Verrucous carcinoma of the oral cavity (OVC) is considered a subtype of classical oral squamous cell carcinoma (OSCC). Diagnosis is problematic, and additional biomarkers are needed to better stratify patients. To investigate their molecular signature, we performed low-coverage copy number (CN) sequencing on 57 OVC and exome and RNA sequencing on a subset of these and compared the data to the same OSCC parameters. CN results showed that OVC lacked any of the classical OSCC patterns such as gain of 3q and loss of 3p and demonstrated considerably fewer genomic rearrangements compared to the OSCC cohort. OVC and OSCC samples could be clearly differentiated. Exome sequencing showed that OVC samples lacked mutations in genes commonly associated with OSCC (TP53, NOTCH1, NOTCH2, CDKN2A and FAT1). RNA sequencing identified genes that were differentially expressed between the groups. In silico functional analysis showed that the mutated and differentially expressed genes in OVC samples were involved in cell adhesion and keratinocyte proliferation, while those in the OSCC cohort were enriched for cell death and apoptosis pathways. This is the largest and most detailed genomic and transcriptomic analysis yet performed on this tumour type, which, as an example of non-metastatic cancer, may shed light on the nature of metastases. These three independent investigations consistently show substantial differences between the cohorts. Taken together, they lead to the conclusion that OVC is not a subtype of OSCC, but should be classified as a distinct entity.

An aim of the detailed analysis of cancer genomes is to discover genomic features that are prognostic for disease outcome and predictive of treatment response. Historically, genetic changes at specific loci have provided this information but more recently examination of the whole genome has been shown to have predictive power. We have illustrated...

Key words: oral verrucous carcinoma, genomics, molecular signature

Abbreviations: CN: copy number; DEGs: differentially expressed genes; FFPE: formalin-fixed paraffin-embedded; FPKM: fragments per kilobase per million mapped; HNSCC: head and neck squamous cell carcinoma; HPV: human papillomavirus; OSCC: oral squamous cell carcinoma; OVC: oral verrucous carcinoma; PCA: principal component analysis; WHO: World Health Organisation

Oral verrucous carcinoma (OVC) is considered to be a variant of oral squamous cell carcinoma (OSCC), due mainly to similarities in appearance. However, observed differences in growth patterns and metastatic behavior have raised questions about their classification. Here, comparisons of genomic data derived from copy number sequencing, exome sequencing, and RNA sequencing indicate that OVC is distinct from its squamous cell counterpart. In particular, OVCs were characterized by fewer genomic changes than OSCCs, and the two lacked common driver events. The unique genomic features of OVC warrant its reclassification within the oral cancer taxonomy.

What’s new?
Oral verrucous carcinoma (OVC) is considered to be a variant of oral squamous cell carcinoma (OSCC), due mainly to similarities in appearance. However, observed differences in growth patterns and metastatic behavior have raised questions about their classification. Here, comparisons of genomic data derived from copy number sequencing, exome sequencing, and RNA sequencing indicate that OVC is distinct from its squamous cell counterpart. In particular, OVCs were characterized by fewer genomic changes than OSCCs, and the two lacked common driver events. The unique genomic features of OVC warrant its reclassification within the oral cancer taxonomy.

Material and Methods
Sample selection
Four different sources of FFPE tissue were used in this study. Fifteen OVC FFPE blocks were retrieved from the Pathology Department, St James’s University Hospital, Leeds, UK; 15 OVC FFPE blocks were provided by the Pathology Division, Queen Victoria Hospital, West Sussex, UK; 40 OVC samples were provided by the Pathology Division, University of Torino, Italy and seven OVC FFPE blocks were provided by the Department of Pathology, National Guard Hospital, Saudi Arabia. Written informed consent was obtained from all patients for the use of their tissue in this research and the study was approved by local ethics committees (REC ref no 07/Q1206/30 and 08/H1306/127). In total, 77 OVC lesions were identified and all diagnoses were confirmed by the study pathologist (AH). World Health Organisation (WHO) definitions and criteria were used for the histological diagnosis of OVC (Figs. 1a and 1b). Squamous cell carcinoma lesions with verrucous appearance were classified as squamous cell carcinoma with papillary architecture (Figs. 1b and 1c). Five of these samples were analysed by CN sequencing (Fig. 2d), following which the samples were excluded from further analysis. For different reasons, such as low yields of the extracted DNA and failed library preparation, 57 of 77 cases were suitable for NGS CN analysis, all of which have previously been shown not to contain human papillomavirus (HPV) DNA. Of these, 12 cases with adequate tissue were used and successfully prepared for RNA and exome sequencing. From our ongoing study of head and neck squamous cell carcinoma (HNSCC), we identified 45 HPV-negative OSCC patients for CN analysis, 16 for RNA-seq and 20 for exome sequencing. Supporting Information Table 1S summaries the clinical data from these patients.

