1 Increased incidence of coronary heart disease associated with "double
2 burden" in a cohort of Italian women

3

4

5 **Abstract**

6 Objective of this study was to assess the risk of coronary heart disease (CHD) associated with
7 the combination of employment status and child care among women of working age, also
8 examining the sex of the offspring. Only two previous studies investigated the effect of
9 double burden on CHD, observing an increased risk among employed women with high
10 domestic burden or providing child care, although the relative risks were marginally or not
11 significant.

12 The study population was composed of all women 25-50 years old at 2001 census, living in
13 Turin in families composed only by individuals or couples, with or without children
14 (N=109,358). Subjects were followed up during 2002-2010 for CHD incidence and mortality
15 through record-linkage of the cohort with the local archives of mortality and hospital
16 admissions. CHD risk was estimated by multivariate Poisson regression models.

17 Among employed women, CHD risk increased significantly by 29% for each child in the
18 household (IRR=1.29) and by 39% for each son (IRR=1.39), whereas no association with the
19 presence of children was found among non-employed women or among employed women
20 with daughters. When categorized, the presence of two or more sons significantly increased
21 CHD risk among employed women (IRR=2.23), compared to those without children.

22 The study found a significant increase in CHD risk associated with the presence of two or
23 more sons in the household, but not daughters, among employed women. This is a new

1 finding, which should be confirmed in other studies, conducted also in countries where the
2 division of domestic duties between males and females is more balanced, such as the
3 European Nordic countries.

7

8 **1. Introduction**

9 During the last decades, participation of women in the labor market has greatly increased in
10 developed countries (Jaumotte, 2003). From 1977 to nowadays employment rate in Italy has
11 increased by 17%, mainly as a direct consequence of the growth among women, who passed
12 from 31.5% to 41.3% of the total employed population (ISTAT, 2013). In contrast with these
13 radical changes in women's labor market participation, women continue to carry out most
14 domestic work and child care, and such an unequal division of domestic activities between
15 women and men overburdens employed women (Gershuny, 2000; Anxo et al., 2011). From
16 the Italian Multipurpose Survey on Time Use, carried out in 2002-2003, it was found that
17 domestic work was entirely accomplished by Italian women in 41% of the interviewed
18 couples (Mencarini, 2012). In 2008, approximately 64% of the employed women in Italy was
19 engaged in paid and domestic work activities for more than 60 hours per week overall, and in
20 presence of children the proportion increased to 68% (ISTAT & CNEL, 2013). A recent study
21 by the Organisation for Economic Cooperation and Development (OECD) has shown that
22 gender differences in domestic work in Italy are the highest among the 28 EU countries, with
23 women performing 11 hours more domestic work than men per week (OECD, 2013).

1 Furthermore, the Italian Survey on the Time Use 2002-2003 showed that support to mothers
2 provided by children differs by gender, with female children more engaged in domestic work
3 than male ones. For example, in the age group 11-17 years: 65% of daughters were engaged
4 in domestic work, against 44% of sons; also, females devoted 44 minutes per day to domestic
5 work, whereas sons only 22 minutes (Romano, 2012).

6 It has been hypothesized that the double burden posed by the combination of work and
7 domestic activities on women may affect their health (Waldron, Weiss, & Hughes, 1998).

8 Different theoretical approaches exist in this research field. According to the “Role
9 Accumulation” hypothesis, multiple roles would contribute to women’s better health because
10 they provide more sources of social and economic support, self-esteem and personal
11 satisfaction (Sieber, 1974; Thoits, 1983; Waldron & Jacobs, 1989; Moen, Dempster-McClain,
12 & Williams, 1992; Lahelma, Arber, Kivelä, & Roos, 2002). On the opposite side, there are
13 theories predicting worse health for women sustaining multiple roles. According to the “Role
14 Strain” hypothesis (Gove, 1984; McLanahan & Adams, 1987; Ross, Mirowsky, & Goldsteen,
15 1990), women who combine multiple roles (wife, mother and/or worker) may experience
16 «role overload and role conflict, which contribute to increased stress and excessive demands
17 on time, energy and psychological resources – resulting in poorer health» (Waldron et al.,
18 1998). The “Negative Spillover” hypothesis is a more recent theory which assumes that the
19 transfer of negative feelings from work to the family environment, and vice versa, may have
20 harmful effects on health (Grzywacz & Marks, 2000).

