ABSTRACT

The decrease in the availability and the increase in the prices of fishmeal and fish oil have prompted the search for sustainable alternatives for aquaculture feeds. Insects, which are part of the natural diet of fish, leave a small ecological footprint and have a limited need for arable land, may represent a good candidate. Over the last decade, studies on the replacement of fishmeal with insects in the diet of fish have emerged, and the promising results have encouraged further research. The present review presents these results in large tables and emphasizes the achievable dietary inclusion levels. It discusses the potential of locusts, grasshoppers, termites, yellow mealworms, Asiatic rhinoceros beetles, superworms, domesticated silkworms, common houseflies, common mosquitoes and black soldier flies for use as fishmeal and/or fish oil replacement in the fish diet. The review only succinctly compares the composition of the insects with the requirements of the fish (proteins and amino acids, lipids and fatty acids, vitamins and minerals). This review also discusses the potential hurdles of using insects in fish feeds (toxicity of insects through bioaccumulation, deficiencies in amino acids or fatty acids, chitin content, palatability, digestibility) and the available ways of avoiding these drawbacks (control of the dietary substrate of insects in mass rearing units, manipulation of the diet of insects, mixture of dietary proteins, use of aquatic insects, processing of insect meal). Finally, it suggests paths worthy of future research on these new fishmeal alternatives.

Keywords: Fishmeal alternative; Chitin; Orthoptera; Coleoptera; Lepidoptera; Diptera

1. Introduction
The steady decline in catches of wild fish (FAO, 2014), and the increased demands for livestock and aquaculture feeds have resulted in a rapid decrease in the availability of fishmeal (FM) and fish oil (FO) and in their concurrent price increase (FAO, 2014). The cost of aquaculture feeds represents 40 to 70% of the cost of the fish produced (Wilson, 2002; Rana et al., 2009), and is especially high in the aquaculture of carnivorous fish that require large amounts of FM (Manzano-Agugliaro et al., 2012). Soya and other terrestrial plants rich in proteins and lipids have been introduced into the diet of aquaculture fish to replace FM and FO (Hardy, 2002; Espe et al., 2006; Gatlin et al., 2007). However, the presence of anti-nutritional factors in plant meals (Tacon, 1993; Francis et al., 2001; Ogunji, 2004; Collins, 2014), the potential problems of the inflammation of the digestive tract (Merrifield et al., 2011) and the decreased palatability of the meal (Papatryphon and Soares, 2001) are of concern. Moreover, the rapid growth in the human population has put pressure on the use of arable land (Doos, 2002), and the ecological footprint of these protein-rich plants, related to the amount of energy and water necessary for their production, may alter the sustainability of such alternatives to FM and FO (Naylor et al., 2009).

Since insects are part of the natural diet of both freshwater and marine fish ( Howe et al., 2014; Whitley and Bollens, 2014) (Table 1), and because they are rich in amino acids, lipids, vitamins and minerals (van Huis, 2013) and leave a small ecological footprint (no need for arable land, low need for energy and water) (Oonincx and de Boer, 2012), they have been considered as potential alternatives to FM and FO. Moreover, insect larvae can rapidly transform low quality organic waste into good quality fertilizer (van Huis et al., 2013), thus reducing the final mass of manure by 50%, of nitrogen waste by 30-50%, and of phosphorus waste by 61-70% (Newton et al., 2005; Diener et al., 2009; van Huis et al., 2013). They also reduce the load of pathogenic bacteria in the microflora of manure (Erickson et al., 2004; Liu et al., 2008). Furthermore, the final product of this very efficient bioconversion of manure is an abundant amount of insect prepupae rich in proteins (40%) and lipids (30%) (Sheppard et al., 1994; Newton et al., 2005), which is suitable for use in fish and animal feeds (Barroso et al., 2014). Many insects (Lepidoptera, Diptera, Hymenoptera, Coleoptera, Trichoptera, Hemiptera, Odonata) also show antifungal activity and/or antibacterial peptides (Ravi et al., 2011) that may increase the shelf-life of insect-containing feeds (Zhao et al., 2010). For all these reasons, nutritional studies on the use of insects in livestock and aquaculture feeds (mainly for freshwater fish) have been conducted, mainly in Asian, African and South American countries (Veldkamp et al., 2012). The present review article has the aim of describing the published results of experiments using insects (larvae, prepupae, pupae and adults) as FM and/or FO replacements in aquaculture feeds for freshwater and marine fish, after briefly presenting the general requirements of the fish and the composition of the insects used in these studies. The review also attempts to establish the best insect candidates and optimal incorporation rates in the fish.
Table 1 and 2

