.6 \pm 5.9$  kg), group 2 (G2) of 43 girls (age:  $8.5 \pm 0.5$  yrs, height:  $125.8 \pm 18.8$  cm, weight:  $28.7 \pm 5.4$  kg), group 3 (G3) of 53 girls (age:  $10.5 \pm 0.5$  yrs, height:  $139.6 \pm 7.5$  cm, weight:  $35.4 \pm 6.4$  kg) and group 4 (G4) of 31 girls (age:  $12.2 \pm 0.4$  yrs, height:  $149.2 \pm 7.9$  cm, weight:  $44.2 \pm 9.5$  kg). Flexibility (sit & reach test), arm strength (handgrip) in the dominant hand, lower limb strength (squat jump) and agility (agility T-test) were measured. Data were analyzed using ANOVA and results are presented as mean  $\pm$  SD. Results Agility differed significantly among groups (G1:  $19.4 \pm 3.8$  sec, G2:  $15.9 \pm 1.7$  sec, G3:  $15.3 \pm 3.7$  sec, G4:  $13.7 \pm 1.7$  sec,  $p < 0.001$ ) and so did arm strength (G1:  $3.0 \pm 3.3$  kg, G2:  $6.1 \pm 3.5$  kg, G3:  $9.7 \pm 4.1$  kg, G4:  $13.9 \pm 5.7$  kg,  $p < 0.001$ ) and lower limb strength (G1:  $19.0 \pm 7.7$  cm, G2:  $25.2 \pm 6.8$  cm, G3:  $29.5 \pm 6.6$  cm, G4:  $34.1 \pm 8.9$  cm,  $p < 0.001$ ) On the other hand flexibility did not differ significantly among groups (G1:  $25.1 \pm 5.9$  cm, G2:  $25.2 \pm 6.0$  cm, G3:  $26.8 \pm 6.6$  cm, G4:  $27.1 \pm 7.7$  cm,  $p = 0.38$ ). Discussion The results of the present study indicate that age has a significant impact on agility and strength of female gymnasts, while it doesn't seem to impair flexibility. ## COMPARISON OF PERCENTAGE OF MUSCLE MASS AND NEUROMUSCULAR PERFORMANCE BETWEEN U15 AND U17 SOCCER PLAYERS

Franciscon, C.A., Spigolon, L.M.P., Medeiros, E.M., Gongora, A., Rossini, F., Mathias, F.H., Borin, J.P.

*Desportivo Brasil Participações Ltda*

Introduction In forming young soccer player, periodic evaluations provide important information for monitoring their performances. This is with body composition, muscle mass percentage and neuromuscular performance, monitored to identify changes related to motor actions that are important in this sport. The present study aimed to evaluate and compare the percentage of muscle mass with the performance of the neuromuscular system of categories of soccer players U15 and U17. Methodology 30 athletes participated in the U15 category ( $14.79 \pm 0.48$  years,  $176.88 \pm 6.01$  cm,  $64.06 \pm 6.41$  kg) and 25 in the U17 category ( $16.76 \pm 0.59$  years,  $180, 19 \pm 6.96$  cm,  $71.86 \pm 5.99$  kg) with two years of training experience. Measurements were made of their percentage of muscle mass (% MMusc) (Martin et al, 1990), their neuromuscular performance, a sprint of 10m (T10M) (photocells Speed Test Fit - Cefise ©) (Svensson, Drust, 2005) and a counter-movement jump (CMJ) (Jump Test - Cefise ©) (Bosco, 1983). The Shapiro-Wilk verified the data normality and variance by ANOVA complemented by Tukey test with significance level of  $p < 0.01$ . Results For MMusc% (U15 =  $40.77 \pm 5.71\%$  and U17 =  $46.19 \pm 5.38\%$  -  $\Delta\% = 11.73\%$ ) and CMJ (U15 =  $45.30 \pm 4.78$  cm and U17 =  $49.97 \pm 5.94$  cm -  $\Delta\% = 9.35\%$ ), there were significant differences between the two categories. As for the T10M, no difference. Discussion The differences for MMusc% from the perspective of biological time (maturation index, U15 =  $1.47 \pm 0.60$  and U17 =  $2.83 \pm 0.56$ ) (Mirwald et al, 2002), favors the morphological changes that are positive in the U17, due to the same training of higher volume of activities that stimulated the increase of muscle mass. As for CMJ, coordinative changes linked to biological time, may explain part of the difference in performance of this variable, in addition to the content of the training U17 present similarity with the action performed on the test. No differences on the T10M. Some variables may not be explained only by biological questions, and body workout, but by motivational factors and interactions of biomechanics and kinematics, beyond the type of muscles fiber recruitment, frequency and speed of stimuli and fatigue level. ## RELATIONSHIPS BETWEEN VO2MAX, MUSCULAR PERIPHERAL OXYGENATION AND FATIGUE INDEXES DURING A REPEATED-SPRINT EXERCISE

Ahmaidi, S., Jabbes, M.W.

*Picardie Jules Verne University*

This study aimed to examine the relationships between the main components of the aerobic fitness (i.e., VO<sub>2</sub>max, muscle deoxygenation level, muscle reoxygenation rate) and the main fatigue indexes (i.e., RSE% distance decrement, [La]-[blo], RPE) during a repeated sprint exercise (i.e., RSE). It was hypothesized that the peripheral aerobic fitness indexes will be the most correlated to the RSE fatigue indexes. Fourteen moderately trained males subjects ( $23.4 \pm 2.6$  years) took part to this study. All the participants performed, in a random order, a maximal progressive aerobic test VamEval to obtain their VO<sub>2</sub>max and a repeated sprint exercise (2 series 15-s all out 20 meters shuttle-sprints, interspersed with 15 sec of passive recovery). The total distance covered (TD), RSEdec%, [La]-[blo], and RPE were retained. Through the sprints, muscles deoxygenation levels and during the recovery, the reoxygenation rates were assessed with near-infrared spectroscopy on the Vastus Lateralis. Results showed the absence of relationships between VO<sub>2</sub>max and the RSE fatigue indexes. However, muscular deoxygenation levels and reoxygenation rates were highly correlated to the %RSEdec, [La]-[blo] and TD (%RSEdec :  $r = 0.86$  ; very large ;  $p < 0.01$  and  $r = 0.65$  ; Large ;  $p < 0.05$  respectively; for [La]-[blo] :  $r = 0.68$  ; large ;  $p < 0.05$  and  $r = 0.70$  ; very large ;  $p < 0.05$  respectively ; TD :  $r = 0.87$  ; very large ;  $p < 0.01$  and  $r = 0.62$  ; large ;  $p < 0.05$  respectively). It was concluded that the muscle oxygenation parameters as the reoxygenation rate and particularly the deoxygenation level, were the main aerobic fitness components which were related to the fatigue and therefore to the performance during a repeated sprint exercise

## THE FEASIBILITY OF USING PERCEIVED EXERTION TO ESTIMATE MAXIMAL HEART RATE

Mamen, A., Fredriksen, P.M.

*University College of Health Sciences-Campus Kristiania*

The linear relationship between work load, heart rate (HR) and Borg Rating of Perceived Exertion (RPE) may be used to estimate maximal heart rate from submaximal exertion. Johnson and Prins (1991), using multiple regression on data from one hundred persons exercising on a modified Balke protocol found that RPE estimated HR<sub>max</sub> was more accurate than the traditional 220-age formulae. To further investigate this, we had 41 subjects to perform a step protocol with five minutes step durations until a blood lactate concentration of 4 mmol/L was reached. RPE and HR were recorded at the end of each stage. After a short rest period, the subjects performed a maximal oxygen uptake test and the maximal HR was recorded at the end of the test. Using linear regression for each individual's submaximal HR and RPE data set, the RPE at the measured HR<sub>max</sub> was found by extrapolation. The mean (SD) RPE value at the measured HR<sub>max</sub> was 18.3 (0.8). Using this value on all subjects, the standard deviation of the estimated HR<sub>max</sub> was 6.8 beats pr. minute and the bias (difference between measured and estimated values) 1.1 beats pr. minute. Using the 220-age formulae, the standard deviation was 5.8 beats pr. minute, but the bias was -5.2 beats pr. minute. These results indicate that using submaximal RPE to predict individual maximal HR is

feasible, but do not offer any clear advantages over using 220- age. References: Johnson, J.H., and Prins. Prediction of maximal heart rate during a submaximal work test. *Journal of Sports Medicine & Physical Fitness*, 1991 (31) 1,44-47.

#### O2 DESATURATION AT MODERATE ALTITUDE: COMPARAISON BETWEEN RUNNING AND ROLLER SKIING FIELD TEST

Gaston, A.F., Hapkova, I., Durand, F.

*Performance Health and Altitude laboratory*

Introduction Biathlon is an endurance sport whose the offseason training consists of running (R) and roller ski (RS) exercises at moderate altitude. Exercise induced hypoxemia (EIH) can develop in highly trained endurance athletes in terms of exercise mode, muscle mass involved in the exercise (Rasmussen et al., 1991) and the altitude (Powers, 1993). Yet EIH decreases performance, so the structures with competitive biathletes must master this phenomenon. That's why this study compares EIH development and cardio-respiratory responses, in younger highly trained biathletes, at moderate altitude, during running and roller ski field tests. Methods 9 younger highly trained biathletes (2 women and 7 men, 15.3±1.5 years) living and training at moderate altitude participated. They performed two incremental maximal field tests R and RS, at 1850 meters altitude. EIH (hemoglobin O2 saturation (SpO2) decreased ≥4% from baseline) was measured indirectly using an ear-lobe pulse oximeter included in the K4 (Cosmed) used for measured cardio-respiratory responses. Results During the R test, 8 athletes developed EIH whereas only 6 in RS test. Tests duration was the same furthermore at the end of tests, delta of SpO2 was significantly higher in R compared to RS (-9.11 ± 1.51 vs -5.89 ± 1.09; p<0.01). SpO2 was significantly lower in R compared to RS from 75% VO2max (p<0.05). VO2max was significantly higher in R than in RS (61.33 ± 6.36 vs 57 ± 6.60 ml.min-1.kg-1; p<0.001). No difference of maximal heart rate, global ventilation, tidal volume or respiratory frequency was present during and at the end of tests. Discussion The difference of VO2max main explains by a utilization of muscular fibers II more important during the RS exercise because of the upper body requested (Koppo et al., 2002). The mean transit time may be slightly longer during RS test than during R test because there is a linear relationship between the VO2 and the cardiac output (Qc) (Rasmussen et al., 1991). Furthermore if the Qc is higher during R test compared to RS test, lung blood pressures are more important causing higher pulmonary capillaries stretching or/and break (West et al., 1995). Better O2 pulmonary diffusion during RS test and gas exchange abnormality during R test could explain the difference of desaturation between these activities. The present study emphasizes the importance of the upper body training in biathletes for master EIH and the reduction of the performance associated. #### THE EFFECTS OF TWO WEEKS OF SEASON BREAK FOR GAME PERFORMANCE OF SOCCER

Maesako, M., Yasumatsu, M., Nakamura, D.

*Rikkyo University*

Introduction: It is well known that the ability to perform in high-intensity activities throughout the soccer game is very important (Iaia et al, 2009), and this ability decreases during season break (Bangsbo, 2007). However it is not cleared how decrease the game performance after season break. The aim of this study was to examine the effects of two weeks of season break for game performance of soccer. Method: Subjects are 26 trained soccer players who belong to two university (age 21.8±0.7 years, height 175.4±3.4 cm, body mass 66.0±3.5 kg). They were analyzed by 2 competitive games, the last game of the season (GAME1), and after 2 weeks of GAME1 almost under the same condition. GAME1 and GAME2 were recorded by 3 cameras (2 fixed and 1 operated) so the whole soccer field is covered. We used the manual tracking system (Track Performance, sportstec). The following active categories were used: standing (0-2 km·h-1), walking (2-7 km·h-1), jogging (7-9 km·h-1), low-speed running (9-13 km·h-1), moderate-speed running (13-16 km·h-1), high-speed running (16-22 km·h-1), sprinting (>22 km·h-1), and high-intensity running, consisting of moderate-speed running, high-speed running, and sprinting (> 13 km·h-1) (Randers et al, 2010). Also, The Yo-Yo Intermittent Recovery test level 2 (Yo-Yo IR2) was tested after 3 days from GAME1 and 4 days from GAME2, respectively. Results: The total distance covered of GAME2 (9.7±0.18 km) was shorter than of GAME1 (10.4±1.14 km). The distance covered with sprinting was 22.9% less (P<0.01) in GAME2 than in GAME1 (0.89±0.25 km vs. 0.52±0.24 km). The distance covered by high-speed running of GAME2 (1.46±0.36 km) was lower than of GAME1 (1.85±0.47 km). The distance covered with high-intensity running of GAME2 (2.82±0.71 km) was shorter than of GAME1 (3.50±0.85 km). Yo-Yo IR2 performance was 18.2% less in GAME2 than GAME1 (850±108m vs. 695±77m). Discussion: The total distance covered during a game was 7% less in GAME2 than in GAME1, on the other hand, the distance covered with high-intensity exercise such as high-speed running, sprinting, high-intensity running was 19.9%, 22.9%, 17.6% less, respectively. Also the Yo-Yo IR2 performance remarkably decreased (18.2%) from GAME1 to GAME2. These data suggest that 2 weeks season break effects to physical performance during soccer game, especially in high-intensity exercise, which is a very important factor in a soccer game. #### A CROSS-SECTIONAL STUDY TO EVALUATE THE SPECIFIC STRENGTH IN WOMEN WATER POLO PLAYERS

Moises, V.I, Solé, J.I, Padullés, J.M.I

*INEFC*

INEFC-UB (Barcelona, Spain) Introduction: The aim of the study was to evaluate the different manifestations of strength in water polo women players of several ages: throwing speed, swimming strength, defense strength, the maximum vertical jump height and the

maintained jump height. Method: Twenty-five women players of different categories and belonging to the Spanish Selection of Water polo took part in the study. The tests used were: the fight strength by means of backward pushing (center offensive), forward pushing (center defensive) and swimming strength. A rubber band connected to the strain gauge of the Musclab 4000e (ErgotestTM, Norway) was used for that purpose. The velocity of throwing was measured by means of the Radar Stalker Pro (Applied Concepts Inc., Flat Texas, TX, USA) in two different situations, that is, a throw without the goalkeeper and a throw demanding accuracy. In both situations two different throwing techniques were used. The height of vertical jump and that of the maintained jump were also measured with a camcorder (Casio ComputerCo., Ltd EXILIM High speed EXFC 100, Tokyo). Results: The results obtained in the test of fight strength are summed up next: backward pushing: 94,2, 134,4 and 8,7 N and forward pushing: 97,1, 116,7 and 133,7 N (14,15, 17 years old, respectively). The results of swimming strength: 97,2, 134,9 and 152,2 N (14,15, 17 years old, respectively). The values obtained in the jump tests are the following: maintained jump height: 0,19, 0,21, 0,22 m and vertical jump height: 0,59, 0,64 and 0,69 m (14,15, 17 years old, respectively). The results of throwing velocity without goalkeeper were: 50, 2, 53,5 and 55,9 km/h (technique 1) and 50,1, 53,3 and 56 km/h (technique 2) (14,15, 17 years old, respectively). Finally, the results of the throw demanding accuracy are: 45,7, 51,3 and 54,7 km/h (technique 1) and 46, 51 and 53,9 km/h (Technique 2). Discussion: The results of this study in throwing velocity go hand-in-hand with the ones obtained by Platanau (2011) (56 vs 59 km/h). The values obtained in the jump height are slightly higher than the ones presented by Platanau (2011) (0,61 vs 0,69 m). With regard to the swimming strength, our results are also higher than those obtained by Stain A. et al 2009 (117,8 vs 152,2). It is not possible to find any written data with which to compare the fight strength and maintained height values since these are new protocols of evaluation in water polo. We consider that they can complement and give a more accurate evaluation of the different manifestations of strength which are given in the game. Finally, we would like to stress that some of the subjects of this sample were medalists in the 2012 London Olympics. References: Platanou, T. (2011). *J S Med Phys F*, 51 (2), 185-93. ### THE RELATIVE AGE EFFECT AMONG ELITE YOUTH MALE TENNIS PLAYERS

Ulbricht, A.1, Fernandez-Fernandez, J.1, Mendez-Villanueva, A.2, Ferrauti, A.1

*1Department of Training and Exercise Science, Faculty of Sports Science, Ruhr-University Bochum, Germany; 2 ASPIRE Academy for Sports Excellence, Doha, Qatar*

Introduction Research in different sports has shown that athletes born early within the selection year are more likely to be part of elite teams and talent development programs. This overrepresentation of older athletes in youth sport has been labeled as the relative age effect (RAE). The purpose of this study was to identify the existence of RAE at youth level in tennis and to analyze if anthropometric and fitness characteristics vary according to birth date distribution. Methods Birth dates of all male players affiliated to the German Tennis Federation born from 1993 to 2000 (n = 120851), including players with official ranking in the under-18 ranking list (n = 7165) and a group defined as "regional selection" (n = 381) (i.e., comprised the most talented players), were analyzed. A third group, "national selection" (n = 57) (i.e., best of regional players selected by the national coaching staff), as well as the first 50 senior players of the national ranking were also analyzed. Moreover, 348 players of the regional selection participated in an anthropometrical (height, weight) and physical (grip strength, counter movement jump, 20m sprint, serve velocity and hit & turn test) testing. Results RAE was found across all age categories and selection levels. We found more players born in the first half of the year for senior (56%), ranked (54.4%); regional (65.1%) and national (70.2%) selection of players, and no bias towards the cut off day for all listed players (49%). Comparing fitness characteristics of players born across different quarters of the year, we were not able to find major differences in any of the characteristics analyzed. Discussion Results show that season of birth bias exists in the selection of youth tennis players in Germany, and suggest that selection level is an important factor regarding the strength of RAE. Present findings do not support the hypothesis that players who are born later in the selection year are likely to differ across a range of anthropometric and fitness attributes, and suggest that the relative age of the tennis player may not always be linked to a significant advantage in physical performance. The relative importance of physical qualities compared to technical and tactical skills in tennis may explain the present results. References Delorme N, & Raspaud M. *Scand J Med & Sci Sports*. (2009) 19: 235-242. Carling C, et al. *Scand J Med & Sci Sports*. (2009) 19: 3-9.