21 A Swedish (Krantz & Ostergren, 2001; Krantz, Berntsson, & Lundberg, 2005) and a Finnish
22 (Väänänen et al., 2004) cross-sectional studies have shown that women who combine child
23 care and paid work report more psychological and physical symptoms than employed women
24 without children. However, most longitudinal studies on the “double burden” have found

1 either no effect or a beneficial effect of these multiple roles on women's general health or
2 mortality (reviewed by Waldron et al., 1998).

3 In contrast, the only two studies investigating specifically the effect of double burden on
4 cardiovascular health observed an increased risk among employed women with high domestic
5 burden or providing child care (Haynes & Feinleib, 1980; Lee, Colditz, Berkman, & Kawachi,
6 2003). The first one is a prospective cohort study conducted by Haynes & Feinleib (1980)
7 within the Framingham Heart Study, which found a CHD risk among employed women with
8 children almost double than that of employed women without children. The second one, also a
9 prospective study, was performed by Lee et al. (2003) within the Nurses' Health Study and
10 showed that nurses caring for non-ill children 21 hours or more per week (and caring for non-
11 ill grandchildren 9 hours or more per week) had a CHD risk 50% higher than nurses not
12 caregiving. In support of these results, Brisson et al. (1999) observed a significantly higher
13 systolic (SBP) and diastolic blood pressure (DBP) in white-collar women reporting large
14 family responsibilities, but only in presence of exposure to high «job strain», defined
15 according to the demand-control model (Karasek, 1979).

16 Considering the scarcity of evidence on the effect of the double burden posed by paid work
17 and child care on the risk of CHD in women, main purpose of this study was to examine this
18 relationship in a large Italian urban population, using number of children in the household as a
19 proxy measure of child care. This study took into account also the sex of the offspring, in the
20 light of the observed differences in terms of participation in domestic activities between sons
21 and daughters in Italy (Romano, 2012).

22

1 **2. Materials and Methods**

2 **2.1. Data collection.**

3 The study population was composed of all women 25-50 years old at 2001 census, resident in
4 Turin and living alone or in nuclear families (with their partners), with or without children
5 (n=109,358). Women living with people other than the partner or the children were excluded
6 because of the uncertainty on their child care support in the household. For example,
7 grandparents, uncles or aunts could be a burden or a resource for women in performing
8 domestic work and child care, depending on their personal choices or their health status.
9 Baseline information on demographics, marital status, family typology, presence and number
10 of children in the household, employment status and educational level was drawn from 2001
11 census data. Records from census data were linked, by means of a shared unique
12 identification number, with those of the Municipality Registry and through this, with the local
13 archives of mortality (registry of all residents' deaths since 1970) and of hospital admissions
14 (which include records of all residents in Piedmont admitted to a hospital in Italy since the
15 1980s, with a satisfactory level of completeness since 1996). As a significant proportion of
16 individuals affected by acute coronary disease usually die before hospital admission, the
17 outcome of the study was represented by a binary variable, where subjects affected by CHD
18 were identified through either first hospitalization or death from CHD during the observation
19 period 2002-2010, as done in other studies using secondary data (Silventoinen, Pankow,
20 Jousilahti, Hu, & Tuomilehto, 2005; Netterstrøm, Kristensenb, & Sjølc, 2006). Women who
21 underwent hospitalization for CHD from 1996 to the start of follow-up (January 1st 2002)
22 were excluded from the study (n=94). During the follow-up period, eventual dates of
23 emigration out of Turin or death were reconstructed. Each subject contributed to person-years
24 from January 1st 2002 until emigration, death, first hospital admission for CHD or end of
25 follow-up (December 31st 2010).

1 CHD admissions and deaths were identified in the corresponding archives through the
2 presence of ICD-IX codes 410-414 in the field of main diagnosis: acute myocardial infarction
3 (n=170), other acute and subacute forms of coronary heart disease (n=71), previous infarction
4 (n=1), angina pectoris (n=79) and other forms of chronic ischemic heart disease (n=27).