2. Insect composition versus fish requirements

The composition of insects has already been studied extensively and is available in various recent review articles (Rumpold and Schluter, 2013; Barroso et al., 2014; Makkar et al., 2014; Sanchez-Muros et al., 2014). Therefore, the present review will not focus on details and will summarize data available on the insect species studied in fish experiments (Table 2).

Before incorporating any insect species into the diet of a fish species, it is necessary to determine the exact composition of the insect, which varies according to its particular life stage, rearing conditions and diet, and to compare it with the requirements of the fish species of interest. These requirements are usually accurately reflected by the fish fillet composition (Oliva-Teles, 2000) and have been widely investigated for the main reared species (NRC, 2011). Table 1 describes the natural diets of the fish species studied for dietary insect inclusion.

2.1. Proteins/ Amino acids

The protein requirements of different fish species range from 28 to 55 percent of dry diets. The protein requirement decreases as the fish grows (Lovell, 1989) and is highest in larvae and fry, especially in carnivorous fish (NRC, 2011). Marine species, which are usually carnivorous, require more dietary protein (40-55%) than most freshwater fish (25-40%) (Boonyaratpalin, 1997; Hasan, 2001; Sales and Janssens, 2003). According to literature, the average protein content of insects varies between 50 and 82% (dry matter, DM) (Rumpold and Schluter, 2013), depending on the insect species or on the method of processing the insect (Fasakin et al., 2003; Banjo et al., 2006). As an example, the protein content of a good quality FM can reach up to 73%, while soybean meal contains up to 50% of proteins (Barroso et al., 2014).

To date, all studies on finfish have shown that they require the usual essential amino acids (EAA) (NRC, 2011; Oliva-Teles, 2012; Takeuchi, 2014). The development of commercial aquatic feeds has traditionally been based on FM as the primary protein source, due to its high protein content and well balanced EAA profile (Nguyen et al., 2009; NRC, 2011; Oliva-Teles, 2012) with high levels of digestible EAA, such as lysine (Lys), methionine
(Met) and leucine (Hall, 1992). Plant feedstuffs usually have lower protein contents and EAA imbalances, and they are often deficient in Lys and Met. Such deficiencies can primarily lead to an increase in feed intake, because the fish will eat more to cover its basic needs, as exemplified with/as has been seen for Lys (Dabrowski et al., 2007). Subsequently, fish growth and the feed conversion rate may be affected (Ostaszewska et al., 2011) and deficiency symptoms may appear, possibly followed by an increased sensitivity to diseases (Cowey, 1994; Helland and Grisdale-Helland, 2006; Kiron, 2012).