### FINE AND GROSS MOTOR SKILLS IN WATER POLO PLAYERS – JUNIORS AGED 14 TO 15 YEARS OLD

Marinescu, G.1, Bota, A.1, Bălan, V.1, Ticală, L.D.1, Moscaliuc, C.2, Hortopan, C.V.3, Zamfir, V.M.4, Timofte, D.1, Pană, G.1

*1UNEFIS (Bucharest, Romania), 2DJST (Suceava, Romania), 3UPB (Bucharest, Romania), 4UCDC (Bucharest, Romania)*

Introduction The water polo game counts among the sports disciplines where acyclic movements are predominant. It doesn't simply mean swimming, but also a great number of other specific movements performed in horizontal and vertical positions, technical elements and procedures with and without the ball, with and without an opponent, all these indicating the game complexity. This complexity should be found in the specific training. Methods In the present study, we administered the Bruininks-Oseretsky Test Battery, second edition (BOT-2). This variant provides the psychomotor proficiency most objective evaluation. The tested subjects are members of two water polo teams – Juniors (14 to 15 years old). 24 players were tested. BOT-2 uses components that are organized around the two motricity types (fine motricity and gross motricity), as well as around the different coordination types. Results In subtest 3 (Manual Dexterity), the scale score shows that 80% out of the tested athletes fall within the investigated population mean and only 20% are above this mean. In subtest 7 (Upper Limb Coordination), the scale score frames 45% out of the tested athletes within the investigated population mean and 55% above this mean. On the opposite side, there are the results obtained in subtest 4 (Bilateral Coordination), where 75% out of the tested athletes fall under the investigated population mean and only 25% are at a mean level. In subtest 5 (Balance), 60% out of the tested athletes fall under the investigated population mean and 40% are at a mean level. Discussions This test evaluates athletes' psychomotor proficiency beyond the aquatic environment, in order to establish if there is a positive transfer/correlation in the expression of the psycho-motricity specific to the water polo game. The analysis and evaluation of the data obtained in the manual dexterity and the upper limb coordination subtests show a good expression of the arm-performed motor actions (specific to the water polo game). In the bilateral coordination and the balance subtests, the negative results confirm that these components should be equally exerted in the dry land physical training and in that specific to the water environment, both of them conditioning sports performance. ### CHANGES IN METABOLIC PARAMETERS DURING DIFFERENT PHASES OF AN AEROBIC TRAINING IN A TYPE 1 DIABETIC PATIENT.

Casiraghi, F., Benedini, S., Rampichini, S., Luzi, L.

*Università degli Studi di Milano*

**INTRODUCTION** Regular physical activity has been showed to have a multiple health benefits for everyone, including those with T1D (Steppel and Horton, 2003). The hypothesis of this project is to verify the improvement on different metabolic parameters in a T1D patient using an insulin pump with a Continuous Glucose Monitoring System (CGMS) performing a specific aerobic training for a purpose of a 1 month walking (1000 km). **METHODS** A 40 years old T1D patient underwent to an incremental test until exhaustion on a motorized treadmill at the beginning of the training (TEST 1) and after 2 months (TEST 2), we evaluated also the resting energy expenditure by indirect calorimetry and estimated the body composition by bioelectrical impedance analysis. We continuously monitored the glycemic profile for 48 hours via CGMS, on the test-day and the day after. **RESULTS** We registered a small increase in the VO<sub>2</sub> max value (TEST 1= 4417 to TEST 2=4491 ml/min), and an increase in the resting energy expenditure (TEST 1=1680 to TEST 2= 1773 kcal/day). Total body weight decreased (TEST 1 = 86.6 to TEST 2= 85.2 kg) and so did Fat Mass (TEST 1= 9.2 to TEST 2 = 8.6 %). Fat Free Mass plus water remained unchanged (TEST 1= 78 to TEST 2 = 78 kg). CGMS data showed a similar average glucose level in the 2 days considered (TEST 1 = 123 to TEST 2 = 119 mg/dl), and showed a decrease average glucose level during the 2 hours in which the subject performed the test [10 AM – 12 PM] (TEST 1= 143 to TEST 2 = 129 mg/dl). The average daily insulin (U) was lower in the second test (TEST 1= 50.9 to TEST 2=46.2 U), resulted from the sum of average daily basal insulin (TEST 1= 25.9 to TEST 2=27.5 U) and average daily insulin bolus (TEST1 = 25 to TEST2= 18.7 U). The glucose level stayed on target longer in the TEST 2 vs TEST 1 (TEST 1= 58% to TEST 2 = 67%), whereas it remained for a shorter period below and above the target in TEST2 vs TEST1 (below: -3%; above: -6%, respectively). **DISCUSSION** These preliminary data show that an aerobic exercise performed for two months can improve the glycemic/insulin control values and the other metabolic parameters in a T1D patient (Yardley et al., 2012; Lehmann et al., 1997). A simple walking exercise without engaging in any risky high intensity physical activity can have overall beneficial effects on health in a T1D patient. **REFERENCES** Steppel JH and Horton ES (2003) *Rev Endocr Metab Disord.* 2003 Dec;4(4):355-60. ### RELATIONSHIPS BETWEEN RESPIRATORY MUSCLE ENDURANCE, EXERCISE PERFORMANCE AND THE METABOREFLEX ACTIVATION TIME

Ahmaidi, S., Oueslati, F.

*Picardie Jules Verne University*

**Purpose of study:** To assess respiratory muscle endurance by (i) measuring the maximum sustainable ventilation (MSV) and the time limit for constant-load exercise at 90% of maximum aerobic speed (MAS), and (ii) studying the relationships that might exist between these parameters and the time required to activate the metaboreflex TMA (through measurement of the oxygen tissue saturation with near-infrared spectrometry, (NIRS)). **Method:** 11 male, moderately trained adult volunteers participated in the study. All subjects underwent spirometry testing (to determine the vital capacity, forced vital capacity and maximum voluntary ventilation (MVV)) and a VamEval VO<sub>2</sub> max test to determine the MAS and the time limit for constant-load exercise at 90% of MAS, with assessment of gas exchanges (with a COSMED K4b2) and measurement of the oxygenation rate at the vastuslateralis (with NIRS). The kinetics of V'O<sub>2</sub> were modeled, in order to calculate the amplitude of the slow component of V'O<sub>2</sub>. Activation of the metaboreflex was identified as a sudden drop in the tissue O<sub>2</sub> saturation index (TSI). All subjects performed a respiratory muscle endurance test, which was initiated at 20% of the MVV. The ventilation rate was increased by 10% of the MVV every 3 minutes, until the subject could no longer maintain the target ventilation rate (fR) and/or tidal volume. **Results:** We observed a statistically significant correlation between respiratory muscle endurance (MSV/MVV%) and time limit during constant-load exercise at 90% of MAS ( $r = 0.95$ ;  $p < 0.001$ ). The mean amplitude of the slow component of V'O<sub>2</sub> was  $420 \pm 85$  ml/min. Recording the TSI at the vastuslateralis identified a sharp drop in the index of tissue saturation of  $6.69 \pm 5.84\%$ , following by termination of exercise  $130.17 \pm 62.77$  s later. There was also a significant correlation between respiratory muscle endurance and TMA ( $r = 0.83$ ;  $p < 0.05$ ). A relationship between respiratory muscle endurance and the amplitude of the slow component of V'O<sub>2</sub> (A2) was observed but was not statistically significant ( $r = -0.47$ ;  $p < 0.2$ ). **Conclusion:** Respiratory muscle endurance was correlated with TMA and the exercise time limit at 90% of MAS ( $r = 0.95$ ;  $p < 0.001$  and  $r = 0.83$ ;  $p < 0.05$ , respectively). In contrast, respiratory muscle endurance was not significantly correlated with the magnitude of the slow component of V'O<sub>2</sub>.

### RELATIONSHIPS BETWEEN SESSION-RPE, GPS MOVEMENT CHARACTERISTICS, AND HEART RATE DURING TRAINING AMONG ELITE YOUTH SOCCER PLAYERS

Lamb, K.

*University of Chester*

**Introduction** Session-RPE has emerged in recent years as a useful subjective method of quantifying training intensity in elite team sports. When expressed as a product of training duration ('training load'), its validity against objective markers of volume and intensity in soccer has been advocated (e.g. Alexiou & Coultts, 2008; Impellizzeri et al., 2004), but to-date, no study has examined its validity against specific movement characteristics, including distance covered in high intensity activity, quantified via GPS technology. Therefore the aim of this study was to examine the relationships between session-RPE training load, GPS movement variables measures, and an objective heart rate load among elite youth soccer players. **Methods** Following ethical approval 13 elite soccer players, aged 16-18 years ( $182.5 \pm 4.9$  cm,  $77.2 \pm 5.9$  kg) were recruited from a youth soccer Academy in central England. All were monitored during training sessions (mean = 30, range = 23-36) over a two-month period in the 2012 season using 2 Hz Catapult GPS devices and heart rate (HR) telemetry. Following each session, a session-RPE score (Borg CR-10-scale) was obtained from each player and subsequently multiplied by the duration of the session to give a session-RPE training load (S-RPETL). Pearson correlations were computed between six locomotive variables and time spent above 85% HRmax and S-RPE TL for the group as a whole and by playing position (Defenders/Mid-fielders/Attackers). **Results** The GPS-derived variables and time spent above 85% HRmax were found to be significantly ( $P < 0.01$ ) correlated ( $r = 0.33-0.64$ ) with S-RPETL. Notably, following Fisher Z-transformations, four of the GPS variables were related more strongly with S-RPETL than 85% HRmax. Position-specific correlations were typically highest for the Midfielders ( $r = 0.33-0.75$ ) and lowest for the Attackers ( $r = 0.10-0.52$ ), and for all three positions stronger for the GPS variables than the HR variable. **Discussion** These findings provide further support towards the notion that session-RPE TL can be a valid indicator of training load during soccer training, and in the absence of expensive equipment (GPS and HR

monitoring) it could be a surrogate measure for monitoring global training load within elite youth soccer players. Whilst there was some position-related variability in the associations observed, the session-RPE TL method may be useful in the development of suitable training strategies for the whole squad, specific positions or even individuals. Moreover, it appears to provide a better representation of GPS movement characteristics than a relative HR measure. References Alexiou, H, Coutts, A (2008). *Int J Sports Physiol Perf*, 3, 320-30. ### **INFLUENCE OF EXERCISE ON P-WAVE DISPERSION FOR EVALUATING THE INDUCTION OF STRESS-INDUCED PAROXYSMAL ATRIAL FIBRILLATION ON HEALTHY MALES AND FEMALES.**

Garrett, A., Faulkner, A.

*University of Hull*

**INTRODUCTION:** Exercise testing is a useful diagnostic tool for evaluating the induction of stress-induced paroxysmal atrial fibrillation. At rest the P-wave dispersion has been suggested to be greater in males than in females but if the P-wave dispersion is to be used in the clinical arena then any gender difference in response to exercise must be determined. **METHODS:** Sixteen healthy subjects (n=8 male, age: 21±0.3; n=8 female, age: 23±1.4) performed an incremental exercise test using the Bruce protocol. Electrocardiograms were recorded at rest, end exercise, 1, 3, and 5 mins recovery. P-waves were measured in each lead with the maximum (P-max) and minimum (P-min) P-wave durations recorded and P-wave dispersion calculated. ECG's were analysed using an established procedure. **RESULTS:** There was a significant decrease in P-max from rest to end exercise in males and females (males, 118.3±7.4 vs. 97.9±6.2 ms; females, 109.±44.5 vs. 94.3±4.6 ms; p=0.001). This response was seen for P-min (males, 65.6±3.3 vs. 50.8±2.7 ms; females, 58.4±3.3 vs. 45.6±2.7 ms; p=0.01). Irrespective of gender there was no significant change in P-wave dispersion in response to exercise. Males had a significantly longer P-max compared to females during the protocol (109.±62.3ms vs. 103.6±1.8ms; p=0.03) but this was not stage specific. There was no significant gender differences in either P-min (p=0.12) or P-wave dispersion (p=0.64) across the protocol or stage specific. **DISCUSSION:** The results from this study indicate that in contrast to P-max and P-min, the P-wave dispersion may not be significantly influenced by the sympathetic nervous system in males and females. Therefore, males and females should be evaluated in the same way when using the P-wave dispersion for predicting the development of stress-induced paroxysmal atrial fibrillation during clinical exercise testing.

### **ANALYSIS OF ACE, ACTN3, ENOS, PPARG, PPARA, HIF1A, PPARGC1B GENE POLYMORPHISMS FOR DETERMINATION OF A GENETIC PREDISPOSITION TO A VARIETY OF SPORTS**

Drozdovska, S.1, Dosenko, V.2, Stroy, D.2, Ilyin, V.1

*NUPESU (Kiev, Ukraine), BIPh (Kiev, Ukraine)*

**Introduction** Effectiveness of athletic talent search is closely linked to the development of methods for determining genetic predisposition to high physical performance in specific sports. In world practice, several models to determine the genetic predisposition to sports which take into account the polymorphisms complex were created but the problem of selecting candidate genes and the number of SNPs still remains unsolved. Therefore, the aim of the study was to create models to determine genetic predisposition to the manifestation of a high physical performance in different sports based on complex analysis of gene polymorphisms. **Methods** In the course of the study a total of 332 persons DNA (110 athletes involved in speed-power sports, 85 – in endurance sports, 51 - in sports that require a combination of strength and endurance, 86 - sedentary control) were examined. Using the polymerase chain reaction method the I/D polymorphism of the ACE gene, R577X polymorphism of ACTN3, T-786 → C promoter polymorphism eNOS, Pro/Ala polymorphism PPARG, G/C polymorphism in intron 7 of the gene PPARA, Pro582 → Ser (C/T) polymorphism of HIF1A, Ala203Pro polymorphism of PPARGC1B were investigated. **Results** Using the method of multifactor dimensional reduction, models of intergenic interaction in assessing predisposition to speed-strength sports (predictive capacity- 65%) and sports with the requirements of the combined effects of strength and endurance (predictive capacity- 64%) were created. I/D polymorphism of ACE, T-786 → C polymorphism of eNOS, R577X polymorphism of ACTN3, G/C polymorphism of the 7th intron PPARA are important markers for determining the genetic predisposition to exercise in speed and power sports, and T-786 → C polymorphism of eNOS gene is a marker of predisposition to sports with the requirements of the combination of strength and endurance. **Discussion** We did not observe any statistic difference between genes distributions in a group of athletes specializing in endurance sports and sedentary control. That fact did not allow us to create an intergenic interaction model for this group. The obtained results match the previously established facts. It is known that such phenotypes as explosive power, high content fast-twitch muscle fibers which are necessary for the manifestation of high athletic performance, have a high degree of inheritance (Tainen et al, 2009) and are determined by a limited number of genes, whereas aerobic endurance is easily changed under the influence of external stimuli, has the lowest degree of inheritance, and is determined by the interaction of a large number of genes and their variations (Williams, 2008; Ahmetov, 2009). References Ahmetov I.I., Williams A.G., Popov D.V., Lyubaeva E.V., Hakimullina A.M. et al *Human Genetics* (2009). 126(6),751–761. Tainen K., Sipilä S, Kauppinen M, Kaprio J, Rantanen T. (2009). *J Appl Physiol*,106(5), 1604-10 Williams A., Folland J. (2008). *J Physiol* 586.1, 113-121.

### **EXPLOSIVE STRENGTH ASYMETRY OF THE LOWER LIMB IN VOLLEYBALL AND BASKETBALL PLAYERS**

Fort-Vanmeerhaeghe, A., Gual, G., Romero-Rodriguez, D., Costa, L., Walsh, M.L.

*EUSES Universitat de Girona*

**Introduction** In order to determine the potential risk of injury, time to return to play after an injury and also optimize strength and conditioning training, the study of strength imbalance between limbs is essential. Taking this into consideration, the aim of this study was to investigate the differences in explosive strength between both legs in a group of male and female volleyball and basketball players. **Methods** Seventy-nine volleyball and basketball players (age: 23,7 ± 4,5 years, weight: 77,1 ± 9,1 kg, height: 182,3 ± 6,2 cm) performed three single-leg vertical countermovement jumps (SLVCJ) on a contact mat. Vertical jumping height and symmetry index (SI) between legs were analyzed. The SI was obtained by comparing both, dominant vs. non-dominant legs and stronger vs. weaker legs. **Results** When comparing leg dominance, significant differences were found in the whole group of players, while after making a comparison by sex, significant differences remained only in women. With regards to weaker vs. stronger legs, significant differences were noted in all the variables under study. SI average between legs ranged from 9.31% (males) to 12.4% (females) and from 10.49% (males) to 14.26% (females), when comparing dominant vs. non-dominant leg and stronger vs. weaker, respectively. **Discussion** This study shows significant differences in unilateral jump performance between legs in basketball and volleyball players. This concurs with previous studies, which

have shown the same significant imbalance between limbs. However, there are others which did not have similar findings (Hewitt, Cronin, & Hume, 2012; Stephens, Lawson, & Reiser, 2005). The results of our study and most of sport science researchers suggested a 10-15% threshold of asymmetry between legs to be considered as the usual physiological difference (Hewitt et al., 2012). The major SI average in females players is correlated with the findings of other authors relating neuromuscular deficits between legs as a risk factor which could address the major injury incidence in female athletes (Myer, Brent, Ford, & Hewett, 2011). ### PHYSICAL ACTIVITY REFERRAL: IMPACT ON PHYSICAL ACTIVITY ADHERENCE AND HEALTH-RELATED QUALITY OF LIFE.