6 **2.2. Analysis**

7 CHD risk was estimated by multivariate Poisson regression models, stratified by employment
8 status (employed or non-employed) and adjusted for age (5-year groups), marital status
9 (married or cohabiting; unmarried; previously married, including separated, divorced and
10 widowed) and education level (primary, secondary, higher and graduate education). The
11 analysis was stratified by employment status, after checking by test for interaction that the
12 risk of CHD associated with having children in the household was significantly different
13 between employed and non-employed women (test for interaction: $p=0.03$). The relationship
14 between CHD incidence and child care was assessed by operationalizing the workload linked
15 to child care in different ways: 1) number of children in the household (continuous), overall
16 and by sex; 2) combinations of number and sex of children in the household (one son, one
17 daughter, one son and one daughter, ≥ 2 sons, ≥ 2 daughters, ≥ 2 sons and ≥ 2 daughters);
18 3) cumulative age of children in the household, computed as the sum of the age of all children
19 at 2001 census, also distinguished by sex, as a proxy indicator of cumulative dose of child
20 care. In multivariate Poisson regression models, all risk estimates for a given sex of the
21 children (e.g. male) were also adjusted for the presence (or number) of children of the
22 opposite sex.

23 The association between CHD risk and cumulative age of the children was examined treating
24 the latter either as a continuous or a categorical variable (up to 14 years, 15-29 years, 30 years
25 or more). Furthermore, given that the effects of the double burden are expected to be stronger

1 in women who work long hours, a test for interaction between presence of children in the
2 household and number of working hours per week on CHD risk was also performed.

3

4 **3. Results**

5 **3.1. Descriptive statistics**

6 In Table 1 are presented descriptive statistics of the study population (age, place of birth,
7 marital status and education level, by employment status and presence of children in the
8 household), as well as CHD incidence in the different groups. At start of follow-up almost 4
9 out of 5 women were employed (78% of total population) and 60% of these had at least one
10 child. The whole population of employed women used to work on average 34.7 hours per
11 week, with those with children working less hours than those without children (33.5 vs. 36.4
12 hours per week, respectively).

13 With regard to the outcome variable, about 3 out of 1,000 women had undergone
14 hospitalization (n=348) or had died (n=16) from CHD during the period 2002-2010, for a total
15 of 364 women affected by CHD during the follow-up.

16 As expected, a positive trend in CHD incidence with increasing age was observed, with a
17 strong increase in the age group 45-50 years at baseline (χ^2 $p \leq 0.001$), consistently with the
18 findings of other studies (Rosengren, Thelle, Köster, & Rosén, 2003).

19 About three quarters of the women were married or cohabiting (75%), 13% previously
20 married (widowed, divorced or separated) and 12% unmarried, with strong differences related
21 to employment status (χ^2 $p \leq 0.001$) and presence of children in the household (χ^2 $p \leq 0.001$).

22 Regarding education, more than half of women had a diploma (39%) or a university degree
23 (19%). The educational level was markedly higher among employed women (χ^2 $p \leq 0.001$) and
24 among those without children (χ^2 $p \leq 0.001$). CHD incidence decreased with increasing level

1 of education and was five times higher in the lowest educational level, compared to the
2 highest one. The only exception was the category of non-employed women with a university
3 degree, whose high incidence (88.4 per 100,000) was however estimated on only two CHD
4 cases.
5

2 Frequency distribution of number and gender of children in the household by employment
3 status is presented in table 2: 17.5% of women had 1 son, 16% 1 daughter, 14% 1 son and 1
4 daughter, 9.8% 2 or more sons, 8% 2 or more daughters and 0.2% (227 women) 2 or more
5 sons and 2 or more daughters. Age-adjusted CHD incidence was higher among non-employed
6 than among employed ones, overall and in most exposure categories. In particular, among
7 women with two or more sons in the household, a very high CHD incidence was observed
8 among those employed (79.8), which was almost the double of the incidence of the non-
9 employed (55.5). An exceptionally high CHD incidence was also observed among employed
10 women with two or more sons and two or more daughters (261.4), although computed on a
11 very small population (n=88), with only two exposed cases.