In general, the AA patterns of insects are taxon-dependent, with the profiles of Diptera considered close to FM profiles and the profiles of Coleoptera and Orthoptera close to those of soybean, with potential deficiencies in Lys or Met (Barroso et al., 2014). However, the AA profiles of most insects studied for fish diets, which are presented in Figure 1, show a good correlation with fish requirement values (Hasan, 2001; NRC, 2011; Alegbeleye et al., 2012), and, in some cases, even exceed these requirements (domesticated silkworms, *Bombyx mori* and yellow mealworm, *Tenebrio molitor*) (Hossain et al., 1997; Barker et al., 1998; Finke, 2002; 2007; Longvah et al., 2011; Rumpold and Schluter, 2013; Yi et al., 2013; Barroso et al., 2014). Other species (1 orthopterous species, the cricket, *Acheta domesticus* and 2 hymenopterous species, ants and bees) have also been included in Figure 1 although they have not been studied in fish diets before, because they also show valuable EAA profiles (Barker et al., 1998; Finke, 2002; 2007; Rumpold and Schluter, 2013; Barroso et al., 2014) and may be worthy of further investigation. Lepidoptera (silkworms) and Hymenoptera are particularly interesting, due to their richness in Met (Hossain et al., 1997; Finke, 2007; Longvah et al., 2011; Rumpold and Schluter, 2013), whereas the termites, *Macrotermes*, and the variegated grasshopper, *Zonocerus variegatus*, have shown several AA deficiencies (Fig.1).

**Figure 1**

Plant feedstuffs lack certain FM components, such as taurine and hydroxyproline, which are beneficial for fish growth and fish health (Aksnes et al., 2008; Kousoulaki et al., 2009; Pinto et al., 2013). Many insects, such as locusts, houseflies, mealworms and mosquitoes, but also the honeybee (*Apis mellifera*), the Eri silkworm (*Attacus ricini*), the common fruit fly (*Drosophila melanogaster*) and the discoid cockroach (*Blaberus discoidalis*), instead contain valuable levels of taurine (up to 26μmol/g) (Clark and Ball, 1952; Whitton et al., 1987; Bicker, 1992; Whitton et al., 1995) and hydroxyproline (Briggs, 1962; Pant and Agrawal, 1964; Sowa and Keeley, 1996).

### 2.2. Lipids/ Fatty acids
The energy requirements in fish are lower than those of mammals (Finke, 2002). Cold-water carnivorous fish, such as salmonids, can adapt to dietary lipid levels as high as 35%, but high dietary lipids can lead to a reduction in fish growth or fat deposition (New and Wijkstroem, 2002), and the dietary protein/lipid ratio (DP/DL) can be as low as 16 g CP/MJ (Bowyer et al., 2013). Warm-water fish require a higher DP/DL level (25-26 g CP/MJ) (Bowyer et al., 2013), and the maximum dietary lipid levels for herbivorous and omnivorous warm-water fish appear to be lower: in general, 10-20 percent leads to optimal growth rates without producing an excessively fatty carcass (Cowey and Sargent, 1979; Boonyaratpalin, 1997; Hasan, 2001; Sales and Janssens, 2003). High dietary lipids (20%) can impair the immune status of some marine omnivorous species (Henry and Fountoulaki, 2014). The lipid level in FM (8.2%) and soya meal (3.0%) is lower than that of insects, in which it usually ranges from between 10 and 30%, even though it is extremely variable (DeFoliart, 1991). It is the diet of insects that is mainly responsible for the variations in the lipids and fatty acids (FAs) composition (Barroso et al., 2014).

The requirements of essential fatty acids in fish depend on the bioconversion and elongation capacity of the FAs of a given fish species (Sargent et al., 1999). Freshwater fish usually require the dietary inclusion of polyunsaturated FAs (PUFA) (Tocher et al., 2008; Tocher, 2010), whereas marine fish generally require the dietary inclusion of highly unsaturated FAs (HUFA) (Rainuzzo et al., 1997; Hasan, 2001; Sargent et al., 2002; Tocher et al., 2008; Tocher, 2010). Aquatic insects that feed on aquatic algae are generally richer in HUFA (Bell et al., 1994; Yang et al., 2006) than terrestrial insects (Rumpold and Schluter, 2013; Sanchez-Muros et al., 2014) and are considered to be a better source of FA for marine fish (Sushchik et al., 2003). HUFA-deficiencies in terrestrial insects could impair both fish growth and health, due to the involvement of the HUFAs in multiple functions such as membrane structure or eicosanoid production (Tocher, 2003). However, a HUFA and/or PUFA deficiency or sub-deficiency in the diet of marine fish may stimulate an adaptation mechanism by enabling a level of bioconversion of C18 to C20 or even to C22 FA (Seiliez et al., 2003; Robin and Skalli, 2007). Thus, the differences in FA composition between diets containing black soldier fly (BSF) and fillets of rainbow trout, *Oncorhynchus mykiss*, fed these diets with different levels of n-3 FA could reflect an adaptive mechanism of the fish to equilibrate their FA profile (Sealey et al., 2011).