Pardo, A., Garcia, J.A., Violan, M., Rubinat, M., Miñarro, C., Gonzalez, A., Roman, B.

*National Institute of Sport Science (INEFC)*

**Introduction** The Plan of Physical Activity, Sport and Health PAFES is a primary-care-based program implemented by the Health and the Sports Departments of the Government of Catalonia. It implanted Physical Activity (PA) prescription and physical activity referrals (PARs) to patients with cardiovascular risk factors (CVRF) in the Catalan primary care (PA) settings. PARs increase patients' PA level, but these increases may not be sustained over time (Morgan, 2005). This study has two aims: (i) to assess the effectiveness of PARs on the adherence to physical activity (PA) at medium- (6 months) and long-term (12 months); (ii) to assess the impact of PARs on health-related quality of life (HRQOL) among patients with CVRF: type II diabetes, hypertension, overweight (BMI  $\geq 25$  kg/m<sup>2</sup>) or dyslipidemia. **Methods** Within the framework of PAFES, a randomised controlled trial of 6-months exercise intervention with 6-months follow-up was conducted. 323 patients with  $\geq 2$  CVRF and contemplation stage of change (Prochaska & Marcus, 1994) were referred by PC to a supervised exercise program (3 sessions / week of 60 minutes of moderate-intensity PA) lead by a Physical education professional. Self-reported PA level and HRQOL were measured by the International Physical Activity Questionnaire (IPAQ) (Craig et al., 2003) and SF-12 (Alonso, 1996) respectively, at baseline, post-PARs and at 6-months follow-up. **Results** 75% (N=242; 75% women; 62.6 $\pm$ 8.5 years) of the sample finished the supervised exercise program, mean attendance of 84.1% (SD 18.5%). 16.5% dropped out due to health deterioration and 7.9% were missed during the follow-up. PAR produced significant improvement ( $p < 0.01$ ) of moderate intensity PA. Adherence to long term PA decreased, but the proportion of physically inactive remained lower than baseline. All domains of HRQL improved, maintaining the positive effects up to one year on physical functioning, mental health and social function ( $p < 0.01$ ). **Discussion** This study presents the first results of the PAFES supervised exercise program. The main results were (i) an increase in PA adherence at medium (6 months) but not long-term (12 months), (ii) a positive impact up to one year in HRQOL, mainly improving physical functioning, mental health and social function, and (iii) the need to study the mechanism to lengthen PA adherence. PARs helps to increase PA adherence at medium term and improve the HRQOL up to one year of patients with CVRF. **References** Morgan, O. (2005). *Public Health*, 119, 361 - 370. ### A PROFILE OF MASTERS ATHLETES: VARIOUS HEALTH AND PSYCHOLOGICAL INDICES

Heazlewood, I.T., Walsh, J., Climstein, M., DeBeliso, M., Kettunen, J., Sevene, T.G.6, Adams, K.

*Charles Darwin University*

**Do not insert authors here** **Introduction** An international team of researchers was formed to investigate the nexus between aging, physical activity, and the global obesity epidemic. **Methods** The team investigated over 10,000 masters athletes competing in international level competitions (2009 World Masters Games, 2010 Pan Pacific Masters Games, 2010 World Rugby Festival/Masters Rugby), presumably among the fittest of our aging population. Findings to date have furthered the understanding of the nexus between aging, physical activity, sports injuries, psychological factors associated with sports competition, health and obesity, providing an overview as to the profile of masters athletes over these various health related fitness and sports factors. **Results** Masters athletes demonstrated significant improvements in various health related indices over an age matched comparative Australian national population. Notable among these indices were body mass index for the majority, but not all participants. This was therefore not mitigated by the presumed propensity for increased muscularity in athletes over age matched national comparative population samples. As well as a number of positive health findings, for masters football athletes, the injury incidence during preparation for the tournament had similarities to, but was in fact significantly less than for other sporting populations. Some gender and sport based differences in injury location and classification type were identified. There were also no significant age related changes in injury nature (classification type, location, incidence, time off work or training). Whilst physical activity is well known to have many health benefits, paradoxically there had been concern for increased injury risk from highly competitive sport at older ages. Our findings do not support the premise of masters' football code athletes having higher incidence of injury as compared to younger athletes. With evidence of improved health indices associated with masters competition, it was logical to investigate factors connected with motivation to compete in masters sport. Socialization with other participants was the most important personal motivation for masters sport participation. Health and fitness were less important motivators than socializing to these masters level participants, but still stronger than competition. **Discussion** Our findings support the efficacy of masters' sport for overall improvement in health. To promote greater participation in this sport, strategies should best be focused on motivating factors such as socialisation with other participants.

### CARDIORESPIRATORY FITNESS AT COLLEGE-AGE AS A PREDICTIVE FACTOR FOR DEVELOPING DIABETES

Someya, Y.1, Kawai, S.1, Kohmura, Y.1, Aoki, K.1, Daida, H.2

*Juntendo University*

**Introduction** Reduced physical activity and low-level physical fitness in middle-aged individuals has been reported as a risk factor of diabetes. However, an association between physical fitness at college-age and diabetes has not been demonstrated in the Japanese population. In Japan, the National Physical Fitness Test is using the 1,500-meter endurance run as a measure of cardiorespiratory fitness from 1964. This test can perform easy and inexpensive compared with almost all cardiorespiratory fitness tests. We studied the relationship between cardiorespiratory fitness using the 1,500-meter endurance run at college-age, and the development of diabetes later in life in Japanese men. **Methods** Questionnaires were sent to 3,539 former students of Juntendo University regarding the occurrence of diabe-

tes and lifestyle between 2007 and 2009. The incidence rate of diabetes was compared with stored data on the 1,500-meter endurance test performed during college-age. Results A total of 639 male alumni had both data of the questionnaire and the 1,500-meter endurance test, and the studied follow-up period was from 17 to 34 years. An inverse association between the risk of diabetes and level of cardiorespiratory fitness was noted after adjustment for age, body mass index, smoking habits, and activity levels. Adjusted odds ratio of the incidence of diabetes according to the category (high, middle and low) was 1.00, 1.72 and 4.33 (for trend,  $p=0.02$ ). Discussion Men with low cardiorespiratory fitness during college-age might have low-level physical fitness in middle-age and had a high incidence of diabetes compared with men with high physical fitness (Okada et al., 2000; Sawada et al., 2003). Our data indicate that maintaining a high level of cardiorespiratory fitness from college-age aids in the prevention of diabetes. The 1,500-meter endurance run, as well as other cardiorespiratory fitness tests (Carnethon et al., 2003; Paffenbarger et al., 1973), could be a predictive factor for the development of diabetes. We propose that 1,500-meter endurance run tests could provide a way of predicting the development of diabetes later in life. These results indicate that a low cardiorespiratory fitness at college-age is an important risk factor for the development of diabetes later in life. #### DEVELOPING A SYSTEM TO MONITOR VERTICAL DEFLECTION IN A TRAMPOLINE BED

Chapman, C., Fischer, A., Rupf, R.

*Canadian Sport Institute Ontario*

**DEVELOPING A SYSTEM TO MONITOR VERTICAL DEFLECTION IN A TRAMPOLINE BED** Introduction The ability to jump high in an Olympic sized trampoline bed is not well understood due to the elastic surface involved. Understanding both the movement of the individual and the trampoline bed may provide more insight into jump height performance. To date, it appears as if no one has tracked the downward deflection (DD) of the elastic surface. The purpose is therefore to demonstrate new instrumentation that has been developed to assess DD of the trampoline bed and to provide general characteristics of the DD from athletes jumping on the bed. Methods Two cameras were positioned at the midline of the trampoline along the width and length of the trampoline bed at a depth around 60 cm below the bed. To find the position of the athlete and the DD, subtraction imaging was performed at 120Hz. An algorithm developed in Labview 7.1 determined the location of the subject on the bed, the DD and the flight time between jumps. These values were compared to visual checks to ensure system tolerances were met. Trampoline athletes (N=3) jumped on the trampoline bed with the three highest consecutive jumps processed for flight time, position and DD. Results Time of flight differed consistently from visual cues by less than 50ms. The ability of the system to determine landing location varied slightly based on landing position in the bed. However, differences could be reduced to less than 50mm. Performance for the DD metric was within system design tolerances, with variance no greater than 1cm. DD reached its maximum around 45.7% (+/-0.3) of the jump cycle. Coefficient of variation for DD between successive jumps is 4.2%. There is no correlation between DD and jump height. While not measured mass, may play a more prominent role. Discussion The outputs from the system aligned well with planned design tolerances. The information around the DD suggests athletes are compressing the bed sooner in the relative jump cycle. Previous work around elastic surfaces (Mortiz, 2004) may suggest that this early maximum DD may increase center of mass movement in athletes. The system provides the opportunity to measure vertical deflection of the bed, and allow for the trampoline bed and human to be modeled in spring mass systems. References Moritz C, Farley T. (2004). *Jrnl Exp Bio* 208, 939-949.

#### GOLF COACHING-BIOMECHANICS INTERFACE: STARTING WITH THE COACH

Morrison, A., Mcgrath, D., Wallace, E.S.

*University of Ulster*

**Introduction** There is a growing concern that the transfer of knowledge between sports science and coaching is unsatisfactory, and biomechanics is no exception (Knudson, 2007). While the integration of quantitative, qualitative and predictive approaches to technique analysis is supposedly imbedded in biomechanical practice, this does not seem to be evident (Lees, 2002), even in a highly technique based sports such as golf. The aim of this study was therefore to determine how elite coaches analyse the golf swing technique, to investigate elite golf coaches' opinions of biomechanics and to identify potential barriers to the integration of biomechanics into coaching practice. Methods Semi-structured interviews were used to record the views of 7 elite UK golf coaches. The transcripts were analysed inductively using a grounded theory approach. Results The process of golf swing technique analysis appeared to start in broadly the same area for all coaches: the curvature, direction and distance of the shots, which, interestingly, does not reflect the current state of the golf biomechanics literature. Coaches assume that these different aspects of the ball's trajectory are correlated to pre-impact conditions of the clubhead. The elements of technique that are thought to have a direct relationship to the pre-impact conditions of the clubhead (e.g. lateral body position in relation to the ball location and, therefore, where on the club's arc the ball is struck) are then adjusted. Subsequently, coaches suggest that there is no perfect swing, and effective swings incorporate movement "compensations" that effectively cancel each other out. The coaches' chief concern with biomechanics appears to be the use of "optimal" models of technique that do not take into account the individual characteristics of a player. Therefore, they struggle to see how they can apply the "optimal" data practically. Nevertheless, the coaches seem to appreciate that biomechanics research has had an influence on their coaching. Due to their different analysis methods, and a self-perceived lack of biomechanics knowledge, coaches suggest a closer relationship is needed between the two disciplines. Discussion This study helps to bring to light the issues that separate golf coaching from biomechanics. While some of the coaches freely admitted that their limited knowledge of biomechanics is a barrier to their use of it, the overriding factor was that it did not complement their existing methods of coaching. Although qualitative and quantitative analysis of technique have traditionally been segregated, considerations for a more circular exchange of information through the coaching-biomechanics interface may be beneficial

if future research is to have a real world application. References Knudson D (2007) Sports Biomech 6(1) 109-118 Lees A (2002) J Sports Sci 20(10) 813-828

### **EFFECT OF NEUROMUSCULAR TRAINING ON KNEE ROTATION IN YOUNG FEMALE: DESCRIPTION BY QUATERNIONS REPRESENTATION**

Santiago, P.R.P., Narayana, V.S., Cunha, S.A., Érica, E.V.

*University of Sao Paulo*

**Introduction:** The neuromuscular control is important for the execution of the movements in the sport, its modification or reduction can result in unnecessary and excessive movements of the joints of the lower limbs in many cases leading to injuries mainly ACL injuries. In order to improve the movement pattern several training protocols have been used as the intervention and the results were diverse. **Objective:** The aim of this study was to investigate the effect of neuromuscular training on knee rotation in young females by the method of quaternions. **Methods:** Five female participants were recruited to participate in the present study (age  $19.8 \pm 2.04$  years,  $65.6 \pm 6.8$  kg,  $1.66$  height  $\pm 0.04$  m, without injury and musculoskeletal pain in the lower limbs. They performed five single-leg drop landings from a platform with a height of  $0.4$  m, before (PRE) and after (POS) training. Six passive markers (three on the thigh and three on the shank) were used to obtain the 3D kinematics. The Matlab software were used to smooth the raw data with the 4th order Butterworth digital filter with  $10$  Hz of cut-off frequency, and to create coordinate systems of the thigh and shank to extract the unit quaternions from the knee joint observed in the task. Then the scalar portion of the unit quaternion was used to calculate the angular variation (AV) in degrees after initial contact with the ground until the time of peak angular rotation. The coefficient of variation in percent (CV) was used to verify the possible effect of neuromuscular training. **Results:** The mean, standard deviation and, CV of de AV were: PRE ( $56.7^\circ \pm 44.7^\circ$  and  $78.8\%$ ) and POS ( $43.4^\circ \pm 8.3^\circ$  and  $19.1\%$ ), that represents a  $59.7\%$  reduction in the CV. **Discussion:** The results of this study indicate that intervention during 7 weeks of neuromuscular training reduced of the knee rotation in young female during single-leg drop landing task. This can be considered as a factor beneficial for the prevention of injuries in this joint. **Acknowledgments:** FAPESP (process: 2010/20538-7 and 2011/14811-5)

### **DEFINING THE OPTIMAL LOAD FOR WEIGHTED STEP POWER TRAINING IN OLDER WOMEN**

Mair, J.L.1, Laudani, L.2, Vannozi, G.2, De Vito, G.1, Boreham, C.A.1, Macaluso, A.2

*1: University College Dublin (Ireland), 2: Università degli Studi di Roma*

**Introduction:** Weighted stepping is a dynamic multi-joint functional task that may enhance important aspects of functional fitness in older adults. However, the optimal load associated with peak power output during such a task is unknown. The aims of this study were three-fold: (1) to investigate the kinetic and neuromuscular responses to different loading patterns during step exercise in young and older sedentary women; (2) to determine the effect of ageing on these responses; (3) to determine the optimal external load associated with peak power output. **Methods:** Sixteen healthy females (8 young (mean, SD; aged  $24.6, 2.7$  years) and 8 older (aged  $69.8, 3.5$  years)) volunteered for this study, which was approved by the local University Ethics Committee. Ground reaction forces were measured during a step-test protocol requiring participants to step from one force platform (at ground level) onto a bench mounted onto a second force platform. Simultaneous measurements of vastus lateralis (VL) and biceps femoris (BF) muscle activation were recorded throughout using a portable bipolar sEMG system. Participants performed ten step-up repetitions as quickly as possible, leading with the dominant limb. Two bench heights ( $20$  &  $25$ cm) and five loads ( $0, 2.5, 5, 7.5$  &  $10\%$  body mass; BM), evenly distributed by means of a weighted vest, were investigated in a randomised order. Power output was calculated by multiplying the vertical force by vertical velocity of the body centre of mass during the ascent phase of stepping. **Results and Conclusion:** Increasing step height resulted in greater peak power ( $p < 0.01$ ) in the older women, while step height had no effect on kinetic responses in the young women. Increasing load had no significant effect in either group, although trends for peak power at  $10\%$  BM in the older and  $7.5\%$  BM loading in the younger group were evident. Peak power generating capacity was  $64\%$  lower in the older than that of the young ( $p < 0.001$ ). Alterations in stepping strategy were also apparent whereby the younger women performed a 'run' step, and older women performed a slower 'basic' step, highlighting an age-related reduction in ability to step at high speed. Normalised VL muscle activation was greater in the old compared with the young ( $p < 0.05$ ). However, peak force was significantly lower ( $p < 0.01$ ), suggesting that older women were operating closer to their threshold of maximum force in order to complete the stepping task. Optimal load at a step height of  $20$ cm was  $10\%$  BM in older and  $7.5\%$  BM in younger women, representing a  $6\%$  and  $11\%$  increase in peak power output over values obtained at  $0\%$  loading, respectively. These findings should be taken into account when designing weighted step power training programmes.

### **EFFICACY OF STRENGTH TRAINING ON MACHINE CONDITIONING ADJUSTMENT OF EXTERNAL LOAD TO MUSCLE WORK ABILITIES**

Karczewska, M., Madej, A., Iwańska, D., Urbanik, C., Staniszewski, M., Mastalerz, A., Gwarek, L.