12

2 **3.2. Presence of children in the household and CHD risk among women**

3 The risk of CHD among employed women was similar to that of non-employed women, after
4 controlling for age, education and marital status (IRR=0.98, 95% CI=0.76-1.24). In the
5 overall population, the presence of children increased the risk of CHD significantly by 18%
6 for each child (IRR=1.18, 95% CI=1.04-1.33), although the risk was significantly different
7 between employed (IRR=1.29, 95% CI=1.11-1.49) and non-employed women (IRR=0.96,
8 95% CI=0.78-1.19).

9 Distinguishing number of children by sex (Table 2, model II), in the whole population CHD
10 risk increased significantly by 24% for each son (IRR=1.24, 95% CI=1.07-1.43), whereas the
11 increase in risk was smaller and non-significant for daughters in the household (IRR=1.11,
12 95% CI=0.95-1.30 for each daughter). The CHD risk associated with sons was significantly
13 modified by employment status (test for interaction: $p=0.02$), with a significant increase
14 among employed women (IRR=1.39, 95% CI=1.17-1.66) and a risk below unity for non-
15 employed ones (IRR=0.96, 95% CI=0.74-1.23). Also examining the effect on CHD risk for
16 the combination of number and sex of children, a significant interaction was found between
17 employment and having two or more sons in the household ($p=0.03$); the associated risk was
18 in fact significantly increased among employed women (IRR=2.23, 95% CI=1.48-3.36), but
19 close to unity among non-employed ones (IRR=0.99, 95% CI=0.50-1.96) (Table 2, model III).
20 In contrast, no significant association was found in either group for having one child,
21 independently of the sex, or two children of opposite sex, or two or more daughters. However,
22 a very high risk was found for women with two or more sons and two or more daughters,
23 although based on only two exposed cases (IRR=8.29, 95% CI=2.01-34.23).

24 With respect to marital status, only among previously married women the interaction between
25 employment and presence (yes/no) of children in the household ($p=0.02$) was statistically

1 significant (among married women: $p=0.94$; among unmarried women: $p=0.27$). However, the
2 risk of CHD associated with having two or more sons was, among employed married women,
3 only slightly lower than that estimated among employed women as a whole (IRR=1.93, 95%
4 CI=1.21-3.10). The risk was markedly higher among previously married women (IRR=5.11,
5 95% CI=2.01-12.96; 9 exposed cases), whereas no exposed cases were present among
6 unmarried women. In the whole population, a significantly increased risk was observed
7 among women exposed to a cumulative age of sons ≥ 30 years (IRR=1.66, 95% CI=1.16-
8 2.36), but again with a striking difference between employed (IRR= 2.28, 95% CI=1.50-3.46)
9 and non-employed women (IRR=0.87, 95% CI=0.45-1.70) (test for interaction: $p=0.004$). In
10 contrast, no significant excess risk was present in any category of cumulative exposure to
11 daughters' care, independently of employment status.

12 Regarding working hours, no significant interaction was found among employed women
13 between working hours and number of children in the household ($p=0.48$), independently of
14 their gender (sons: $p=0.47$; daughters: $p=0.06$). Similarly, the interaction between working
15 hours and the different combinations of children by gender (model III) was not statistically
16 significant ($p=0.27$).

17

2 **4. Discussion**

3 The present study showed a significant relationship between CHD risk and the double burden
4 posed by combining paid work and child care among women in Turin. While among non-
5 employed women the presence of children did not increase the risk of CHD, among those
6 employed the risk increased by 29% for each child. This association between such an
7 overburden and incidence of CHD is consistent with the only two studies on the subject in the
8 literature (Haynes & Feinleib, 1980; Lee et al., 2003). In both studies, in fact, intensive child
9 care was associated with an increased CHD risk among employed women, although the risk
10 estimates were marginally or not statistically significant.

11 With respect to the studies cited above, the most original aspect of our research was that the
12 risk of CHD was assessed according to the sex of the offspring; the results showed that only
13 the presence of two or more sons in the household increased the risk of developing CHD.