2.3. Minerals and vitamins
Minerals (potassium, calcium, iron, magnesium, zinc and selenium) are found in insects (DeFoliart, 1992; Finke, 2002; Banjo et al., 2006; Schabel, 2010; Rumpold and Schluter, 2013). However, the Ca and P levels are usually lower than that of FM, except for Ca in BSF and P in housefly (Makkar et al., 2014). The vitamin requirements of fish can be found in Lall (1991). Insects provide several vitamins, as can be seen in a recent review (Schabel, 2010). However, as far as the FA composition is concerned, the vitamin and mineral profiles of insects depend to a great extent on the composition of the insect diet. For example, feeding yellow mealworm larvae with different diets containing organic wastes has resulted in different vitamin and mineral compositions of in the larvae (Ramos-Elorduy et al., 2002).

2.4. Nitrogen Free Extract - Chitin

Nitrogen-free extracts include carbohydrates, sugars, starches, fibre and chitin. Insects are usually poor in carbohydrates, but they contain chitin, a primary component of the exoskeleton of arthropods (crustacean shells, insect exoskeletons), which is composed of an unbranched polymer of N-acetylglucosamine (Lindsay et al., 1984; Ng et al., 2001). Chitin is discussed in more detail in section 4.5.

3. Incorporation of insects in fish feeds

The first studies on the incorporation of insects in fish feeds mainly investigated herbivorous/omnivorous catfish, tilapia and carp. Over the last decade, interest has increased, and many feeding experiments have looked at different fish, including carnivorous species (see Table 1). The review by Makkar et al., (2014) discusses the use of insects in livestock, fish and crustaceans feeds. Another recent brief and informative review has looked at the incorporation of insects in the diet of juvenile fish and crustacean (Riddick, 2014). The present review is extended to some insect species that were overlooked in the previous reviews and it refines the analysis of all the fish studies through the use of large tables in which the optimal and detrimental dietary inclusion levels of Orthoptera, Isoptera and Coleoptera (Table 3), of Lepidoptera (Table 4) and of Diptera (Table 5) are given. The first studies were mostly conducted in Asia and Africa, where the locally available FM is often of poor quality, with a lower protein content than that of the tested insects (Heuzé and Tran, 2013). These studies investigated the supplementation of these cheap reference diets with insect larvae used whole, cut into pieces or transformed as a meal (Jeyachandran and Raj, 1976; Boscolo et al., 2001; Achionye-Nzeh and Ngwudo, 2003; Idowu et al., 2003;
3.1. Use of whole or cut, live or frozen insects in freshwater fish diets

Common house mosquitos, black soldier flies, common houseflies and yellow mealworms have been tested whole or chopped, live or frozen, on mudfish, Clarias anguillaris, African catfish, Clarias gariepinus, Channel catfish, Ictalurus punctatus, blue tilapia, Oreochromis aureus, Nile tilapia, Oreochromis niloticus and rainbow trout. The growth of rainbow trout fed exclusively on frozen common house mosquito, Culex pipiens, has been shown to be affected, probably because the diet was unbalanced and/or the particulate size of the diets was different (Ostaszewska et al., 2011) (Table 5). Feeding 120g channel catfish or 32g blue tilapia in monoculture settings with 100% of BSF larvae (whole or chopped) was also shown to strongly suppress fish growth, compared to a commercial diet (Bondari and Sheppard, 1987) (Table 5, trials 2 and 3). Partial substitution of FM could be more successful. This was verified in a polyculture settings, where 64g channel catfish and 30g blue tilapia were fed successfully on chopped BSF larvae (50 or 75% larvae with 50 or 25% commercial diet) combined with high-protein (45% crude protein, CP) or low-protein (30% CP) commercial diets (Bondari and Sheppard, 1981) (Table 5). No differences were found in the body weight of these two species between the experimental diets, thus suggesting that BSF is suitable for use in the diets of both fish species (Bondari and Sheppard, 1981) (Table 5).