*Jozef Pilsudski University of Physical Education in Warsaw*

**Introduction** Machines commonly used for strength training allow to control loads applied on muscles precisely. Since in human joints only rotatory movements are possible, the length of the muscle and its strength are dependent on joint angle (Biscarini 2003, Philippou 2003). In connection with the above some inconsistency may be noticed between the constant external load, obtained in training machines with discs, and muscle work. Therefore use of specific cam of various radius, which allows to adjust the external load to muscle work abilities in the function of joint angle, seems to be justified (Folland 2003). There was a test experiment taken of effectiveness of 8 weeks elbow flexors training on machine with disc and specially constructed cam. **Methods** Thirty untrained male students participated in the study. Subjects were divided into 2 groups of 15 each. Group A trained with variable-cam, group B with disc. Subjects from both training groups performed strength training in 8 series with 3 min rest intervals (I:  $4 \times 75\%$  max, II:  $2 \times 85\%$  max, III-VIII:  $1 \times 1RM$ ). Control measurements of muscle torques of elbow flexors under isokinetic conditions at 3 velocities of  $30^\circ \cdot s^{-1}$ ,  $60^\circ \cdot s^{-1}$  and  $180^\circ \cdot s^{-1}$  (Biodex System 3 Pro) took place before experiment, after 4 weeks, on the last day of experiment and 3 weeks after experiment (4 measurement sessions). Multi-Factor ANOVA for repeated measurements (Statistica 2000) was used to analyze differences in variables between groups. **Results** There were no significant interactions found between variables (training, load of cam and disc or velocity of measurements)  $F(6.261) = 0.43$ ;  $p = 0.858$ . The grade of muscle torques changes, at the velocity most adequate to the one of the movement while training, as a result of training was  $7.2\%$  in group A (variable-cam) vs.  $4.0\%$  in group B (disc). Significant interactions were related to influence of training and various isokinetic conditions ( $F(6.261) = 3.52$ ;  $p < 0.01$ ). The highest values of muscle torques in both groups sub-

jects achieved at the velocity of  $30^{\circ}\cdot s^{-1}$ , and the lowest at  $180^{\circ}\cdot s^{-1}$ . Discussion Results of many studies indicate the importance of training loads. It's being also pursued the loads would involve muscles to work in the highest degree (Oliveira 2009). Therefore various training machines are used in training. Nevertheless in the present study there was the same, significant progress in strength training with use of cam and disc. References Folland J, Morris B (2008). *J Sports Sci*, 26(2):163-169. ### **DETERMINATION OF RESISTANCE TRAINING VARIABLES USING A SINGLE TRIAXIAL ACCELEROMETER**

Brown, N., Hellmann, N., Alt, W.

*University Stuttgart*

**Introduction** Objective measurement of resistance training parameters is a requirement to be able to quantify training strain in resistance training. At present, no valid methods are known to reduce the complexity of the high amount of relevant data (Toigo & Boutellier, 2006) and simplify the protocolling of training variables. Chang et al. (2007) used two accelerometers to identify a specific task and to determine the numbers of repetitions in resistance training using the main axis of the detected task. This method showed high reliability, but cannot be integrated into the training process due to complexity and limitation to one axis of movement. The following study uses only one accelerometer to determine the numbers of repetitions with a specific algorithm. **Methods** The validity of the algorithm was tested with 11 male subjects (age=  $24.8 \pm 0.6$  years, height=  $180.8 \pm 10$  cm, weight =  $75.3 \pm 7.1$  kg). The subjects executed 10 standard exercises with 8-12 repetition maximum. The acceleration data was collected using a 3-dimensional accelerometer (XSens Mtx) positioned on the right wrist. Video-analysis was used to control the validity of the algorithm. **Results** After a screening of the acceleration data by an expert, 90 of 110 exercises were integrated into the analysis. 20 exercises could not be analysed due to an error in data collection. 86.7% of the exercises were calculated correctly by the algorithm. The false calculations showed a mean deviance of  $35.3 \pm 31.1\%$  in counted repetitions. At most, too many repetitions were counted (91.7%). The bench press exercise showed the highest number of wrong calculations of repetitions (60.0%) **Discussion** This study shows, that a high amount of standard exercises can be quantified using only one accelerometer positioned on the subjects wrist. Wrong calculations of training variables was mainly found in specific exercises characterised by a high degree of freedom and therefore a high amount of oscillations in the movement, requiring for a modification of the algorithm. In further studies more training variables have to be examined to further optimise training quantification in resistance training and enhance the usability of the presented method. **References** Toigo, M., & Boutellier, U. (2006). New fundamental resistance exercise determinants of molecular and cellular muscle adaptations. *Eur J Appl Physiol*, 97, 643-663. Chang, K., Chen, M. Y., & Canny, J. (2007). ### **COMPARISON OF RELATIONSHIP BETWEEN ANTHROPOMETRIC MEASURES AND THE SHOULDER ROTATORS ISOKINETIC POWER**

Zapardiel Cortés, J.C., Rodríguez, M.L.

*Universidad de Alcalá*

**Introduction** The relationship between strength and anthropometric measures is an area of particular interest to a number of coaches. This relationship is especially important in sports where the powerful throwing can be the cause of success. Therefore, the aim of this study was to compare the relationship between several anthropometric measures and power generated in the rotational motion of the shoulder joint complex in three groups of athletes: multisport female athletes, multisport male athletes and handball male players. **Methods** Seventy multisport male athletes (5 left-handed, 65 right-handed), twenty-nine multisport female athletes (8 left-handed, 21 right-handed) and twenty-six handball male players (6 left-handed, 20 right-handed) participated in the study. Their ages ranged from 19 to 30 (mean 23.5). The anthropometric variables studied were the size, height, weight and body fat percent, and the isokinetic variable studied were the power. In order to measure the power, a System 3 Biodex isokinetic dynamometer is used. In order to measure the anthropometric parameters we followed the standardized techniques recommended by the International Society for the Advancement of Kinanthropometry. **Results** Statistically significant correlations were found between the strength and weight and percent body fat to angular velocities of 60 and  $180^{\circ}/s$  at the internal rotation, and also with the size in external rotation. The higher relationships were found in multisport female athletes, followed by multisport male athletes and lowest relationships were found in handball players. **Discussion** Handball players group results may indicate that the greater number of hours of training lowers correlation of anthropometric variables with the power. In this sense, Mayer et al (1994) supports this assertion. Similarly, strength training for the recruitment of large motor units, which made the handball players, could also be the cause of lowest relationships between the power and the anthropometric variables studied. Another reason that could make understand the lowest relationship observed in handball players is the type of training they did, combining strength training with technical and tactical training (Aguilar-Martínez et al, 2012). **References** Mayer F, Horstmann T, Roecker K, Heitkamp HC, Dickhuth HH. (1994). *Int J Sports Med* 1994;15(1):S19. Aguilar-Martínez D, Chiroso LJ, Marfín I, Chiroso LJ, CuadradoReyes J. ### **JUMPING ONTO UNSTABLE SURFACES DOES NOT IMPAIR SUBSEQUENT STABLE JUMPING PERFORMANCE**

Pollitt, L., Bissas, A.

*Leeds Metropolitan University*

**Introduction** Although interest has grown over recent years in training using unstable surfaces, its acute and chronic performance effects are still not fully understood. Furthermore, this has excluded consideration of dynamic exercise where instability during landing may cause a heightened neuromuscular response to negotiate increased stability demands. An increased neural drive may then be directed towards the agonistic muscles when stability demands are reduced. This study was therefore designed to compare the effects of drop-jumps (DJ) onto unstable and stable surfaces on subsequent stable countermovement jump (CMJ) performance. **Methods** In a random crossover design 14 males ( $21.09 \pm 2.4$  yrs) completed 3 experimental conditions, with each condition consisting of an activation exercise (3 sets of 5 DJ from 0.4m) onto either unstable (BOSU, mini-trampoline (MT)) or stable (ground) surfaces, and a control condition. The experimental conditions represented a typical post-activation potentiation (PAP) protocol for an acute study (Saez Saez de Villareal et al., 2007). Testing consisted of 3 maximal CMJ on a force plate (1000Hz) before and after ( $t=5$ ,  $t=9$ min) each protocol and the best jump at each point was analysed. Four practice sessions were also conducted beforehand, with absolute and relative reliability statistics establishing the level of reproducibility for CMJ and DJ performance so the magnitude of any pre-post differences could be appreciated. Data

were analysed using Repeated Measures ANOVA. Results No differences were observed between conditions with respect to any kinetic, temporal or performance variables. With regards to the time factor each condition, including the control, followed a similar trend. No pre-post significant differences were observed for temporal variables (e.g. eccentric phase), while the reductions observed for key kinetic variables (e.g. peak power, take-off velocity) and specifically jump height (control (-5.5%), BOSU (-5.3%), MT (-2.6%), ground (-5.4%)) were within the reproducibility random error limits. Discussion The results across conditions with respect to time do not indicate that PAP was present, as no significant changes were observed during post-testing. This may arise from failure to employ the optimal protocol to evoke PAP, for which there is no uncontroversial standard. Nevertheless, these findings suggest that acute DJ sessions onto unstable surfaces yield similar effects to commonly performed DJ onto stable surfaces. Dynamic training onto unstable surfaces may therefore be beneficial during all stages of structured training, including rehabilitation, by reducing impact forces upon landing while maintaining performance and possibly conditioning the neural circuit. References Saez Saez de Villareal et al., (2007) *Eur J Appl Phys* 100(4): 393-401

## AN INERTIAL-SENSOR BASED METHOD TO QUANTIFY THE VERTICAL MOVEMENT OF RIDER AND HORSE IN DRESSAGE RIDING

Eckardt, F., Münz, A., Witte, K.

*Otto von Guericke University Magdeburg*

Introduction The rider should be sitting well-balanced, elastic, and smoothly absorbing the motion of the horse (FEI, 1994). So far, motion analyses of riders are limited to videometry and measurements on treadmills. However, today inertial sensors make it possible to quantify kinematic data with comparable accuracy to optical motion capture systems (Pfau et al., 2005). The purpose of this study is to quantify whether significant differences exist in the range of motion (ROM) and in the variability (CV) of vertical movement of the rider and the horse under field conditions. Materials and Methods Ten high level riders (age:  $23.4 \pm 5.25$ , riding experience:  $17.3 \pm 5.6$  years) participated in the study. They rode their own horses in walk (W), sitting trot (ST), rising trot (RT), right lead canter (CR), and left lead canter (CL) on a 30m track. Kinematic data from riders were collected using an inertial motion capture system (IMS, 120 Hz, Xsens). Further one inertial sensor (120 Hz, Xsens) was attached close to the sternum of the horse (saddle girth). One gait cycle was defined as the time between two successive ground contacts of the left front limb of the horse by using an acceleration sensor. We captured at least 28 strides for each rider and gait and normalized each stride in time. The vertical acceleration of the sensor on horse and segments from riders (head, trunk, pelvis) were integrated twice to obtain vertical displacement by using a method described by Pfau (2005). The ROM [cm] and the CV of vertical movement for rider and horse were calculated. We compared at a significance level of .05 mean values (ANOVA) of ROM and CV. Results ANOVA showed no differences in ROM of riders segments in each gait. Significant differences were found between ROM of rider segments and ROM of the horse. For all segments pairwise follow up-test showed no differences between ST (pelvis:  $15.98 \pm 0.89$ ) and RT (pelvis:  $16.94 \pm 3.0$ ) and between CR (pelvis:  $41.79 \pm 3.2$ ) and CL (pelvis:  $43.25 \pm 2.7$ ). Compared to all other gaits, CV in W was different. Discussion The IMS is suitable to quantify the vertical movement of rider and horse in different gaits under field conditions. Also, all calculated vertical displacement curves showed characteristic gait-dependent features. The CV in vertical movement for ST and RT are corresponding with the results of Peham et al. (2004). ## INFLUENCE OF RIDING SKILL ON COORDINATION DYNAMICS BETWEEN HORSE AND RIDER

Münz, A., Eckardt, F., Witte, K.

*Otto von Guericke University Magdeburg*

Introduction By connecting the body of the rider to the horse especially the rotation of the human pelvis is supposed to play a key role in horse riding (Pfanni & Tulli, 1994; Blokhuis et al., 2008). Regarding coordination between horse and rider, Lagarde et al. (2005) assume the exchange of information through the seat to be an important factor. We therefore suggest the coupling between the pelvis and the horse to be part of the skill of the rider to control the horse and to follow its movement. The aim of this study is to quantify the coordination between the pelvis and the horse. Materials and Methods Ten professional riders (age:  $23.4 \pm 5.25$ , BMI  $21.5 \pm 2.47$ , training hours/week:  $33.9 \pm 11.89$ ) and ten beginners (age:  $16.4 \pm 2.88$ , BMI  $20.2 \pm 2.32$ , training hours/week:  $2.6 \pm 1.36$ ) participated in the study, riding their own horses in walk (W), sitting trot (T) right lead canter (CR) and left lead canter (CL). One six degree of freedom inertial sensor (120 Hz, Co. Xsens) was mounted dorsally on the rider's pelvis. Another sensor was attached close to the sternum of the horse (saddle girth). For stride segmentation a third sensor was mounted laterally on the left cannon bone. A complete stride was defined as the time between two successive ground contacts of the left front limb of the horse. We captured 30 strides for each rider and gait. Strides were normalized to 101 samples (MATLAB, 2012b) and the continuous relative phase (CRP) between horse and rider was assessed. Based on rotations about the transversal axis of both, rider and horse, we tested mean CRP values for differences. Results Independent t-test showed significant ( $p < .05$ ) lower values for professional riders only in CL ( $-65.94 \pm 17.87$  vs.  $-86.61 \pm 9.54$ ) and CR ( $-72.99 \pm 18.73$  vs.  $-89.50 \pm 6.42$ ). Discussion Controlling the pelvis is a crucial skill in horse riding. Coordination in canter seems to be depending on the riding level. Professional riders showed smaller CRP values, indicating a slightly more in-phase behavior. However, this finding is not applicable to slower gaits (W and T). Wolfram et al. (2013) observed lower mean CRP values in CL and CR compared to W or T, which corresponds with our findings. References -Blokhuis, M., Arnosson, A., Hartmann, E., Van Reenan, G. ## POST ACTIVATION POTENTIATION AND ACHILLES TENDON STIFFNESS IN ATHLETES

Gago, P.1,2, Arndt, A.2,3, Tarassova, O.2, Ekblom, M.M.2,3

1:University of Beira Interior (UBI/CIDESD), Covilha, Portugal, 2:The Swedish School of Sport and Health Sciences (GIH), Stockholm, Sweden, 3:Karolinska Institutet, Stockholm, Sweden

Introduction The enhancement of muscle contractile properties caused by post activation potentiation can be related to improvements in excitation-contraction coupling, increased sensitivity to calcium and/or increased stiffness in the series of elastic components (I). This

study aimed to assess how Achilles tendon stiffness (ATS) was affected by a 6 s maximal voluntary contraction (MVC) and how any changes in stiffness were associated with changes in contractile properties. Methods Six power athletes participated. Initially supra maximal electric stimulation of the tibial nerve was used to evoke plantar flexor twitches before and up to 600 s after a 6 s MVC. In a second visit, ATS measurements were taken before and up to 600 s after a 6 s MVC. For ATS measurements, subjects performed standardized plantar flexor torques (0, 30 and 50% of MVC) while the insertion of the Achilles tendon was monitored by a real time ultrasound and a four-camera motion capture system. Torque was measured by an isokinetic dynamometer. From the twitches, Peak twitch (PT) and rate of torque development (RTD) were measured. ATS was calculated from plantar flexor torque and Achilles tendon length. Two-way ANOVAs and Tukey post-hoc tests were used to ascertain statistical significance ( $p < 0.05$ ). Results PT was significantly increased by  $39.5 \pm 15.5\%$ ;  $17.0 \pm 7.5\%$  and  $9.9 \pm 5.9\%$  at 30, 120 and 300 s after MVC. RTD was significantly increased by  $67.5 \pm 20.5\%$  and  $18.2 \pm 7.8\%$  at 30 and 120 s after MVC. At the same time points, no significant decreases or increases were found in ATS for any of the torque levels. Discussion While a decrease in ATS may lead to a decrease in performance an ATS increase might improve performance but also predispose to injury (2). Our data showed that in power athletes post activation potentiation of contractile properties can be induced without greatly affecting ATS. This conservation of ATS may make it possible for athletes to use conditioning MVCs to enhance muscular contractile properties without increasing the injury risk due to high stiffness. ## EFFECTS OF RUNNING ON ACHILLES TENDON FATIGUE IN THE FREE AND GASTROCNEMIUS TENDON COMPONENTS

Lichtwark, G.1, Cresswell, A.1, Newsham-West, R.2

1. *The University of Queensland, Australia*. 2. *Griffith University, Australia*

**Introduction** The elastic properties of the human Achilles tendon are important for locomotion, however in vitro tests suggest that repeated cyclic strain leads to tendon fatigue represented by an increase in length in response to stress applied (Ker et al., 2000; Wren et al., 2003). In vivo experiments have yet to demonstrate mechanical fatigue in the human Achilles tendon. The aim of this study was to determine whether either the free Achilles tendon (calcaneus attachment to the soleus) or the gastrocnemius tendon (calcaneus attachment to the gastrocnemius) demonstrate tendon fatigue after running exercise. **Methods** Nine male participants (age = 22 (mean)  $\pm$  4 (SD) years, height =  $173. \pm 11$  cm, mass =  $74 \pm 9$  kg) volunteered to participate in this study. A test-retest protocol was used to examine the influence of running on tendon mechanical properties. Participants initially underwent a test to examine Achilles tendon strain during isometric contractions at four different torque levels (passive, 14, 42 and 70 N.m). They were then instructed to run continuously on a treadmill for 5km at a comfortable self-selected pace (10-14km.h<sup>-1</sup>). Immediately after the run, participants were re-tested to examine Achilles tendon strain in response to the same isometric contraction torque levels. Freehand three-dimensional ultrasound scans of the Achilles tendon were performed during all isometric contractions to accurately determine the free Achilles tendon and gastrocnemius tendon length and cross-sectional area (Farris et al., 2013). Results Prior to exercise, the free Achilles tendon underwent more strain than the gastrocnemius tendon across all torque levels ( $p < 0.001$ ). The length of the free Achilles tendon increased significantly across all torque levels after the run ( $p < 0.001$ ) indicating a small amount of tendon fatigue. In contrast there was no significant change in the length of the gastrocnemius tendon as a whole ( $p = 0.098$ ). A significant increase in the passive length of free Achilles tendon was found, however this effect was small (0.85%, effect size = 0.03) and did not correspond to any change in tendon volume. **Discussion** Our results have shown the first in vivo evidence of Achilles tendon fatigue after running exercise. This was, however, only evident in the free tendon and the effect was small and due primarily to a change in resting length and not tendon stiffness per se. These results may have implications for understanding Achilles tendon injury, because they suggest that some changes in material properties occur in the free tendon, which is commonly associated with tendinopathy. **References** Farris D, Trewartha G, McGuigan M, Lichtwark, G. ## CHANGES IN OPTIMAL CADENCE MINIMIZING MUSCULAR ACTIVATION WITH POWER OUTPUT AND MUSCLES INVESTIGATED.