14 Parity has been found associated with an increased risk of CHD or cardiovascular diseases
15 (CVD) in several studies, although the two main articles reviewing the available evidence on
16 the subject got to opposite conclusions (Ness, Schotland, Flegal, & Shofer, 1994; De Kleijn,
17 Van der Schouw, & Van der Graaf, 1999). However, the results of more recent studies would
18 indicate that CHD risk is actually higher among women with children than among nulliparous
19 (Lawlor et al., 2003; Catov et al., 2008; Parikh et al., 2010). From a biological point of view,
20 the finding of an increased CHD risk limited to women with male children could, in theory,
21 be explained by higher intrauterine growth (Hindmarsh, Geary, Rodeck, Kingdom, & Cole,
22 2002) and greater weight of male foetuses compared to female ones (Maršál et al., 1996)
23 which would involve higher energy expenditure during sons' than daughter's pregnancies

1 (Tamimi et al., 2003). However, differences observed between sexes in these parameters are
2 likely too small to exert a negative influence on women's health (Maršál et al., 1996).

3 Number of children has also been found positively associated with several risk factors for
4 CHD, such as metabolic syndrome (Catov, 2008), hypertension (Brisson et al., 1999;
5 Zimmerman & Hartley, 1982), high levels of triglycerides and low HDL cholesterol levels
6 (Catov, 2008), high BMI (Lawlor, 2003; Hardy, Lawlor, Black, Wadsworth, & Kuh, 2007),
7 increased tone of the sympathetic nervous system (Eller, Kristiansen, & Hansen, 2011) and
8 diabetes mellitus type II (Hardy et al., 2007). Therefore, these CVD risk factors have been
9 proposed as possible mediators of parity on CHD risk, but no studies, to our knowledge,
10 reported differences related to the sex of the offspring in these intermediate outcomes.

11 With regard to socio-cultural factors, the association between the presence of male children in
12 the household and the risk of developing CHD could be explained in the light of the results of
13 the Italian Survey on the Time Use 2002-2003, showing that in Italy female children are more
14 engaged in domestic work than male ones. The gap starts to be relevant in the age group 11-
15 17 years, in which the proportion of females engaged in domestic activities is almost 50%
16 higher than that of males (65% vs. 44%) and the time spent per day is about the double for
17 females than males (44 vs. 22 minutes) (Romano, 2012). Such a difference between offspring
18 gender in term of domestic activities appears consistent with the observation that CHD risk
19 was associated with cumulative exposure to sons child care only in higher class of exposure
20 (15-29 years and ≥ 30 years), which suggests a chronic effect of exposure to the "double
21 burden" on CHD risk.

22 Another possible explanation of the different CHD risk among employed women by the sex
23 of their children comes from the results of Italian Health Behaviour in School-aged Children
24 (HBSC) international survey, promoted by the World Health Organization. These findings
25 showed some gender differences, with higher frequencies in males, with respect to the abuse

1 of alcohol and cannabis (Cavallo et al., 2013). Therefore, employed women may be
2 overburdened by the combination of working outside the household for many hours and
3 responsibilities and concerns due to the deviant behaviour of their adolescent sons.

4 Although no study investigated women's CHD risk by sex of the offspring, a few focused on
5 the relationship between children's sex and women's longevity or mortality; however, most of
6 these studies were conducted in pre-industrial or traditional developing societies, which limits
7 their generalizability to developed contemporary ones (Helle, Lummaa, & Jokela, 2002; Van
8 de Putte, Matthijs, & Vlietinck, 2004; Hurt, Ronsmans, & Quigley, 2006). Some of them
9 found an increased risk of mortality associated with the number of sons, but not of daughters
10 (Helle et al., 2002; Van de Putte et al., 2004; Hurt et al., 2006), although other studies did not
11 find significant differences in mortality by sex of the offspring (Jasienska, Nenko, &
12 Jasienski, 2006; Cesarini, Lindqvist, & Wallace, 2007).

13 These findings suggest that the association between parity and CHD risk is more likely
14 attributable to the physical and mental workload associated with child-rearing, rather than to
15 biological factors related to pregnancy. The higher risk observed among previously married
16 women, compared to married ones, would also support a causal relationship between child
17 care burden and the CHD occurrence, given the higher burden expected among these women,
18 who need to provide child care without partner's support.