All the other studies using whole or cut insect larvae (maggots or yellow mealworms) have been very successful, often giving better growth results than the control fish: Nile tilapia fed a mixture of wheat bran and 20% of live maggots showed a better growth performance, specific growth rate, feed conversion ratio and survival than fish fed wheat bran alone (Ebenso and Udo, 2003) (Table 5), probably because the diets were more balanced and better adapted to the needs of the fish. Feeding mudfish with whole frozen maggots has led to better growth than a soybean diet or a commercial diet, but the composition of these two diets was not stated and it is not known whether they actually provided all the necessary nutrients for optimal fish growth (Achionye-Nzeh and Ngwudo, 2003) (Table 5). Similarly, African catfish fed 50% live maggots in conjunction with 50% of an artificial diet poor in FM (3.5%) grew better than fish fed an artificial diet alone (Oyelese, 2007) (Table 5). This was also true when this diet was compared to a diet rich in FM (40% crude protein, CP) (Madu and Ufodike, 2003). Interestingly, an
alternation of feeding catfish pellets and whole yellow mealworms cut into small pieces, which is very palatable to African catfish, enhanced both feed efficiency and protein utilization, compared to a control diet containing 34% CP (Ng et al., 2001) (Table 3). However, all the fish fed live yellow mealworms (50 or 100%) had a higher body lipid content than that of the control fish, due to the high lipid content of mealworms (Ng et al., 2001). Fish fed only yellow mealworms demonstrated a reduced FI and weight gain (WG), thus suggesting the advisability of using an alternation of pellets and whole insects (Ng et al., 2001). Feeding fish with maggots or yellow mealworms live or chopped is therefore a good option, especially in countries where the usual feeds used are of poor quality.

3.2. Use of insect meal as an FM replacement in fish diets

In order to assess the use of insects in fish diets, it is scientifically more convincing to compare a control diet that covers all the fish requirements with an isonitrogenous and isoenergetic diet containing insect meal. The results of such a feeding experiment, pertaining to Orthoptera, Isoptera and Coleoptera, are summarized in Table 3.

Table 3

3.2.1. Use of Orthoptera as an FM replacement in fish diets

Orthoptera, including many species of locusts, grasshoppers and crickets, are major crop pests. The adult insects are highly nutritious and have already been described accurately in a review paper (Makkar et al., 2014). Briefly, a dietary inclusion of 13-25% of adult Orthoptera did not reduce the digestibility or growth of catfish or tilapia (Alegbeleye et al., 2012; Emehiniaiye, 2012) (Table 3). Catfish growth was actually improved by the 13% inclusion of variegated grasshopper meal, a diet that showed an EAA profile very close to the requirements of African catfish and high in PUFA (Alegbeleye et al., 2012). On the contrary, the dietary inclusion of dried grasshopper significantly reduced the specific growth rate of walking catfish, Clarias batrachus, after 60 days of feeding (Johri et al., 2011). Growth reduction was only found for higher inclusion levels than 34% of grasshoppers, and this result may be associated with reduced protein and lipid digestibility and/or deficiencies in arginine (Arg) and Lys (Alegbeleye et al., 2012).