Hintzy, F.1, Samozino, P.1, Horvais, N.1

1. *Université de Savoie*

**CHANGES IN OPTIMAL CADENCE MINIMIZING MUSCULAR ACTIVATION WITH POWER OUTPUT AND MUSCLES INVESTIGATED.** **Introduction** Previous studies have reported inconsistent results, including linear, curvilinear, parabolic and steady muscular activity when cadence increased (Marsh and Martin 1995, McIntosh et al. 2000, Neptune et al. 1997). Two explanations can be proposed. Firstly, each muscle may be activated differently as cadence increased. Secondly, the differences observed for a same muscle between the studies are probably related to the methodology used as the power output or the range of cadences. Thus, the aim of this study was to investigate the influence of cadence on the muscular activity of various lower limb muscles at different power outputs. **Methods** Fourteen healthy noncyclists participated in this study. All subjects cycled on a friction-loaded ergometer during five 3-min periods of steady-state cycling with cadences ranging from 40 to 120 rpm, at five randomized power outputs (40 to 200 W). EMG activity of six major muscles of the lower limb (gluteus maximus GMx, biceps femoris BF, rectus femoris RF, vastus lateralis VL, gastrocnemius medialis GM, tibialis anterior TA) was continuously measured at 1000 Hz. The averaged root-mean-square value for each muscle was computed across 10 consecutive pedalling cycles. The individual EMG-cadence relationships were fitted by linear or parabolic regressions, which allowed the determination of optimal cadence minimizing EMG (Copt): at 40 rpm or at the minimum point of parabolic EMG-cadence curves, respectively. A two-ways analysis of variance for repeated measures (muscle x power) and a post-hoc LSD Fisher were used with a statistical significance limit defined as  $P < 0.05$ . Results The EMG-cadence relationships were mainly fitted by parabolic regressions, linear positive regressions being only observed in some subjects at low power outputs on GM, TA and VL muscles. Copt ranged from  $40 \text{ rpm} \pm 0.2$  for the GM muscle at 40 W to  $76.3 \text{ rpm} \pm 16.7$  for the GMx muscle at 200 W. ANOVA showed a significant muscle effect ( $P < 0.01$ ; VL and GM having the lowest Copt) and power output effect ( $P < 0.001$ ; 160 and 200 W allowing to obtain the highest Copt), without muscle-power interaction. **Discussion** Present results showed that each muscle responds differently to cadence increase at a given power output, what explained the unique Copt corresponding to each muscle. Moreover, the minimum muscular activity occurs at a progressively higher cadence as power output increases (excepted for the VL muscle), due to the force-velocity properties of muscles. This result was previously observed by McIntosh et al. (2000) with seven lower limb muscles averaged together. **References** Marsh AP, Martin PE (1995). *Med Sci*

##### EXPLORING S-SHAPE MOTOR LEARNING CURVES WITH PHASE TRANSITION

Liu, Y.T.1, Newell, K.M.2

1:National Taiwan Normal University, 2: Penn State University

**Introduction** Although many different shapes of motor learning curves have been suggested in textbooks, most of the motor learning curves observed in the literatures were based on tasks such as single limb positioning; the nature of learning those types of tasks is very different from learning the multi-segment coordination tasks. According to the frameworks of the dynamical systems theory, a new attractor emerges in the dynamic landscape during the coordination learning (phase transition), therefore a discontinuous jump (S-shape) on the learning curves may be observed (Newell et al., 2001). The purpose of the study was to examine the motor learning curve at the phase transition of acquiring the coordination pattern of the roller ball tasks based on the dynamical systems theory. **Methods** The roller-ball, a top encapsulated in a 7-cm diameter spherical shell, was prepared for the initial spinning speed of 20 rps and handed to the participants. The goal of the task was for the participants to produce the appropriate relative phase between the hand motion and the spinning ball in order to accelerate the ball to 50 rps by the end of each 10 s trial. All the participants practiced 50 trials a day for 10 days, and another 50 trials at 1 week retention test. In addition to plotting the average acceleration of each trial for 500 trials to observe qualitatively the S-shape learning curves for each participant, the One way ANOVA on the average acceleration of the trial was examined for the 1st, 10th, and the retention sessions, and the Level Crossing method (Wagenmakers et al., 2005) was used to test the phase transition during the learning process. **Results** The ANOVA result shows a significant effect on the performance segments, and the post hoc paired t-tests show the significant difference between the 1st and 10th practice sessions, and between the 1st and retention sessions; no difference between 10th and retention sessions was found. The results of the level crossing method performed on the individual 500 trials of performance measure show distinct bi-modal distributions indicating two stable equilibrium states over the 500 trials. **Discussion** The results provide preliminary evidence of a phase transition during the learning of a new coordination task and the related S-shape learning curve in the task outcome. Further experimental and modeling work will elaborate the generalization of these new findings on phase transitions and learning curves. **References** Newell K M, Liu Y-T, Mayer-Kress G. (2001). ##### THE INFLUENCE OF DIFFERENT TEACHING METHODS ON MOTOR LEARNING IN SCHOOL CHILDREN

Braun, C., Focke, A., Stein, T., Seidel, I.

Karlsruher Institute of Technologies

**Introduction** Augmented feedback and observational learning are essential factors in motor skill learning (Magill, 2007). To our knowledge there is no study comparing the effectiveness of these two aspects in a school setting. Therefore, the aim of this study was to investigate different teaching methods (feedback, observational learning and their combination) for children in elementary school (2nd grade) and high school (5th grade) by learning the sport lacrosse. **Methods** Two hundred and eight subjects, 2nd grade (N=99) and 5th grade (N=109), performed lacrosse two times a week for 45 minutes in their sport class over five weeks. All subjects were divided into four different learning groups: feedback group (A), observational group (B), combination group (feedback and observation, C) and a control group (no lacrosse training, D). The feedback for group A and C was given as knowledge of performance, verbal, terminal, qualitative with a reduced frequency (systematical reduction) and as a combination of error and correction cues. For the observational learning groups B and C the model was always the same person. A pre-post-retention test design was used. After the pretest (T1) and a five week training program, the post test (T2) was conducted directly after the last training session. The retention test (T3) followed after another four weeks. The test battery includes throwing and catching of straight and variable balls in lacrosse. Physical activity and emotions were used as moderator variables. The experiment is not completed yet, so only the N=64 subjects (all 2nd grade, A=17, B=15, C=12, D=20) were analyzed so far. **Results** No significant interaction between test time and learning group was found for the straight catching task. All groups improved their performance from T1 to T3. In contrast for the tasks throwing and variable catching a significant interaction between test time and learning group was revealed ( $p = .014$ ,  $\eta^2 = .122$ ;  $p = .012$ ,  $\eta^2 = .125$ ). In the throwing task post hoc tests showed significant differences between T1 and T3 for all treatment groups (A, B, C) but not for the control group (D). For variable catching post hoc tests revealed significant differences between T1 and T3 only for the feedback (A) and the observation group (B) but not for the combination (C) and the control group (D). **Discussion** For 2nd graders both feedback and observational learning improved lacrosse performance after a five week training. Further analysis of the data could give information about differences between 2nd and 5th graders and might help to understand which teaching method is best for different school settings. **References** Magill, R.A. ##### THE DEVELOPMENTAL ACTIVITIES OF FEMALE PROFESSIONAL INTERNATIONAL SOCCER PLAYERS

Ford, P.R., Datson, N., Andersson, H., Williams, A.M.

Liverpool John Moores University

**Introduction** Expert male athletes engage in the developmental activities of practice, play and competition via somewhat predictable pathways. These are early specialisation, early diversification, and early engagement. Females engage in less physical activity during their youth compared to males (Troost et al., 2002), although whether this finding extends to the activities of expert female athletes has not been explored. The aim of this study was to examine the developmental activities of female professional international soccer players,

thereby providing information to aid the development of future players. It is expected that their activities will follow the early engagement pathway as per male players. Method Participants were adult female professional international soccer players from England (n=18) and Sweden (n=16). They completed the Participation History Questionnaire (PHQ) under supervision. The PHQ records milestones, such as start age, engagement in other sports, and hours in the soccer activities of practice, play and competition across childhood and adolescence. Preliminary between-group difference tests were used to compare groups on all dependant variables. Results Start age was earlier in Sweden (5 years of age) compared to England (6 years) ( $P < .05$ ). English players joined an elite academy (12 years), started as a senior professional (15 years), and started as an international (18 years) earlier compared to Swedish players (15, 17, and 21 years, respectively) (all  $P$ 's  $< .05$ ). During childhood, players engaged in more soccer play (233 hrs/yr) compared to practice (145 hrs/yr) and competition (33 hrs/yr), with English players (308 hrs/yr) engaging in more soccer play than Swedish (149 hrs/yr) (all  $P$ 's  $< .05$ ). Players engaged in 2 to 3 other sports during this period. During adolescence, they engaged in more soccer practice (344 hrs/yr) and competition (254 hrs/yr) compared to play (199 hrs/yr), although English players (317 hrs/yr) engaged in more soccer play than Swedish (66 hrs/yr) (all  $P$ 's  $< .05$ ). They engaged in 2 to 3 other sports during this period, although this reduced to 1 other sport at 18 years of age. Discussion This study is the first to examine the developmental activities of female professional international soccer players. Their developmental activities most closely followed the early engagement pathway, albeit with some variation from it. This pathway involves higher amounts of engagement in soccer play and lower amounts of engagement in other activities during childhood. It involves higher amounts of soccer practice during adolescence. Early engagement, as opposed to specialisation or diversification, may be a more optimal developmental pathway to expert performance. ## MOTOR SKILLS EVALUATION IN SCHOOL CHILDREN WITH DOWN'S SYNDROME: MABC TEST

Rodríguez, M., Zapardiel, J.C.

*Universidad de Alcalá*

Introduction In the present study it has been analyzed the applicability of different tasks, included in the motor test -Movement Assessment Battery for Children (MABC)-, which measures motor competence in children without disabilities, to children with Down's Syndrome (DS) aged nine to twelve years old. The aims of the study were to ascertain the applicability of this motor test in children with DS, and to evaluate the motor skills of these children with the above-mentioned test. Methods A total of 50 learners with DS participated in this study. We applied the MABC designed for the evaluation of motor skills in children from 4 to 12 years old. This battery is composed of 32 items divided in four sets of eight each and it was designed for its use in children of different groups of ages (Spanò et al, 1999). The selection of the different tasks of this battery was the band designed for 4 to 6 years old children made accordingly to the opinion of the professors. Results The degree of motor development in nine to twelve year old children with DS is lower than that of the four to six years old non-disabled children as measured with the MABC test. The motor test used has shown a level of difficulty and appropriate applications. In this study we can say that boys got better scores than girls in the static tasks and dynamic balance and visual-motor coordination. When we analyzed the motor competence of children with DS slightly lower to the chronological age from 9 to 10 years old, both sexes showed similar results (Rodríguez et al, 2002) and the differences began to accuse beyond 11 years old, present in the sample with DS, as the results of this study. Discussion In general population between 2 and 7-8 years of age the fundamental motor skills are consolidated (Ruiz et al, 1997). However, the results obtained in children with DS have not completed this process of consolidation of basic motor patterns. Despite being between 9 and 12 years old, this study show motor difficulties and more important than children without DS of 5 to keep balance and move according to different patterns of movement. The most serious DS disabilities in this study are related to balance, postural control and learning by cerebellum abnormalities (Pueschel, 1987). ## QUIET EYE TRAINING: WHAT INFLUENCE HAS QUIET EYE DURATION?

Wilson, M.R., Lee, D., Uiga, L., Vine, S.J.

*University of Exeter*

Introduction: Recent research has identified that Quiet Eye Training (QET) is effective for both expediting novices' learning of golf putting, and making performance more resilient to the effects of pressure (e.g., Moore et al., 2012). However, while QET participants tend to have longer QE durations than control group counterparts, it is not clear that this extended duration of programming is responsible for the performance advantages found. We therefore compared two QET interventions, which differed only in terms of the duration of the final QE fixation in order to further our understanding of why QET 'works'. Methods: We randomly assigned 18 novice golfers into short (n = 8) and long (n = 10) QET groups. Both interventions followed a QET pre-shot routine (e.g., Moore et al., 2012) where the timing and duration of fixations on the hole and the ball were driven by an audio recording, which the participants followed. These recordings differed only in terms of the duration of the final fixation on the ball (800ms - short; 2500ms - long) before the initiation of the putting stroke. Participants made 40 putts from ten feet in a baseline (pre-training) condition before completing 320 putts under their specific QET protocol. Finally 20 putts were taken in both retention and pressure conditions (as Moore et al., 2012). 2 (Group) x 3 (Condition) ANOVA were performed on radial error (cm), QE duration (ms), and self-reported anxiety data (1-11). Results: A main effect for condition revealed that both groups significantly improved putting performance after training (Baseline = 47cm; Retention = 24cm;  $ps < .005$ ), however, there was no effect of pressure on performance (Pressure = 25cm), and no significant group or interaction effects ( $ps > .400$ ). Differences in QE durations were effectively manipulated by the training protocol as a significant interaction effect was found ( $p = .001$ ): 'Long': Baseline = 1520ms, Retention = 3177ms; 'Short': Baseline = 1202ms, Retention = 1003ms. No further changes occurred under pressure ('Long': Pressure = 2858ms; 'Short': Pressure = 996ms). The pressure manipulation was successful in significantly increasing anxiety (3.9) for both groups compared to baseline (2.2) and retention (2.0) conditions ( $ps < .001$ ). Conclusions: QET supported effective skill acquisition and performance under pressure, but surprisingly this was the case whether a long or short QE duration was trained. Previous research has suggested that such short QEs (~1000ms) leave performers susceptible to choking under pressure. We propose therefore that other elements of the QET routine warrant further research attention to further our understanding of why QET 'works'. Quiet eye training expedites motor learning and aids performance under pressure: The roles of response programming and external attention. *Psychophysiology*, 49, 1005-1015.

### TMS OF HUMAN SMA LEADS TO SIMILAR MEP AS THOSE FOR M1 BUT WITH SMALLER SILENT PERIODS IN A PRECISE FORCE CONTROL TASK.