19 The results of the present study, however, should be interpreted in the light of some
20 limitations in the study design and methods. First of all, it was not possible to control for
21 several potential confounders or mediators of the association between double burden and
22 CHD, such as BMI, diabetes, smoking, alcohol and physical inactivity, all CHD risk factors
23 potentially correlated with parity, since these data were not available at census. Nonetheless,
24 given that the increase in CHD risk was limited to employed women with male children, it
25 does not seem plausible that the observed association was attributable to lack of adjustment

1 for these variables, unless their prevalence was different between employed women with male
2 and female children. For example, a higher BMI among employed women with children may
3 have confounded the relationship between number of children and CHD incidence, but only a
4 higher BMI among employed women with sons, compared to those with daughters, would
5 explain the specificity of the association with male offspring. To answer this question, we
6 analyzed data from the National Health Interview 2005 on physical activity, BMI, and
7 smoking, restricting the analysis to women 25-50 years old living in Northern Italy
8 (N=7,021). In this survey, very small differences were found in average BMI (χ^2 p=0.99), or
9 in the proportion of women performing physical activity (χ^2 p=0.88) or smoking (χ^2 p=0.88),
10 by number or sex of the children living in the household (personal elaboration of the authors).
11 Another limitation concerns the possible misclassification of the number of children and the
12 professional status of the women enrolled, deriving from the impossibility of detecting
13 newborn children (and therefore also the change in the condition of mother), as well as
14 changes in employment status during the follow-up period. Therefore, it was assumed that
15 during the follow-up the number of children remained constant and that the professional
16 status of women did not change, with the expected consequence of a non-differential
17 misclassification of exposure to these factors and an underestimate of the associated relative
18 risks. Similarly, lack of information on women's employment status before 2001 census could
19 have led to identify as non-employed also women who have worked just until before 2001
20 census, and vice versa, making uncertain the duration of combined exposure to paid work and
21 child care.

22 With regard to the employment status of women, the absence of work stress indicators in the
23 available databases could represent a significant information bias. Recent reviews on the
24 relationship between exposure to psychosocial factors at work and CHD incidence have
25 confirmed the presence of a significant excess risk associated with exposure to stress defined

1 according to the two most popular models (Kivimäki, Nyberg, & Batty, 2012; Siegrist, 2010),
2 i.e. the demand-control (Karasek, 1979) and the effort-reward imbalance model (Siegrist,
3 1996). It is therefore expected that the effect of the double burden of employed women on
4 CHD risk would be theoretically higher for women exposed to stress factors at work. For
5 example, using the demand-control model, Brisson et al. (1999) observed a significant
6 increase in blood pressure only among employed women exposed to both high job strain and
7 high household workload, whereas the increase was lower and not significant among women
8 exposed to high levels of only one of these factors.

9 In conclusion, this study found a significantly increased risk of CHD associated with the
10 presence of children in the household among employed women, which was limited to women
11 with two or more male children, whereas no association was present among non-employed
12 women. This is a new finding, which should be confirmed in other studies conducted also in
13 countries where the division of domestic (and specifically child care) duties between males
14 and females is more balanced, such as the European Nordic countries (Francavilla, Gianelli,
15 Mangiavacchi, & Piccoli, 2013). In fact, the generalizability of the results of the present study
16 may be limited by the peculiarities of the Italian traditional family model, which tends to
17 overload the female gender with most of the burden of domestic responsibilities.

18 Our results suggest the need to foster social discussion in Italy on the distribution of
19 household duties and child care activities, which may help to go beyond the Italian
20 “traditional” family model. The repetition of similar research in countries with a more
21 gendered equitable division of the domestic work and child care, such as Nordic countries,
22 may help clarifying the mechanism through which employed women with sons are at higher
23 risk of CHD. The eventual persistence of such a strong association in these countries would
24 suggest that it may be attributable to other characteristics differentiating sons and daughters,
25 rather than the extent of their domestic work; for example, a more deviant behavior of sons

1 than daughters, made even more stressful and problematic for the working mothers by their
2 engagement for many hours per day outside the family.

^a age in five years classes.

^b education in 4 classes: no school or elementary school, middle school, high school and graduation.

^c place of birth in 2 classes: Italy and abroad.

^d marital status in 3 classes: unmarried, married and previously married (separated, divorced and widowed).

^e continuous variable

HIGHLIGHTS:

- 1) retrospective study (2002-10) on women aged 25-50 years at baseline
- 2) CHD risk increased significantly by 18% for each child, only among employed women
- 3) having two or more sons doubled CHD risk, also only among employed women
- 4) no significant increase in CHD risk was present among women with daughters
- 5) results may be due to a gendered division of domestic work among Italian adolescents