3.2.2. Use of Isoptera as an FM replacement in fish diets

Isoptera are termites, Macrotermes, and are rich in proteins (37-49% CP) and lipids (30%), but poor in minerals (Sogbesan and Ugwumba, 2008). A study on the use of termites in the diet of fish showed that they were very
palatable to vundu catfish, *Heterobranchus longifilis*: a 15% dietary inclusion produced the best growth performance, which, however, was not significantly different from the growth of fish fed FM or a 7.5% termite meal. Fish growth was significantly reduced for higher inclusion levels (22.5 and 30%) (Sogbesan and Ugwumba, 2008). Solomon et al (2007) fed fingerlings of African catfish, *Heterobranchus bidorsalis*, with FM based diets supplemented with termites and soybean meal (SBM) at different ratios. They found increased growth performance and better nutrient utilization when termites were included in the blend. However, the results were not very reliable, given/considering the errors in the calculations of the percentages of termite inclusion and the variation in SBM and FM between the experimental diets, which made it difficult to establish whether the improved fish growth was due to the dietary termites or to the increased dietary FM (Solomon et al., 2007). Despite the good results of the partial replacement of FM, even compared with a very high quality FM (71% CP), termites (46% CP), being high producers of methane (Martius et al., 1993), being seasonal (Jamali et al., 2008) and being very difficult to rear, may not be a very good choice for large-scale use in aquafeeds.

3.2.3. Use of Coleoptera as an FM replacement in fish diets

3.2.3.1. Mealworms. Mealworms, such as the easily bred yellow mealworm, *Tenebrio molitor*, are beetles (Coleoptera), and are grain and flour pests (Ramos-Elorduy et al., 2002). Although the adults may not be used in feeds as they contain quinones, their larvae, mealworms, are a high quality feed that is rich in protein and lipids and poor in ash; their composition can be found in a previous/another review (Makkar et al., 2014). Mealworm larvae are usually fed live (see section 3.1), but can also be used as meal (Aguilar-Miranda et al., 2002; Veldkamp et al., 2012). They are currently being produced at a large industrial scale in China (Veldkamp et al., 2012). When the highly palatable yellow mealworm larvae was sun-dried or oven-dried, low inclusion levels of 9% of mealworm meal (20% FM replacement) led to the optimal growth of African catfish, and showed a significantly improvement compared to fish fed the FM based diet. Mealworm larvae could even replace up to 60% of dietary FM (26% dietary inclusion), without significantly affecting the growth or feed utilization of African catfish, but higher inclusion rates (35-43% corresponding to 80-100% FM replacement) have been shown to decrease fish growth performance, as well as feed and protein efficiency (Ng et al., 2001). In a pre-fattening trial performed on common catfish, *Ameiurus melas*, the total replacement of FM with dried mealworm larva meal significantly reduced fish growth performances, compared to control fish fed 50% FM, but growth was still considered satisfactory for this species (Roncarati et al., 2014). Yellow mealworm larvae have also been successfully used in rainbow trout, where they could be included at dietary levels of up to 50% (Gasco et al., 2014a) and in marine carnivorous fish, gilthead
seabream, *Sparus aurata*, and European sea bass, *Dicentrarchus labrax*, where 25% FM replacement did not affect fish growth significantly (Gasco et al., 2014b; Piccolo et al., 2014). The growth of both these marine fish was significantly affected at a 50% FM replacement level (Gasco et al., 2014b; Piccolo et al., 2014), and European sea bass showed a reduced n-3 HUFA concentration in the fillets (Gasco et al., 2014b).

Asiatic rhinoceros beetles (*Oryctes rhinoceros*) or palm weevil (*Rhynchophorus spp.*). The former, which is another member of the Coleoptera order, and is known to be a beetle pest of palm trees, was overlooked in previous review papers on the subject (see Makkar et al., 2014; Riddick, 2014). It was described in two publications as “palm grub”, but was associated with/erroneously given the Latin name of the Asian rhinoceros beetle (*O. rhinoceros*). It could also be confused with the palm weevil (*Rhynchophorus spp.*). The larvae of *O. rhinoceros* have very successfully been used to replace large amounts of FM in the diet of catfish (Table 3). A dietary inclusion of 14% (16% FM replacement) led to the optimal growth of both African and Vundu catfish (Fakayode and Ugwumba, 2013), but higher dietary inclusions of 33, 57, 80 or even 100% palm grub meal did not affect fish growth significantly (Fakayode and Ugwumba, 2013). However, the results are not very reliable: the FM replacement levels were overestimated (erroneous calculations) in this publication. *O. rhinoceros* processed into a meal and fed to Nile tilapia reduced both the WG and the survival of the fish (Omoyinmi and Olaoye, 2012), but both parameters were also very low in the control fish (2g WG in 10 weeks), perhaps because of the low quality of the used FM (35% CP) or the stressful conditions / disease of the fish.