Entakli, J.1, Bonnard, M.2, Chen, S.1, De Graaf, J.B.1

1 ISM (Aix-Marseille University, France), 2 INS (Marseille, France).

**Introduction** The corticospinal (CS) system plays an important role in fine motor control, especially in precision grip tasks (Lemon et al., 1995). Most of the CS projections originate in the primary motor cortex (M1). However, in monkey, CS projections have also been found originating in Supplementary Motor Area (SMA) (He et al., 1995). We recently showed direct communication between human SMA and intrinsic hand muscles that seems to be related to the precision of force control (Chen et al, submitted). This suggests that CS projections from human SMA exist and become functional when manual force control needs high precision. In order to further study these CS projections from SMA, we compared the muscle responses to transcranial magnetic stimulation (TMS) of human M1 with that of SMA during a fine visuomotor force tracking task. **Methods** Eight right handed subjects maintained a cursor on a target profile, moving from right to left on a computer screen, by applying a force on a custom device with their right hand precision grip. The precision level of the control was imposed by two cursor sizes (smaller cursor = higher precision). Neuronavigated TMS was used to stimulate left M1 and SMA. We compare the motor evoked potentials (MEP) between SMA and M1 stimulation on an intrinsic right hand muscle. Results The MEPs for both stimulation sites were very stable across trials. SMA stimulation evoked MEPs on right FDI with similar latency, amplitude, and duration as M1 stimulation but with a significant shorter silent period (SP) ( $p < 0.0005$ ). Also, for M1 stimulation but not for SMA stimulation, SP was longer for the force control with high precision ( $p < 0.04$ ). **Discussion** The CS projections from SMA on hand muscle motoneurons seem to be as functional as those from M1 during precise force control tasks. However, the SP following TMS of SMA is shorter than that following TMS of M1, which suggests that the intracortical circuits are different for the two cortical sites. Moreover, the difference observed between SP for the high and low precision for M1 but not for SMA stimulation suggests that M1 and SMA are differently involved in the fine force control. **References** He SQ, Dum RP, Strick PL. ### A DYNAMICAL SYSTEM APPROACH OF HORSE-RIDER COORDINATION DURING ENDURANCE RACE

Viry, S.1,2, Sleimen Malkoun, R.1, Temprado, J.J.1, Frances, J.P.3, Berton, E.1, Laurent, M.1, Nicol, C.1

1: ISM (Marseille, France), 2: BRD Concept (Anglet, France), 3: JPF Stables (Venelles, France)

**Introduction** In riding, most biomechanical studies have focused on the description of the horse locomotion and its variability in unriden condition. The coupling concept, inspired from the dynamic approach of complex systems, is particularly appropriate for the analysis of the horse-rider coordination (Lagarde et al. 2005, Wolfram et al. 2013). The recent development of mobile technologies allows combined horse and rider recordings during long lasting natural events. In the present study, we aimed to provide a method to characterize the dynamics of the horse-rider system using simple and unified representations of macroscopic variables capturing the horse-rider coupling in the various contextual situations of an endurance race. **Methods** An international horse-rider dyad was thus recorded during a 120 km race by using two tri-axial accelerometers (Equimetrix® and Locometrix®) placed as close as possible to their respective center of masse. Accelerometer data analysis concentrated on the relative horse and rider's vertical displacements to identify horse's gaits, riding techniques and horse-rider coupling patterns through Lissajous plots. Results The obtained shape and inclination of Lissajous plots allowed us to characterize four patterns of horse-rider coupling. These data revealed the use of two riding techniques per horse's gait (trot and canter) that could be quantified along the endurance race. The relative phase values between the respective horse and rider's vertical displacements at the lower reversal point of their mean cycle were found to be more dependent on the riding technique than on the horse's gait pattern. **Discussion** We showed that the concepts, methods and tools of self-organizing dynamic system approach offer new directions for understanding horse-rider coordination. The four specific patterns identified for the horse-rider coupling were found to depend more on the riding technique than on the horse's gait. The ridden horse model should therefore be differentiated from the unriden one. The identified horse-rider coordination patterns may thus be taken as basis to study their evolution and variability along endurance races. This analysis revealed for present horse-rider dyad a change in strategy toward the end of the race, leading to a clear victory. In case of fatigue that is expected to affect most horse-rider dyads in such races, it would be of interest to determine whether changes may also be triggered by rider-related constraints (e.g. muscle fatigue) or horse-related constraints or a subtle combination of both. **References** Lagarde J, Kelso JA, Peham C, Licka T (2005). *J Mot Behav* 37: 418-424. ### DEVELOPMENT OF SYNERGY IN TIME FOR A CONTINUOUS ACTION PERCEPTION TASK

Vázquez, P.1, Martín, J.M.2, Hristovski, R.3, Balagué, N.1

1: INEFC Barcelona (Spain), 2: University of Las Palmas, Gran Canaria (Spain), 3: Ss. Cyril and Methodius University, Skopje (Rep. of Macedonia)

**Introduction** According to the uncontrolled manifold (UCM) hypothesis different components co-vary producing compensatory actions in order to stabilize a motor synergy (Scholz & Schöner, 1999). A negative co-variation of these components has been demonstrated in discrete tasks (Latash, 2008). We aimed to connect the UCM hypothesis to a continuous action perception task and hypothesized that control of constant cycling frequency (RPM) is a dominantly anti-persistent process. **Methods** Six elite male triathletes performed a cycling exercise (Excalibur Sport 925900) consisting in pedalling for 1 min/resting for 1 min at different workload intensities (ranging from 50W to 550 W) and maintaining 70 RPM at each intensity. The RPM, sampled with a time resolution of 100 Hz and magnitude resolution of 1 RPM, were continuously recorded for further analysis. The DFA method with linear fit was applied to the residuals of the RPM time series in order to obtain spectral slopes ( $\alpha_1$  and  $\alpha_2$ ) from the log-log plot of the strength/time relationship in interval 0.2-0.9s and 0.9-10s, respectively. The Chow test was used to compare the slopes and to obtain the corresponding p values. Results Anti-persistent fBm of the RPM variable was found in 70% of the time series for interval  $\tau \leq 0.9s$  and 76% of the series for interval  $\tau > 0.9s$  across different subjects and different exercise intensities. A crossover in the slopes of the log-log plot of the strength - time interval relation ( $\alpha_1 = 1.25 \pm 0.25$  and  $\alpha_2 = 1.39 \pm 0.15$ ;  $t(46) = -3.47$ ;  $p < 0.001$ ) was observed. Persistent fBm was found in 13% of the time series for the shorter time interval (0.2-0.9s) and in 24% for the longer time interval (0.9-10s) of fluctuations. A persistent Gaussian noise (fGn) profile was found exclusively in the shorter time interval ( $\tau \leq 0.9s$ ), specifically in 17% of the time series. **Discussion** While persistent fGn correlations were detected at the beginning of the task when the system sought to stabilize the cycling synergy, the anti-persistent fBm served to confine the system close to

the target value (70 RPM). So, the crossover between persistent fGn and anti-persistent fBm may be seen as a compromise strategy between exploring and confining close to a constant cycling frequency on different time scales. These observations comply with the UCM hypothesis and show that the stabilization of the continuous cycling RPM is of an anti-persistent nature. References Latash, M.L. (2008). Synergy. ### PERCEPTION AND ACTION DURING INDOOR CLIMBING: EFFECTS OF SKILL LEVEL

Orth, D.1,2, Seifert, L.1, Davids, K.2,3

*University of Rouen*

1: CETAPS (Rouen, France), 2: SENS (Brisbane, Australia), 3: FiDiPro (Jyväskylä, Finland) Introduction Ecological dynamics is an applied ecological psychology and behavioral dynamics framework for educating perception and action based on representative individual, task and environmental constraints (Davids et al., 2012). During climbing, skill level shapes the intentions, perceptions and actions of individuals (Seifert et al., 2013). For example, perceptions of low experienced (LP) climbers appear principally constrained by information and cognitions related to stability (hold size, depth) whereas, experienced (EP) climbers appear constrained by performance goals (movement progressions, crux points) (Boschker et al., 2002). It is unclear, whether perceptual-cognitive characteristics are commensurate with behavioral dynamics observed during climbing performance. Hence, the aim of this study was to explore skill effects on the relationship between perception and actions when climbing an indoor wall. Method Six LP participants (5b-5c ability) and six EXP (6a-6b), were observed undertaking one ascent on the same indoor climbing route (5c). The climbing wall was vertical, 10.3 m high, with 20 holds. Each hold included at least one vertical and one horizontal grasping edge. Instructions were to fluently climb at a self-preferred pace without falling, allowing perception and action processes to naturally emerge. Behavioural data were video-recorded for each hold and perceptions recorded via a validated questionnaire. Results The occurrence of falls in the LP group was higher than in the EP group,  $U=3$ ,  $z=2.80$ ,  $p=0.01$ . At crux points, differences emerged in left vertical,  $U=7.5$ ,  $z=2.02$ ,  $p=0.04$ , and left horizontal,  $U=6$ ,  $z=2.17$ ,  $p=0.03$ , grasping between the LP (respectively:  $Mdn=1$ ,  $Mdn=1$ ) and EP ( $Mdn=1.5$ ,  $Mdn=0.5$ ) groups. The LP group reported, on average, lower ratings of graspability and usability for the holds ( $M=3.04$ ,  $SD=1.24$ ) than the EP group ( $M=4.67$ ,  $SD=1.13$ ),  $t(12)=2.43$ ,  $p=0.48$ . Discussion Data suggested interrelated differences in perception and action based on skill level. LP climbers did not appear to have clear perceptions of structural or functional hold properties. At crux points this may be related to a tendency to touch holds dedicated to the feet and utilize holds in an intrinsically stable manner. In contrast, the higher levels of perceived structural and functional aspects of the holds in the EP group may be related to a richer behavioral repertoire at the crux points, reflecting acquired functional grasp variability (Seifert et al., 2013). Future work should develop learning design that educates functionality in both perceptions and actions of individuals. References Boschker, M., Bakker, F., & Michaels, C. ### THE CONSTRAINT IN THE IMAGERY OF HAND-FOOT COORDINATED MOVEMENT.

Nakagawa, K.1,2, Kawashima, S.1, Muraoka, T.3, Kanosue, K.4

*Waseda University*

1Graduate School of Sport Sciences, Waseda University (Saitama, Japan) 2Research Fellow of the Japan Society for the Promotion of Science 3College of Economics, Nihon University (Tokyo, Japan) 4Faculty of Sport Sciences, Waseda University (Saitama, Japan) INTRODUCTION Rhythmic multi-limb coordination is restricted by various constraints. For instance, moving the ipsilateral hand and foot in the sagittal plane in the opposite direction is much more difficult than the one in the same direction (Baldissera et al., 1982). The relative contribution of motor and cognitive processes in generating this constraint (directional constraint) has not been well understood. The purpose of the present study is to investigate the cognitive contribution to the directional constraint by comparing physically executed and imagined coordinated movements. METHODS Subjects performed three kinds of tasks. First, they did 10 cyclical coordinated movements of right hand and foot as fast and precise as possible. Second, the same movement was done in imagery. Finally, the movement was done in the combination of real execution in one limb and imagery in the other. Each task was performed under two modes; the same directional and the opposite directional movement. To evaluate the performance of imagined coordination, we measured the time that is taken to accomplish each task (Guillot & Collet, 2005) by pressing the switch in subject's left hand at the start and finish of a task. RESULTS & DISCUSSION In the imagery and combination tasks, the opposite directional movement significantly took longer than the same directional movement, which is the same as observed for executed movements. It has been shown that when a motor imagery task is difficult, the time spent for imagery tends to be longer. Thus, it indicated that even in imagery, the opposite directional movement was more difficult than the same directional movement. This result suggests that the directional constraint can be occurred only with cognitive process. ADDITIONAL EXPERIMENT To investigate the possibility that the directional constraint in the mental imagery were the result of subject's preconception about the constraint, we asked subjects who were perfectly naïve about the directional constraint to perform the imagery task before they experience/know the constraint by physically execution. The result showed that the temporal difference between the opposite and the same directional movement in imagery appeared irrespective of preconception. CONCLUSION The constraint in hand-foot coordination should depend substantially on cognitive process. REFERENCE Baldissera F. et al. (1982). *Neurosci Lett*, 34(1): 95-100. Guillot A. & Collet C. ### MOVEMENT SELF-CONSCIOUSNESS AND CONSCIOUS MOTOR PROCESSING <'REINVESTMENT'> IN A SURGICAL CONTEXT

Malhotra, N., Poolton, J.M., Wilson, M.R., Fan, K.M., Masters, R.S.W.

*The University of Hong Kong*

Objective This study investigated how two dimensions of movement specific reinvestment (conscious motor processing or movement self-consciousness) explained differences in performance of a laparoscopic surgery task under pressure. Background The impact of psychological pressure on performance has been extensively investigated in the sport science and motor skill learning domains. Surgical educators have recently recognized the potential benefits of interdisciplinary research, yet the focus remains on identifying external factors that cause performance breakdown, without accounting for individual differences in the ability to cope with stress. One individual difference that has been implicated in failure to meet task demands in motor skill learning and recently in laparoscopy is 'reinvestment', the propensity to consciously monitor and control movements. The potential to 'reinvest' is reflected in the propensity to become self-conscious about movements (movement self-consciousness; MSC) and the propensity to manipulate conscious knowledge to control the

mechanics of movements (conscious motor processing; CMP). Methods Undergraduate medical students with no prior experience in laparoscopy were scored on the Movement Specific Reinvestment Scale and subsequently trained to proficiency on a fundamental laparoscopic task. Participants were invited back for a delayed retention condition followed by two conditions designed to evoke either movement self-consciousness or conscious motor processing. In the delayed retention condition, participants were simply asked to do their best, as they had in training. In the reinvestment conditions participants performed under time constraints and were informed that they would be evaluated by a senior surgeon. In the MSC condition, the surgeons' assessment was on the basis of a video of the participant and in the CMP condition the assessment was based on performance as seen from the laparoscopic camera. Performance measures included completion time and number of errors and kinematic data was collected using a previously validated motion analysis system. Stress levels were assessed using a shortened version of the State Trait Anxiety Inventory (STAI). Results All participants demonstrated increased anxiety levels from delayed retention to the reinvestment conditions as indicated by their STAI scores. Overall there was a positive relation between total reinvestment scores and completion times at delayed retention as well as in the MSC reinvestment condition. Similar trends were observed for the movement self-consciousness factor which seemed to be explained by the kinematic data. Scores on the conscious motor processing factor, however, were not associated with performance at delayed retention or either of the two reinvestment conditions. Conclusion The relationship between reinvestment and laparoscopic performance under normal and pressured situations for trained medical students seems to be better explained by the movement self-consciousness factor.

### SENSORIMOTOR INTEGRATION FOR TACTILE PERCEPTION IN ARCHERS

Shih, Y.L., Tseng, L.W., Wen, S.P.

*National Taiwan University of Physical Education and Sport*

Introduction Sensorimotor integration is the foundation of movement coordination. The cerebellum has been long regarded as an essential brain organ for movement coordination. In our previous study of visual duration perception, findings from healthy participants suggest that cortical computation could be saved by receiving integrated sensory information from the cerebellum (Shih, Yeh, Kuo, Tzeng, & Hsieh, 2010; Shih, et al., 2009). The present study aims to extend our previous findings by examining the sensorimotor integration for tactile perception in archers, who are mastery of movement coordination. Methods 47 participants, 16 archers, 15 runners and 16 novices, were recruited in the current study. Participants were instructed to passively sense or actively compare the tactile stimulation on their finger. Functional magnetic resonance imaging was used to investigate the difference of sensorimotor adaptation among these three groups. Results It was found that the somatosensory associative cortex (BA7) and the cerebellum yielded significantly higher activations in both runners and novices than in archers. Discussion In accord with the predictions of sensory acquisition hypothesis of the cerebellum (Bower, 1997), the cerebellum plays an important role in tactile discrimination (Gao, et al., 1996). In addition, through the process of the sports training, the expert brain adapts itself to a more economic mode for saving the neural processing loading in the related sensory areas, i.e. somatosensory associative cortex and the cerebellum. ### WRIST PROPRIOCEPTION ACCOUNTS FOR PERFORMANCE IN FREE-THROW SHOOTING IN BASKETBALL

Sevrez, V.1,2, Bourdin, C.2

*1: Lyon 1 University (Lyon, France), 2: CNRS and Aix-Marseille University (Marseille, France)*

Introduction The free-throw in an unhindered basketball shot generally awarded to a player as an opportunity to score points after being fouled by the opposing team. Theoretically, it should be considered one of the easiest shots, as the player stands close to the basket with no interference from the opposing team, but NBA statistics (<http://www.nba.com>) do not necessarily confirm this relative simplicity. Given that the trajectory of a thrown ball is fully determined by conditions at release, those conditions dependent on the configuration of the entire body, and given the critical role of proprioceptive information in controlling multi-segmental motor skills (Cordo et al., 1994; Sarlegna et al., 2006), this study questions the possible link between success rate and players' proprioceptive ability at the wrist and/or elbow joints. Methods Fifteen members of the Aix-Marseille University basketball team volunteered to participate in this study. We designed an experimental protocol to directly correlate their performance on a seated free-throw task (to emphasize the role of upper-limb) and on an elbow and wrist Joint Position Matching (JPM) task (Goble, 2010). Results A Pearson product correlation coefficient revealed an interrelation between performances at the seated free-throw and JPM tasks at wrist joint; with both JPM absolute errors (AE) and variable errors (VE) being negatively correlated with free-throw success rate ( $N=-0.59$  and  $N=-0.73$  for AE and VE respectively,  $p<.05$ ). No correlation was found between the success rate and the JPM task at elbow level. Discussion The main result of our study concerns the significant relationship between the free-throw success rate and the basketball players' joint position sense for the wrist but not for the elbow joint. This result reveals that free-throw success rates are, at least partly, determined by the wrist proprioceptive ability of the subjects. From a motor control point of view, our results suggest that basketball players organize their throwing behavior on the basis of this sensory modality. At a more practical level, it can represent a first line of evidence to explain why some highly skilled basketball players remain poor shooters after many years of practice and may therefore lead to new techniques to enhance throwing efficiency. M.; Bourdin, C.; Vercher, J.-L. & Blouin, J. (2006). *Brain Res Bull*, 69, 404-415.