DNA isolation for CN analysis
Tissue blocks were cut into sections and epithelial cells of interest macrodissected as described previously using stained slides as a guide. DNA extraction was performed on macrodissected FFPE tissue using Qiagen DNA extraction kits (Qiagen, Sussex, UK) according to the manufacturer’s instructions. DNA concentration and purity were quantified using a Nanodrop UV spectrophotometer: Nanodrop-8000 (Thermo Scientific, Loughborough, UK). Additionally, double-stranded DNA

the use of whole genome architecture to predict survival in squamous cell lung carcinoma patients. Genomic analysis has been used to reclassify breast cancer tumours providing better prediction of disease outcomes and recently, molecular classification using multiple platforms has effectively clustered subtypes across different cancer tissue types, identifying unexpected associations that could influence choice of therapy.

Patients with oral cancer would benefit from a biomarker that would indicate outcome, specifically regional metastatic spread. A “wait and see” approach could expose patients to the risk of under treatment of occult node metastases. Unnecessary elective neck dissection does have an associated morbidity and may remove or destroy a natural barrier to cancer spread. This is of utmost importance when considering the high risk of developing second primary tumours in case for oral cancer patients.

OVC is a case in point. The WHO classification of oral cancer recognises verrucous carcinomas as a subtype of oral epithelial cancer. It has a different morphological appearance being exophytic in its growth patterns and a different behaviour in that it is not associated with metastatic spread. However, some classical oral squamous carcinomas can have a verrucous appearance creating diagnostic uncertainty and subsequent dilemmas of clinical management. We questioned whether genomic profiling could distinguish true verrucous carcinomas from classical squamous carcinomas that may have a verrucous appearance to produce a useful diagnostic biomarker. We used formalin-fixed paraffin-embedded (FFPE) blocks as a source of tumour DNA for both next-generation sequencing at low coverage to generate copy number (CN) profiles, and exome sequencing. Additionally, RNA was isolated from the same blocks and transcription profiles generated using RNA-seq. Parallel analyses were undertaken for classical oral squamous cell carcinoma (OSCC). Comparing the profiles, we found that true verrucous carcinomas were easily distinguishable from their classical counterparts; indeed, no overlap was seen in patterns of genomic damage and transcriptional profiles could be used to clearly separate samples into their groups. Unlike classical oral tumours, TP53 was not inactivated either by mutation or HPV infection, leading us to conclude that verrucous carcinoma should be considered a separate entity from classical squamous carcinoma.
concentration was precisely measured using the Quant-iT PicoGreen dsDNA BR assay (Invitrogen, Paisley, UK).

**Nucleic acid isolation for exome and RNA sequencing**

DNA and RNA were simultaneously isolated from further macrodissected tissue from the same patients using the All-Prep DNA/RNA FFPE kit (Qiagen) according to the manufacturer’s instructions. Nucleic acid concentration and purity were quantified as before. RNA concentration was measured using The Qubit RNA Assay kit (Invitrogen).

**Copy number analysis: library preparation, sequencing and data analysis**

DNA libraries were prepared following two previously described protocols: for the Illumina Genome analyser GAIIx sequencer, and later, using NEBnext library preparation kits (New England BioLabs, Hitchin, UK) for the Illumina HiSeq 2500. Samples were pooled for cluster amplification and multiplexed up to 20 samples per lane for Illumina Genome analyser GAIIx single-end sequencing, and up to 40 samples per lane and paired-end sequenced (2X100 bp) on an Illumina HiSeq 2500.