### INVESTIGATION OF THE ACQUISITION OF A SERIAL MOVEMENT TASK AS A FUNCTION OF ATTENTIONAL FOCUS INSTRUCTIONS

Chow, J.Y.1, Woo, M.T.2, Koh, T.H.2

*1:Nanyang Technological University, 2: Republic Polytechnic*

Introduction The effect of externally-focused and internally-focused attentional instructions have been extensively investigated in both discrete and continuous skills rather than serial skills. External focus of attention instructions seem to be beneficial as it promotes a more automatic type of control as it reduces conscious interference to the lower levels of control at the central nervous system (CNS) (Peh, et al., 2011; Wulf, et al., 2001). However, novice learners can also benefit from internal focus of attention instructions especially in learning of movement forms in some instances. The purpose of this study was therefore to examine the effect of different attentional focus instruc-

tions on learning a serial task (i.e., taekwondo routine). Methods Fifteen participants, aged  $30.4 \pm 4.5$  years, with no prior experience in any form of martial arts, were assigned to either an internal focus condition (IFC,  $n=8$ ) or an external focus condition (EFC,  $n=7$ ). Participants underwent 12 training sessions with their respective instructional conditions over 8 weeks with 30-minute per session during the intervention phase. Serial skill tasks (hand techniques, kicking techniques and 10-step routine) were recorded at three different periods – “the 12th training session”, “1-week after last session”, and “1-month after last session”. Performance videos were viewed by 3 certified coaches, and assessed in three main categories – Accuracy, Mastery and Presentation. Results EFC group has significantly greater number of high scorers in 10-step routine compared to IFC for ‘1-week after last session’ compared to “the 12th-training-session” ( $p < 0.05$ ,  $r = -0.51$ ). Performance scores of the “Mastery component” at EFC was significantly higher for kicking techniques at ‘1-week after last session’ ( $p < 0.05$ ,  $r = -0.59$ ). Scores from IFC decreased significantly from “1-week after last session” to “1-month after last session” for 10-step routine ( $p < 0.0167$ ,  $r = 0.63$ ) and kicking techniques ( $p < 0.0167$ ,  $r = 0.63$ ). Discussion In general, participants from EFC performed better in all three components of the serial skill task, highlighting the effectiveness of such instructions for a serial movement. However, some individuals of this study also benefited from internal focus of attention instructions. Future studies could examine learner’s inclination for different types of attention instructions by assessing individual performer’s preferences. References Peh, Y.-C. S., Chow, J. Y., & Davids, K. #### IDENTIFYING DEVELOPMENTAL CAPACITY IN A PHYSICAL EDUCATION SETTING; THE KÖRPER KOORDINATIONEN TEST FÜR KINDER

de Niet, M., Platvoet, S., Visscher, C., Elferink-Gemser, M.T.

*HAN University of Applied Sciences*

Introduction According to Dutch physical education (PE) teachers, a main capacity of a child with the potential to reach the elite level is ‘developmental capacity’ (Platvoet et al). This is in line with Bailey and Morley’s model of talent identification (2006). The next challenge is to identify developmental capacity in a PE setting which is currently not feasible. The Körper Koordinations Test für Kinder (KTK) is a valid and reliable tool to evaluate gross motor skills from 5-15 years (Kiphard and Schilling, 2007). These skills are mandatory to become an elite athlete (Vandorpe et al., 2012). The aim of the current study was to test whether a longitudinal design applying the KTK repeatedly is suitable to measure developmental capacity in 6-8 year old children. Methods In this study, 147 children (90 girls) participated with mean age of  $6.7 (\pm 1.6)$  years. The KTK consists of four subtasks; (1) Walking backward over beams, (2) hopping on one leg over piles of pillows, (3) moving sideways on wooden boxes for 20s and (4) Jumping sideways (two feet) for 15s. The raw scores of the subtests were corrected for age and gender (based on normative values) and result in one motor quotient (MQ). The KTK was assessed three times (Week 1, 4 and 7). In each of the four PE lessons between the KTK assessments, children trained gross motor functioning for about 10 minutes. The total scores of the KTK were tested using a repeated measures ANOVA ( $\alpha=0.05$ ) and post-hoc t-tests. Results The mean MQ of the KTK for T0, T1 and T2 were respectively  $78.04 \pm 11.9$ ,  $84.36 \pm 13.5$  and  $87.06 \pm 13.3$  ( $F(1,146)=88.141$ ,  $p < .001$ ). The MQ-scores increased per assessment ( $T1 > T0$ ;  $p < .001$ ,  $T2 > T0$ ;  $p < .001$  and  $T2 > T1$ ;  $p = .024$ ). Further, Cohen’s effect size values ranged from small to large with the largest effect between T2 and T1 ( $T0-T1$ ;  $d = .50$ ,  $T1-T2$ ;  $d = .20$ ,  $T0-T2$ ;  $d = .70$ ). Discussion The results show that, in 6 weeks of just one hour of PE per week, scores on the KTK improve. This suggests that the KTK can be used to measure developmental capacity on gross motor skills. The next step is to study whether children with high developmental capacity are indeed children with potential to become an elite athlete in the future. References Bailey R, Morley D. #### BALANCE AND BILATERAL SKILLS OF SELECTED ADOLESCENTS IN THE STELLENBOSCH REGION, SOUTH AFRICA

Africa, E., Van Deventer, K., Breytenbach, R.

*STELLENBOSCH UNIVERSITY*

Introduction Physical development is crucial for the holistic well-being of all children. Thus, it is vital that physical development is addressed during the early years of maturation. Methods One school was selected from a previously disadvantaged community in the Stellenbosch region. The study sample consisted of children ( $N=67$ ) between the ages of 10 and 12 years-old. Two classes in the school were recruited and thereafter randomly selected as either the experimental ( $n=35$ ) or control group ( $n=32$ ). The experimental and control groups completed the Short Form of the Bruininks-Oseretsky Test of Motor Proficiency-2 (BOT-2) (Bruininks & Bruininks, 2005), during the pre- and post-tests. Only the experimental group participated in a self-designed motor skills development programme for 12 weeks. Results are presented as means and standard deviations and a 5% significance level ( $p \leq 0.05$ ) was used as a guideline. Results No significant improvements in mean standard scores or mean percentile ranks were found for the experimental or the control group. There was very little variance in the scores achieved by all the participants as most of them were able to achieve the maximum score on the selected subtests activities according to the Short Form of the BOT-2. No significant improvements were observed in either the experimental or control group for the fine motor precision, fine motor integration and upper limb coordination subtests of the Short Form. The experimental group, however, showed a significant improvement in manual dexterity when compared to the control group after participation in the motor skills development programme. An unexpected significant improvement was observed in the running speed and agility score of the control group, compared to relatively no change in the score of the experimental group. No significant improvements were observed in either the experimental or control group for the full push-up activity. Discussion Balance and bilateral coordination plays such an important role in the physical activity participation of children. According to literature, children should have mastered the

basic fundamental motor skills (FMS) by the age of seven. Yet, as seen in this study, children between the ages of nine and 12 years still struggle to perform some of the most basic balance and bilateral coordination tasks, such as skipping or balancing on one leg. This suggests that the children of today are struggling to master their FMS during the relevant windows of opportunity and thus experience delays in motor skill proficiency, subsequently affecting their participation in physical activity. REFERENCES BRUININKS, R.H. & BRUININKS, B.D. (2005). BOT2 Bruininks-Oseretsky test of motor proficiency manual (2nd ed.) Minneapolis: NCS Pearson.

### **SELF-PERCEIVED MOTOR COMPETENCE, PHYSICAL ACTIVITY LEVEL AND FITNESS IN ADOLESCENTS.**

Perez Soto, J.J., Garcia-Canto, E., Rodriguez, P.L., Lopez-Minarro, P.A.

*University of Murcia*

**Introduction** Motor competence has been considered to be a possible determinant of children's physical activity. Earlier studies have found a relationship between poor physical fitness outcomes and a reduced level of physical activity for children with low motor competence compared with their peers with better motor skills. The aim of this study was to determine the relation between self-perceived motor competence and physical conditioning in adolescents. **Methods** A total of 533 adolescents (mean age:  $15.43 \pm 1.14$  years) participated in the study. Physical fitness measures included the handgrip strength, the number of curl-ups in 60 seconds, Ruffier-Dickson test and sit-and-reach test. The short version of the International Physical Activity Questionnaire was used to determine physical activity patterns. Self-perceived motor competence was determined by adolescents among three categories (high, intermediate or low). **Results** In total, 25.5% of the adolescent were classified as physically active. Males were significantly more active than females. The results showed a moderate and significant correlation between self-perceived physical competence and level of physical fitness. Sex differences were also found with males demonstrating more physical fitness and reporting higher perceived physical competence compared with females. **Discussion** Motor competence is a variable which predicts the adolescents' positive behavior towards physical activity (Moreno et al., 2007). The current study showed a positive relation between self-reported motor competence and fitness level. Vedul-Kjelsås et al. (2012) reported that physical fitness was highest correlated with perception of athletic competence in boys but with perception of social acceptance in girls. Ruiz et al. (2008) found that subjects with low motor coordination abilities had a poor fitness self-perception. In another study, Cairney et al. (2005) suggested that young with coordination disorder are less likely to be physically active. The results of this study indicate that physical activity level and fitness condition are positive and significantly associated with the self-reported motor competence in adolescents. Because motor competence is a determinant of physical activity, then strategies that increase movement skills in childhood and adolescence may be an important target for helping to increase physical activity and health in youth. **References** Cairney J, Hay JA, Faught BE, Wade TJ, Corna L, Flouris A. ### **RELATIONSHIP BETWEEN THROWING MOVEMENT AND MOVEMENT RECOGNITION IN ELEMENTARY SCHOOL CHILDREN**

Fukuda, T.1, Ueda, T.1, Murosaki, K.1, Ueda, M.2, Ishii, Y.1, Kurokawa, T.1

*1)Hiroshima University, 2)Yamaguchi University*

**Introduction** The purpose of this study was to examine if elementary school children can recognize and improve their own throwing movements. **Methods** Subjects included 17 children (8 boys and 9 girls) aged 10 to 12 years. Subjects were asked to throw a tennis ball twice with a maximal effort. No other instructions were given. After the first trial, they were instructed regarding four points about their throwing form: 1) lifting the elbow over the shoulder, 2) extending the elbow, 3) pulling the elbow of the throwing arm and following through with the shoulder, and 4) turning the shoulder after turning the waist. They were then asked to throw a tennis ball twice with maximal effort again. In addition, they answered questions about how they thought they did in regard to the four points. The four throwing attempts were analyzed using a three-dimensional movement analysis system (Venus 3D, Tokyo). The relation of self-knowledge about throwing form to real biomechanical movements was compared between before and after instructions using t-tests. **Results** Children who could recognize their movements did not always improve their throwing form after receiving instructions. On the other hand, children who could not recognize their movements did not always get worse after receiving instructions. Children who indicated they focused on the single point of extending the elbow or pulling the elbow of the throwing arm and following through with the shoulder showed significant improvements in their movements ( $p < 0.05$ ) after receiving instructions. However, children who indicated they focused on lifting the elbow over the shoulder or turning the shoulder after turning the waist did not show improvements in their movements after receiving instructions. **Discussion** In the present study, the throwing form did not affect whether children were able to recognize their own form or not. It appeared that children were not able to recognize any series of actions involved in their throwing motion. After they focused on one of two specific points of movements provided in the instructions, it was possible to improve their movements. However, they could not improve their movement when they focused on other points of the instruction.

### **COORDINATIVE CONTROL OF POSTURE AND EQUILIBRIUM IN HIGH LEG KICK**

Liang, Y., Sakaguchi, M., Kanosue, K.

*Waseda University*

**Introduction** In the organization of a given motor act, the central nervous system has to not only coordinate the movement with posture but also coordinate equilibrium control with the postural stabilization of specific segments. The goal of this study was (1) to investigate whether or not non-acrobatic (N-A) athletes can accomplish a stable dynamic equilibrium than novices during single leg stance of high leg kick; and (2) to investigate whether or not the instruction on arm movement is helpful to maintain a good posture. **Methods** Ten collegiate male players with at least 7 years experiences in baseball or track and field, and ten college male students without any experience in intensive or long term training were asked to perform high leg kick. The movement was carried out in two conditions: with and without instruction on arm movement. Participants performed with barefoot while their body motion was captured with an 8-camera motion analysis system (Motion Analysis Corp., Santa Rosa, CA). **Results** ANOVA revealed the significant effect of condition in ML direction of CoM-ankle inclination angle ( $F=15.822$ ,  $p < 0.05$ ) and trunk angle to supporting leg ( $F=29.981$ ,  $p < 0.05$ ) at initial in single leg stance, and a significant interaction between condition and group in range value of CoM-ankle inclination angles in direction of A/P ( $F=6.573$ ,  $p < 0.05$ ) and M/L ( $F=4.915$ ,  $p < 0.05$ ). The post hoc paired t-test showed ML direction of CoM-ankle inclination angle was significantly less in with instruction condition. ANOVA revealed a main effect of condition ( $F=33.581$ ,  $P < 0.05$ ) and a main effect of group ( $F=8.764$ ,  $P < 0.05$ ) in A/P

direction of trunk inclination angle at initial; an interaction between condition and group ( $F=4.569$ ,  $p<0.05$ ) in peak value of trunk inclination angle in A/P direction as well, and no significant difference in post hoc paired t-test. Discussion In the condition of with instruction, the novices presented inferior dynamic equilibrium in whole motion of single leg stance after instruction was given. Arm instruction was incapable of helping both groups to maintain a good posture in single leg stance, and novices seemed performed more hard than non-acrobatic athletes. Our results in favor of the general motor ability hypothesis from Adams that is any human skill should remain observable among various tests. We suggest that arm movement is better to coordinate after beginners are capable to control their posture with unconsciously. References 1. Massion, J. (1992). ### **MOTOR SKILLS AMONG 4 TO 7 YEAR-OLD SERBIAN PRE-SCHOOL CHILDREN**

Jaksic, D., Bala, G., Krneta, Z., Vujkov, S., Drid, P.

*University of Novi Sad*

Introduction In preschool ages, it could be very big impact on forming motor development of children. Based on previous practical experiences in work with children, we can suppose that motor skills, which could be observed like motor development, are qualitative different in compare with school age and especially with older children. Education and motor activities at kindergarten contribute significantly to the development of motor abilities (Bala & Katic, 2009; Bala, Krneta, & Katic, 2010). Methods Sample of participants was conducted of 200 preschoolers. It was applied 7 motor ability tests. Before we started, we divide sample of participants into three subgroups. The criteria for dividing was years of age, where subsamples were made according to decimal years, i.e. first subsample – 4.5 to 5.5, second 5.5 to 6.5 and third 6.5 to 7.5. Differences between subcategories were calculated with using MANOVA and ANOVA statistics techniques. Results Differences between first and second subgroup were distinguished in: 20m dash, Polygon backwards, Arm plate tapping, Standing broad jump, Bent-arm hang and Crossed-arm sit-ups. In second case, between second and third subsample differences were in following tests: 20m dash, Polygon backwards, Arm plate tapping, Standing broad jump and Crossed-arm sit-ups, almost same like previous but without Bent-arm hang test. Discussion Determination of quantitative differences in selected variables between children of different years of age had final goal to show those differences and significance, not to explain them. It was seen that significant differences were between "neighbor" age categories, but not at all. Motor abilities have great impact on successfulness in most of sports activities. Because of that, in development of those abilities must devote a full attention in working with preschool children. During the many-years training process there are much greater requirements for development of those motor abilities, and it must be take into account that manifestations of motor abilities are not only result of genetic predispositions and environment's factors but, also, timely and methodic adequate prescribed plan and program of training. ### **COMPARISON OF 3 KINDS OF ENDURANCE RUNNINGS IN JAPANESE HIGH SCHOOL IN VIEW OF PHYSIOLOGICAL AND BIOMECHANICAL CHARACTERISTICS**

Kenta, N., Takashi, K., Goro, M., Dota, O., Keita, A., Takashi, U.

*Hiroshima university*

Introduction The aim of this study was to investigate the characteristics of 3 kinds of endurance runnings performed in the physical education class of Japanese high school by observing continuous change in physiological and biomechanical variables during running. Methods Twenty-seven male high school students were coached by three methods. The all-out method, in which the students ran 3,000m at full exertion, the inner/outer track (I/OT) method, in which the duration of exercise was nearly equalized by having slower/faster runners use the inner/outer running tracks (210m, 250m, 300m), and the RPE method, in which the students ran 3,000m according to Borg's RPE13 (ratings of perceived exertion) scale. The heart rate (HR) was measured by a HR monitor (Poral Electro co.), and the running pace, the stride length, and the stride frequency were measured by a stride sensor (Poral Electro co.) every 5 seconds during the whole running. The average of these parameters were calculated by every 300m laps. Result In the all-out method, the maximum running speed was 310 m/min in the 1st lap, and the minimum was 267 m/min in the 8th lap. It decreased significantly within the progress of running ( $p<0.01$ ). The maximum stride frequency was 94.2 steps/min in the 2nd lap, and the minimum was 89.2 steps/min in the 10th lap. Continuous change of the running speed was similar to change of stride frequency, not to the change of stride length. In the I/OT method and in the RPE method, the running speed was kept between 223-264 m/min and 208-243 m/min from the 2nd lap to the 9th lap, respectively. In the I/OT method and the RPE method, the continuous change of running speed was similar to the change of stride length not to the change of stride frequency. Discussion In the all-out method, the running speed may have decreased in the middle and final stages of running due to the high energy demand by the high stride frequency in the early stage of running (Högberg, 1952). Therefore, it was suggested that maintaining the appropriate stride frequency, considering the running ability of each runners, was important for maintaining the running speed. In the I/OT method and the RPE method, the running speed was maintained by the adjustment of stride length. It was considered that the running speed was maintained by the external information of following the other runners in the I/OT method, and by the internal information due to the ratings of perceived exertion in the RPE method. Therefore, it was suggested that the I/OT method and the RPE method were effective coaching methods in learning the pacing of running. Reference Högberg P(1952) *Arbeitsphysiologie*, 14: 437-441.

### **CONTENT ANALYSIS OF BODY REPRESENTATION IN AN EARLY CHILDHOOD EDUCATION TEXTBOOK**

Marfínez-Bello, V.