Sample reads were split into separate files according to tags and aligned to the human reference genome. A control sample was pooled from a group of 20 British normal individuals downloaded from the 1000 Genomes Project. Reads were trimmed of adaptors using cutadapt, aligned to the human genome (hg19) using BWA, Genomic CN was analysed using CNAnorm. The genome was split into 400 kb

(a) H&E stain of oral SCC with papillary architecture at low power (magnification: $\sim \times 25$), but with cytological atypia and invasion present (b) seen at magnification: $\sim \times 100$. (c) H&E stain showing OVC classical features at low power (magnification: $\sim \times 40$) and without cytological atypia or invasion (d) seen at magnification: $\sim \times 100$, (e) magnification: $\sim \times 200$ and (f) magnification: $\sim \times 250$. 

---

Int. J. Cancer: 00, 00–00 (2015) © 2015 UICC
Cumulative frequency karyograms were constructed for the OVC and OSCC cohorts by counting how many samples had gain and loss for each position along the genome. The CN profiles of OVC and OSCC were also categorised using GISTIC2,15 identifying genes within CN-altered regions, and generating segmented CN heat maps.

The ability to distinguish OVC and OSCC samples using their CN profiles was also tested using a novel logistic regression technique.16 Each sample was removed from the total data set in turn. The remaining samples were then used to build a predictive model. Each genomic window was given a score based on its ability to distinguish the two groups. The model was then applied to the test sample and a subtype prediction was made. This process was repeated for each sample, with the model being retrained on all other samples each time, so that no sample was predicted based on a training set of which it was a part.

**Exome sequencing: library preparation, sequencing and data analysis**

DNA sequencing libraries were separately prepared using the NEBNext singleplex library preparation kit (New England BioLabs) and then exome DNA was captured with Agilent exome capture kit (Agilent Technologies, Stockport, UK). Briefly, 750 ng of each library was hybridized for target enrichment, followed by washing, indexing and ten-cycle PCR amplification. Indexed samples were pooled up to four samples per lane and paired-end sequenced (2X100 bp) on an Illumina HiSeq 2500. Sequencing was performed to an average of 90× coverage. Reads were trimmed using cutadapt12 to aligned to the human genome (hg19) using BWA.13 PCR duplicates were removed using Picard (http://picard.sourceforge.net), and indel realignment and quality score calibration were performed using GATK.17 Variant calling was performed by Varscan2 in somatic mode,18 and variant consequences were then predicted using the Variant Effect Predictor.19 Variants were filtered using a number of criteria to enrich the mutation list for functionally important genes: Mutations had to pass a Varscan2 Phred somatic score of threshold of 15 (p values <0.05); mutations had to be present in more than 50% of tumour cells, calculated taking into account tumour cell percentages and local CN, as well as absent in the matched normal sample; mutations that have a predicted possible consequence on protein function (deleterious, splice variant, probably deleterious, possibly deleterious, stop gained).

The DAVID (Database for Annotation, Visualisation and Integrated Discovery) Bioinformatics Database 6.7 was used to produce lists of significantly enriched pathways from the mutated genes passing filters in the OVC and OSCC cohorts.20

**RNA-seq: library preparation, sequencing and data analysis**

cDNA libraries were generated from the total RNA using ScriptSeq complete gold low input kit (Epicenter Biotechnologies, Madison, WI, USA). All libraries were constructed according to the manufacturer’s instructions and Ribo-Zero reagents were used to remove ~99% of rRNA (Supporting Information Table 4S).

Libraries were sequenced to an equivalence of six samples per lane of a HiSeq2500. Fastq files were processed using trim_galore to remove low-quality bases, trim adaptors and fix paired-end reads. Processed reads were aligned to the human genome GRCh37.p11 by Tophat2.0.7, using the
DNAs were sequenced to an average of 90× coverage with a ratio of C/T mismatches. The remaining patients' tumour samples had low coverage, high mismatch rate and disproportionally high copy-number variation (CNV).

Results

DNA CN analysis of OVC versus OSCC

Between 1 and 10 million reads per sample were generated for CN analysis, equating to one read to every 300 bp–3 kb, or 0.033×–0.33× coverage. CN karyograms were constructed from 57 OVC and 45 OSCC cases using CNAnorm. Individual karyograms representative of normal epithelium, OVC, and OSCC with verrucous architecture are shown in Figure 2. In general, visual inspection of OSCC karyograms showed more whole chromosome and localized gain and loss, and a higher degree of aneuploidy across the whole genome when compared to OVCs. Cumulative frequency karyograms and GISTIC heatmaps for each tumour type are shown in Figure 3.

OSCC and indeed SCC from other sites have characteristic genomic features such as gains in chromosomal arms 3q, 5p, 7p, 8q and 20p, and losses in 3p, 4p, 8p and 18q. All these chromosomal abnormalities were seen in our OSCC tumours but none was detected in the OVC group. However, OVC has its own characteristic features, namely: gains of 7q11.2, 7q22, 3p21, 15q15, 16q22 and 17q23. Chromosomal losses were infrequent in OVC but detected at 6p21 and 17q12. Samples of OSCC with verrucous architecture all showed karyograms consistent with classical OSCC.

Visual inspection of individual and cumulative karyograms indicated that there was a substantial difference between the CN landscape of OVC and OSCC genomes. We tested this by applying a novel logistic regression method that blindly predicts the subtype of a “unknown” sample based on the CN of two groups of “known” samples. Of the 45 OSCC samples, four were misclassified, whereas only one of 57 OVC samples was incorrectly predicted.

Mutation detection in OVC compared to OSCC

Exome sequencing data were produced from the tumours and matched adjacent normal epithelium for 12 OVC and 20 OSCC patients. Two OVC patients were excluded owing to evidence of severe DNA damage resulting from tissue fixation, i.e., low coverage, high mismatch rate and disproportionally high ratio of C/T mismatches. The remaining patients' tumour DNAs were sequenced to an average of 90× coverage.

From the 12 OVC patients, a total of 224 somatically mutated genes passed filters, ranging from between 9 (V-123-01) and 53 (V-116-01) genes per patient. OVC patients' individual mutation profiles are listed in Supporting Information Table 2S. From the 20 OSCC patients, 1347 mutated genes passed filters, ranging from 32 (PG-105) to 143 (PG-144) per patient.

For both tumour cohorts the most frequently occurring mutations are listed in Table 1. The top five genes (TP53, CDKN2A, NOTCH1, NOTCH2 and FAT1) in the OSCC cohort have previously been identified as significant HNSCC cancer genes. None of these genes was found to be mutated in the OVC cohort. However, four genes (DSPP, MUC4, NEFH and ANP32E) were mutated in the verrucous cohort with a frequency >30% (Table 1 and Supporting Information Table 2S). These genes were not unique to OVC, being also detected at lower frequencies in our OSCC cohort (Table 1) although not detected in other HNSCC exome studies.

For verrucous carcinoma, no genes were mutated in more than 50% of patients. Nonetheless, the use of DAVID functional analysis revealed involvement of significant number of OVC-mutated genes involved in cell adhesion and keratinocyte proliferation (Supporting Information Table 3S), while mutated genes in the OSCC cohort were more involved in cell death and apoptosis pathways (Supporting Information Table 3S).

Gene expression in OVC compared to OSCC

Gene transcription profiles were generated using RNA-Seq for all 12 OVC, with an average of 51412094 reads (ranging from 25602577 to 569763697), and with a median of 82% mapped reads. Ribosomal RNA ranged between 0 and 0.1% of the total reads (Supporting Information Table 4S). Gene expression was quantified as FPKM (fragments per kilobase per million mapped) for each protein-coding and non-coding gene. The threshold of 0.1 FPKM was used to determine whether a gene was expressed. Gene transcription data were similarly obtained from 16 OSCC samples. Significant differential expression lists for protein-coding genes in oral verrucous cancers versus OSCCs are illustrated in Table 2.