*University of Valencia*

Introduction Bodies are naturally and socially constructed. The social construction of the body influences the perception of self and others. Textbooks transmit a society's cultural capital to its youngest citizens. The aim of the study was to describe how the body is portrayed in images featured in a Preschool textbook for the first grade of early childhood education. Methods A content analysis of the images was performed using a coding frame based on previous studies. Results Girls and boys appeared nearly twice than adolescents, adults and

older people. There was an equal representation of women and men regardless of age. It was found noticeable representation of a whole body dressed with street clothing. The activity level was predominantly static and in more than half of the images was not possible to distinguish the space where the bodies were located. Conclusions The textbook as a conventional curricular material should be analyzed in terms of the hidden curriculum, in order to provide alternative forms of understanding the body as a social and cultural construction. The results suggest the need for further analysis of the textbooks in early childhood education system.

### **PREVENTION AND AMELIORATION OF OBESITY FOR CHILDREN OF PRIMARY SCHOOL THROUGH ATHLETICS AND MOVEMENT GAMES**

Țifrea, C., Hangu, S., Costache, R.

*NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORTS BUCHAREST*

**Introduction** This research is intended to be a descriptive one and experimental, whose results will be implemented in practical activity in order to improve the quality of life for children of primary cycle, aged 6-11 years by the implementation of one program of athletics and movement games aimed to prevent and to fight against the obesity. Parents and teachers as well, are asked to be aware of the risks that this "disease", involves and to intervene in order to fight against and to prevent it from childhood. A major cause of obesity occurs at a young age and it is the lack of exercise related with an unhealthy eating. The purpose of this work is to contribute in order to realize a project having the reason fighting against the obesity in primary school using athletics and moving games, practicing physical exercises regularly, except physical education and collaborating with specialists: doctors, counselors, nutritionists. **Methods:** To carry out a medical check up, their lifestyle, cardiology investigations on body mass index, adiposity, physical activity index, previous driving experience, as well as the FC drive. **Pedagogical experiment** was conducted over a period of one academic year within several schools from Romania, during the experiment the students aged 6-11 were tested. And there were realized: Anthropometric measurements and somatic, driving tests, moving games, statistical and mathematical method (arithmetic mean of the group, the mean, coefficient of variation, Student test, ANOVA) **Results** After the experiment was applied to the samples, the scientific research revealed that: applying a physical exercise program of athletics and movement games 3 times per week for children from primary cycle having obesity problems lead to losing weight and resistance increasing to effort. Practicing systematically these exercise programs lead to integration into society easier and a better intellectual development. The integration of these children into a movement organized system makes them more responsible and their families as well and accustomed to independent practice exercises and diet control and health status. The implementation of this program leads to the improvement of the quality of life. **Bibliography:** Allen J.B. - Social motivation in youth sport, *Journal of Sport and Exercises Psychology*, 2003 Craplet C., Craplet R., Craplet M., - Alimentation y nutricion del despertista, Ed. ### **ANALYSIS OF THE STUDENTS' COLLECTIVE ACTIVITY ENGAGED IN SITUATIONS OF COOPERATION IN PHYSICAL EDUCATION**

Evin, A.

*MIP universit  de Nantes*

**Introduction** This study is part of a line of research that focuses on social learning in physical education (PE) and especially on the students' activity in cooperative learning tasks (e.g., Evin et al., 2012). It aimed to characterize the dynamics of the collective activity of a group of students during a unit devoted to circus and leading to a mini show. This study was carried out according to the assumptions of the "course of action" scientific program (Theureau, 2006). It focused more particularly on the students' "courses of experience", i.e., the activity that is meaningful from the students' perspectives. **Methods** Three 6th-grade students participated in this study. Their activity was studied during a circus unit of seven lessons in which they had to build a mini-show together that was to be shown to the class during the last lesson. Their behaviours and communications were recorded on video. After each lesson they participated in self-confrontation interviews. The analysis aimed to characterize the dynamics of articulation of the students' courses of experience, to describe their modalities of cooperation and their evolution during the unit. These were described in terms of collective meaningful stories. The analysis also meant to identify the situational conditions involved in these transformations. **Results** The results showed different dynamics of transformation of cooperation modalities between the students. They are differentiated by (a) typical modalities opening and closing of collective meaningful stories (e.g., an opening after a misunderstanding between students), (b) the structure of interactional network among students (e.g., two students acting simultaneously to produce something together and the other partner was juxtaposed in relation to personal interests), and (d) the forms of these interactions. Concerning the situational conditions, the analysis highlighted several key elements involved in the dynamics of transformation of cooperation modalities: (a) the teacher's interventions, (b) the materiality of the situation, (c) the common past experiences of the students, and (d) the shared knowledge among them. **Discussion** These results show that (a) the cooperation is a co-constructed phenomenon that changes over time, (b) the cooperation within a group is not isolated in the classroom environment. These results are discussed from the point of view of the analysis of the conditions for a cooperation among the students to produce a 'collective work', and from the point of view of the design of mechanisms to promote cooperative interactions between the students in this type of situation. **References** Evin, A., S ve, C., Saury, J. ### **LEVEL OF DEFINITION AND COHERENCE OF THE UNITS OF BODY EXPRESSION IN PHYSICAL EDUCATION TEACHER EDUCATION PROGRAMMES**

Lorente, E., Montilla, M.J., Romero, R.

*INEFC University of Lleida/ University of Zaragoza*

**Introduction** There has been in recent years an increase of the literature that emphasizes on the importance of the teaching planning and its evaluation (P rez-Juste, 2000; Zabalza, 2007). In fact, the quality of the programmes plays an important role in European Higher Education Area (Leuven/Louvain-la-Neuve Ministerial Conference, 2009). The purposes of this study are: a) assess the level of definition and clarity of the elements that make up the units of Body Expression, a subject based on creative and mime dance, and b) analyse the coherence between assessment and the other unit constituent elements. **Methods** Eighteen units of Body Expression in different pro-

grammes of Physical Education Teacher Education (PETE) belonging to fourteen Spanish universities have been analysed. The study was conducted through a documentary analysis of the units using ad hoc rubrics elaborated by three university experts in Didactics; later on a descriptive statistical analysis of the results was made. Results The elements of the units better defined are the contents (88.9%), assessment criteria (77.2%) and objectives (44.4%). The 33.3% of the units do not mention the methodology and 83.3% of the cases do not describe the competencies. Regarding to the degree of coherence, the relationship between objectives and assessment criteria represents 76.7% and 77.8% for the coherence between contents and assessment criteria. Otherwise in the methodology, 'nothing or little coherent' values account for more than 50% of the cases. Discussion As main results we highlight the existence of a high degree of definition and clarity in the wording of the objectives, contents and assessment. On the other hand, methodology was little defined and competencies were hardly mentioned. There were important differences between units regarding the coherence between each of the elements and the assessment. The results of this study suggest the need to clearly define the components of the units, which ultimately are the staging of the teaching model of a Department or Faculty. Therefore it will be important that learning outcomes are well defined and consistent with the general and specific lines of the degrees. #### COMPARATIVE ANALYSIS OF THE LEVEL OF PARTICIPATION IN RECREATIONAL RUNNING EVENTS POLAND AND THE UNITED STATES

Czajka, K., Pluta, B., Stannard, A.B.

*University of Physical Education in Poznan*

**Introduction** Recreational sports such as running events have become increasingly popular in Poland over the last several years. Interest in taking part in recreational running depends often on one interests in the sport developed at an early age. Research is needed in this area in order to understand participants' background, motivation behind participation in such events, as well as the environment that could foster this increasing trend in popularization of running as a form of recreational sport. For this reason, an attempt was made, to analyze the status of participation in recreational running events based on the characteristics of the educational system from elementary school to high school for sports and recreation at universities in selected Polish and United States cities. This analysis was compared to the responses obtained from questionnaires distributed among runners participating in recreational races. Special attention was paid to runners' motivation behind sport participation and their training status.. **Methods** The study was carried out in selected areas in Poland and USA, similar in many aspects,. In Poland, Poznan was chosen as the city for analysis while in the U.S., it was the city of Lansing, Michigan. In this paper, a diagnostic survey was used. Data was obtained from 70 runners, of which 40 participants were Polish runners. The study used graphical and tabular methods of data presentation. **Results** Surveyed runners from both countries competed in road racing running events 1 to 6 times a year, which indicated a typical recreational approach towards training and competition. The major impact on sport participation was being a former athlete. Runners from US started to run earlier than Polish runner, and also their mileage was higher than Polish runners. Large differences were also visible in the infrastructure and healthcare system, between both areas. **Discussion** Based on this study carried out in Poland and the United States, it can be concluded that physical education classes as well as the culture for physical activity is more developed in US than in Poland. Also, infrastructure in the United States is much better and more accessible than in Poland. Recreational runners were motivated to partake in the running events for internal reasons, while in the United States it resulted from external reasons and was shaped by the educational system. In spite of these differences, participation as well as organization of running events by runners is remarkably similar between the two countries. **References** Gracz J. Sankowski T. #### COMPARE THE SATISFACTION WITH LIFE BETWEEN WATERPOLO WITH DEAF AND HEARING PLAYERS AND THEIR NON SPORTING PAIRS

Balogh, L., Gemes, I.

*University of Szeged, Faculty of Juhász Gyula Pedagogy*

**Introduction** The Hungarian national waterpolo team won the Olympics Games nine times, also the national deaf waterpolo team has similar results: they won six Deaflympics. One sport, in which they are the leadings, however they meet different difficulties in the life and in the swimming-pool as well. 10% of the habitants of Hungary live with impaired hearing. They live with discrimination and sociocultural differences, but there's a field where they can forgot about all of them: getting out from their closed community they enter in a new group and change their lives with sporting The actuality of my topic is the lack of the literature of deafsport. There are only a few scripts about sportsmen's satisfaction with life, mainly about the disabled people's. As an athlete I am interested in a language minority's waterpolo's life. **Methods** In Hungary 66, 8% of the men don't do any sports, from this group I asked 15-15 deaf and hearing men (n=30) with the questionnaire of Satisfaction With Life Scale (there are 5 statements that you may agree or disagree with, using the 1 (strongly disagree) – 7 (strongly agree) likert scale). Furthermore, I examined more 15-15 deaf and hearing waterpolo men (n=30). As sampling I used the simple reaching technique. I used descriptive statistic, I calculated min., max., standard deviation, mean. **Results** I worked with the Statsoft statistic program and I measured with ANOVA for each statements in the 4 groups. The probability of these results, assuming the null hypothesis are: 1) In most ways my life is close to my ideal  $p < 0,0003$  2) The conditions of my life are excellent  $p < 0,0006$  3) I am satis-

fied with my life  $p < 0,0037$  4) So far I have gotten the important things I want in life  $p < 0,001$  5) If I could live my life over, I would change almost nothing  $p < 0,071$  It is clearly seen that the deaf waterpolo players' satisfaction is much more higher ( $M1=5,73$   $SD1=1,28$ ) than the non-sporting hearing-impaired's ( $M1=4$   $SD1=1,25$ ) However, for the hearings this result is not true: they are almost equal, but the non-sporting group's results are little bit better ( $M2=5,7$   $SD2=1$ ) than the waterpolo players' ( $M2=5,27$   $SD2=1,03$ ) Discussion From these results we can see it's worth considering care for the deaf's or disabled's sport, because for a hearing-impaired the sport means more possibilities, than a hearing person. Furthermore, sport is about social contacts, this is a great chance to integrate them to the society. References Balogh, L., Szabó, A. et al. (2008) An Analysis of the Components of the "Psychological Contract" in Interactive Hungarian Team Sports. ### TO DIFFERENTIATE SELF-EVALUATION AND SELF-SATISFACTION IN THE PHYSICAL SELF: A MULTITRAIT-MULTIMETHOD ANALYSIS

Margas, N.1,2, Fontayne, P.3

1: Normandy University, France ; 2: UNICAEN, CESAMS, F-14032, France; 3: University Paris Ouest Nanterre La Défense, CeRSM, France

Introduction This study aims to show that the affective component (self-satisfaction) and the evaluative component (self-evaluation) of the physical self can be empirically differentiated in each dimension of the physical self (e.g. physical appearance and sport ability) whereas they are confused in the physical self theory, instruments and terminology. A multitrait-multimethod (MTMM) design is conducted to test convergent and discriminant validity of our proposition. Methods 389 university students (148 women, 241 men;  $Mage=20.07$ ,  $SD=1.85$ ) in sport sciences ( $n=283$ ) or other departments ( $n=106$ ) fill in a questionnaire. Two methods are used to measure self-evaluation (the sport ability and physical appearance scales of the physical self-description questionnaire (PSDQ; Marsh et al., 1997) and two scales adapted to the same dimensions from the self-competence scale of Tafarodi and Swann (1995). Three methods are used to measure self-satisfaction relative to the same dimensions (adaptation to sport ability and physical appearance dimension of the general physical scale of the PSDQ, the self-liking scale of Tafarodi and Swann (1995) and a measure of ideal-actual self discrepancy (Cash & Szymanski, 1995). Results According to our proposition, correlations between methods which measure the same component in the same dimension are always stronger than the ones which measure one component in different dimensions or one dimension in different components. Our theoretical model proposes a good fit of the data according to structural equation modeling ( $GFI=.94$ ;  $NNFI=.96$ ;  $CFI=.98$ ;  $RMR=.03$ ). Moreover, ANOVAs with self-evaluation and self-satisfactions as repeated measures reveal significant interactions between men and women on the appearance dimension [ $F(4, 1548)=7.74$ ;  $p < .0001$ ] and between sport sciences and other students on the sport dimension [ $F(4, 1548)=23.26$ ;  $p < .0001$ ]. Discussion This study shows that self-evaluations and self-satisfactions are different components of the physical self. Moreover, as the scales used here are in part issued from a classic tool of the physical self where they are supposed to measure one same construct, these components appear to be confused in that tool. As terminology, measurement, theory and empirical research are inexorably intertwined (Marsh et al., 1994), further studies are needed to show the specific roles of self-evaluation and self-satisfaction in sport, exercise and health. ### EXPERIENCING AMOTIVATION IN PHYSICAL EDUCATION: THE ROLE OF ACHIEVEMENT EMOTIONS

Jackson-Kersey, R.

LOUGHBOROUGH UNIVERSITY

Introduction Amotivation is multifaceted and is evident in physical education (PE) when a student lacks the intention and willingness to participate in compulsory activities (Deci and Ryan, 1985). Achievement emotions are critically important for students' motivation, learning and performance in educational settings (Pekrun and Stephens, 2010). The aim of the current study was to investigate whether change in achievement emotions experienced over the course of a unit of work predicted change in self-reported amotivation (deficiency in ability beliefs, deficiency in effort beliefs, low task value, and unappealing task characteristics). Methods A total of 179 male students (mean age = 14 years) participated in the study by completing a questionnaire at the end of a scheduled PE lesson. Measures included adapted versions of the Academic Amotivation Scale - Physical Education (Shen, Wingert, Weidong, Sun and Rukavina, 2010) and the Achievement Emotions Questionnaire (Pekrun, Goetz and Perry, 2005). Students completed the measures on three occasions during the unit of work which lasted for six weeks. Results Multilevel modeling analyses showed that, at the first measurement occasion, positive achievement emotions such as enjoyment, confidence and pride, were all negatively associated with the four amotivation dimensions. Negative achievement emotions such as anger, tension, hopelessness and boredom, positively predicted 'unappealing task characteristics', whereas embarrassment, hopelessness and boredom positively predicted 'deficiency in ability beliefs'. Across time, for every unit increase in enjoyment, there was a 0.08 decrease in 'deficiency in effort beliefs', whilst for every unit increase in tension, there was a 0.11 increase in 'deficiency in ability beliefs' and a 0.14 increase in 'deficiency in effort beliefs'. Discussion Overall, the findings suggest that discrete achievement emotions are linked with students' experience of amotivation in PE. An increase in tension over time, for example, may have a detrimental effect not only on students' beliefs about their lack of skills but also views about their inability to exert effort. Further work is necessary to determine the causal role played by specific emotions in the development of students' chronic amotivation in PE. References Deci EL, Ryan RM. (1985). New York: Plenum. Introduction Current unemployment rates in Western countries are worryingly high. In an attempt to enhance the employability prospects of individuals and promote positive and healthy experiences, a number of sports-based educational programs have been delivered. Despite this emerging trend, little theoretically driven evidence exists for the efficacy of such programs. Grounded in self-determination theory (SDT; Vansteenkiste, Niemiec, & Soenens, 2010), this study examined potential interpersonal and motivational processes that

facilitate self-esteem, efficacy beliefs, and future employment in a sample of disadvantaged unemployed adults. **Methods** Participants (N = 39) completed a weekly multi-section questionnaire over the 11-weeks of a sports-based educational program measuring an interpersonally supportive coaching style, three forms of motivation for attending the program (i.e., intrinsic, identified, and introjected motives), self-esteem, and efficacy beliefs. **Results** At the intra-individual level, the relationship between interpersonal support and efficacy beliefs was mediated positively by intrinsic motivation and introjected regulation. At the inter-individual level, identified regulation positively mediated the relationship between interpersonal support and efficacy beliefs, while introjected regulation negatively mediated the relationship between interpersonal support and both outcome variables. Moreover, participants who gained employment reported higher average self-esteem during the program, compared to their unemployed counterparts. **Discussion** This study contributes to the existing literature by suggesting specific processes that may help develop or forestall employment skills amongst disadvantaged adults, as well as offering potential theoretical advancements of self-determination theory. In particular, results support the potential role of interpersonal support in facilitating self-determination, but also present a word of caution by proposing that coaches who socio-emotionally invest in program attendees may also promote introjected motives for participation that reflect only minimal internalization. Thought-provoking differences between time-varying and average relationships among motives, esteem, and efficacy beliefs also emerged, which may add insight into the consequences of promoting different behavioral motives. **References** Vansteenkiste, M., Niemiec, C., & Soenens, B.