The use of DAVID functional analysis revealed that significant differentially upregulated genes in OVC versus OSCC are involved in keratinocyte differentiation and epithelium development (Supporting Information Table 5S), while the significant differentially upregulated genes in OSCC versus OVC were more involved in cell growth and migration and angiogenesis (Supporting Information Table 5S). PCA of all expressed protein-coding genes in OVC and OSCC revealed an evident separation of the two cohorts (Fig. 4).

Comparing genomic changes and expression levels

The CN and expression levels of all significantly DEGs were correlated. Most genes showed no link between expression and CN. Only three genes, SERPINE1, CDH3 and PLA2G4D, were both significantly overexpressed in OVC samples and found in recurrent regions of gain.
Only one gene reported as mutated in the exome data was significantly differentially expressed. A missense variant in CXCL5 was reported in one OVC sample. This gene was under-expressed in OVC samples compared to OSCC.

**Discussion**
Clinically, OVC appear as exophytic masses with a verrucous surface but, less often, they may be relatively smooth. Furthermore, OSCC can have a superficial verrucous appearance,
thus morphological features alone can lead to misclassification with consequences for patient management that may include unnecessary neck dissections.\textsuperscript{25} For this reason, new approaches are needed. Recognising that genomic changes drive tumour development, we reasoned that verrucous carcinoma with its more indolent natural history would have a simpler genotype compared to the more aggressive classical oral squamous cell tumours. In fact, this had already been demonstrated superficially by flow cytometry studies\textsuperscript{26}; our intention was to define these genomic changes more precisely, providing information that could be developed for diagnostic biomarkers. Previously, we showed that whole genome sequencing at low coverage could reveal differences in HPV-positive and -negative head and neck cancers\textsuperscript{10} and therefore we applied this approach, creating karyograms to compare OVC and OSCC. Additionally, we included exome sequencing and RNA-seq in our comparative analysis to provide further precision in defining genomic regions that distinguished the two oral cancer subtypes. This study represents the largest and “first” study, to date, to inspect genomic CN differences, correctly identifying 56 of 57 OVC samples and 41 of 45 OSCCs.

Interestingly, losses were detected frequently in OSCC genomes but rarely in OVCs. Losses on chromosomal arms 3p, 4q, 9p and 18q, and gains on 3q, 5q, 8q and 20p are chromosomal signatures commonly linked with OSCCs\textsuperscript{21,22} and were frequently identified in this OSCC cohort but were absent in OVC, suggesting that these CN alterations may be related to the more aggressive behaviour of OSCC. However, OVC karyograms revealed their own distinctive features that were consistent for the subtype, namely gains at 7q11.2, 7q22 and 17q23, as well as loss at 17q12 at a frequency of \textasciitilde 50%. These changes have not been previously identified as common CN altered chromosome lesions in oral cancer.

Comparison of the mutation profiles of the two subgroups provided further evidence that they had distinguishable genotypes. Four genes are mutated in more than one OVC sample, suggesting that they may have a role in the development of OVC lesions. These genes are: \textit{DSPP} gene (mutated in 40\% of OVC cohort), \textit{MUC4}, \textit{NEFH} and \textit{ANP32E} (mutated in 30\% of OVC cohort). These four genes are also mutated in at least one OSCC sample and have all been seen in other cancers. Earlier studies reported upregulation of \textit{DSPP} along with other genes in histologically aggressive and poorly differentiated OSCC and in some oral epithelial dysplasia.\textsuperscript{30} Other studies have demonstrated a positive correlation between \textit{MUC4} expression and tumour growth and malignant progression in pancreatic lesions.\textsuperscript{31} \textit{NEFH} was downregulated along with other genes in metastatic lung squamous cell carcinoma samples when compared with non-metastatic samples.\textsuperscript{32} \textit{ANP32E} expression was upregulated in gastric cancer cells when compared with non-neoplastic epithelial cells.\textsuperscript{33} All three OVC samples with an \textit{ANP32E} mutation had missense mutations in exactly the same position, which makes this gene a strong candidate for a role in the development of oral verrucous tumours. \textit{ANP32E} has a variant that has been reported to be associated with breast cancer development.\textsuperscript{34} Two of the four samples showing \textit{DSPP} mutations exhibited identical in-frame deletions, as did two of the three were \textit{NEFH} mutations.

Interestingly, analysis of the exome data for all ten OVC samples showed no mutations within the \textit{TP53}, \textit{CDKN2A}, \textit{NOTCH1}, \textit{NOTCH2} and \textit{FAT1} genes, all of which were frequently mutated in OSCC samples in this study and previously published work.\textsuperscript{23,24} In particular, mutation of the tumour suppressor, \textit{TP53} gene, is among the earliest identified genetic changes and the most common in HNSCC, arising in over half of all cases.\textsuperscript{35} No mutations were found in any of the ten OVC samples. The most recent gene expression study compared six patients with primary OSCC and five patients with primary OVC using microarray technology.\textsuperscript{36} Of the 167 DEGs reported, 39 were shared between OSCC and OVC, and eight (\textit{HLF}, \textit{TGFBI}, \textit{SERPIN1}, \textit{MMP1}, \textit{INHBA}, \textit{COL4A2}, \textit{COL4A1} and \textit{ADAMTS12}) were

Log FC refers to the log of the fold change. P.adj is the adjusted p-value. Positive log fold change indicates genes overexpressed in OVC, while negative values indicate genes overexpressed in OSCC.
significantly differentially expressed between the two groups. Seven of the eight were upregulated in OSCC compared to OVC, with only HLF being comparatively upregulated in OVC. For all eight significantly DEGs between the two groups previously reported, similar significant expression changes were observed for in our study, with HLF being the only gene from that previous list significantly upregulated in OVC compared to OSCC. HLF is thought to be tumour suppressor gene that plays a role in the detoxification processes.

Several of the genes differentially expressed between the two groups offer plausible explanations for the relatively benign nature of OVC lesions, and their correspondingly low metastatic potential, when compared to classical OSCC. The TNFRSF12A, IGFBP6, FSTL3, SMR3B and LAMC2 protein-coding genes have previously been reported as highly expressed in head and neck cancer. These were overexpressed in the OSCC cohort compared to the OVC samples. In contrast, downregulation of the DLG2, HBB and DSC1 genes has been associated with progression. These all were expressed more highly in the OVC samples. Similarly, KRT76 and KRT2 have been reported to be downregulated in OSCC and were again more highly expressed in our OVC samples.

Amongst genes associated with metastasis, downregulation of HPGD has been shown to be a marker for metastasis. This gene is more highly expressed in the OVC cohort. In contrast, overexpression of CXCL5, THBS1, MT2A and MT1X has been linked to metastasis. All of these genes were more highly expressed in the OSCC cohort.

DAVID functional enrichment and pathway analysis on RNA and exome sequencing OVC data revealed that a significant number of the DEGs and mutated genes are located in the plasma membrane, participated in cell adhesions and keratinocyte differentiation and implemented in calcium ion (Ca$^{2+}$) binding. On the other hand, the OSCC data revealed that the majority of the upregulated and mutated genes located in the cytoskeleton, participated in cell adhesion and migration, angiogenesis and cell death and were implemented in nucleotide and growth factor binding.

We have undertaken to better define the genomic and transcriptomic changes associated with oral verrucous carcinoma, and compare them to the changes observed in a similar group of classical OSCCs. We used the three independent, complementary techniques of CN sequencing, exome sequencing and RNA sequencing. For all three methods, there were clear differences that distinguish the OVC and OSCC cohorts. Taken together, these three independent analyses offer persuasive evidence that OVC should not be classified as a subtype of OSCC, but should be considered a separate disease entity.

Using a number of genomic platforms, it has recently been shown that tumours are not always closely related by tissue of origin. We have shown here that this applies to these two tumours, verrucous and squamous, both arising in the oral cavity. Verrucous carcinoma although rarely metastatic can be locally destructive and invasive and may benefit from therapeutic approaches in addition to surgery. The genomic and transcriptomic changes described here may suggest routes to the identification of a drug target, specific for these verrucous tumours. It would be of interest to determine if verrucous carcinomas that occur at other tissue sites share the same molecular signatures as those we have described for the oral cavity and possibly grouped together for the identification of treatment targets.