3.2.3.2. Superworm (*Zophobas morio*). The superworm is very rich in protein and contains adequate quantities of the EAA required for optimum fish growth, except for Met, which seems to be low (Yi et al., 2013; Barroso et al., 2014), but it is poor in minerals such as calcium and phosphorus (Ghaly and Alkoaik, 2009). The dietary inclusion of 7.5 and 15% (25 and 50% FM replacement) of superworm meal (47% CP) has led to the optimal growth of Nile tilapia. Even a 22.5% inclusion (75% FM replacement) was tolerated well, in terms of growth, feed efficiency and protein digestibility, and showed no significant difference from FM-fed fish. Only a total FM replacement (30% dietary inclusion) reduced fish growth significantly, compared to FM-fed fish (Jabir et al., 2012). Although the diets decreased in proteins and increased in lipids with the increasing inclusion of superworms, the fillet composition was enriched in proteins and poorer in lipids at all the dietary levels tested, compared to the fish fed good quality FM (57% CP) (Jabir et al., 2012), a result that was surprising.
Overall, Coleoptera have been used successfully as a partial replacement of FM in fish diets, although the reliability of the studies on palm grub is questionable. Meals made from superworm led to the optimal growth of Nile tilapia, while mealworm larvae showed positive results in the diets of both freshwater and marine fish.

### 3.2.4. Use of Lepidoptera as an FM and FO replacement in fish diets

<table>
<thead>
<tr>
<th>Table 4</th>
</tr>
</thead>
</table>

The domesticated silkworm, *Bombyx mori*, is mainly produced in India (Heuzé et al., 2014). Dried silkworm pupa (SWP) meal is a valuable source of protein (50-71% dry matter, DM) and lipids (30%) (Wei and Liu, 2001; Rumpold and Schluter, 2013). SWP meal has been used in many fish nutrition studies, which are summarized in Table 4. Silkworm meal, unlike other insect meals, seems to lead to good results, whether defatted or not, and the fat of SWP could even be considered an asset. SWP oil was reported to attract and stimulate the appetite of common carp, *Cyprinus carpio* (Begun et al., 1994). A study showed comparable growth and organoleptic parameters when sardine oil was replaced with SWP oil in the diet of common carp, suggesting that SWP lipids are satisfactory for use in cyprinids and that SWP could cheaply replace both FM and FO (Nandeesha et al., 1999). Increasing dietary non-defatted SWP meal or SWP oil led to an increase in lipid digestibility, without significantly increasing fat deposition (Nandeesha et al., 1990; Nandeesha et al., 1999). Moreover, the dietary addition of defatted or non-defatted SWP meal led to very good digestibility values, not only in cyprinids (Jayaram and Shetty, 1980; Begun et al., 1994), but also in tilapia (Hossain et al., 1992; Boscolo et al., 2001) and in catfish (Hossain et al., 1991; Borthakur and Sarma, 1998), even in the case of the total replacement of FM (Habib et al., 1994). In cyprinids, the digestibility of both defatted and non-defatted SWP was even better than that of FM (Hossain et al., 1997), although the defatted SWP was shown to be less digestible than FM in another study on common carp (Kim, 1974). Numerous studies have shown the potential of the dietary inclusion of SWP in the diets of fish larvae or juveniles, mainly in cyprinids, but also in many other fish species (Table 4). The growth, the feed performances and the organoleptic quality of the fish were not affected by the dietary inclusion of SWP at levels below 50%, even when not defatted (Begun et al., 1994; Rahman et al., 1996; Hossain et al., 1997; Nandeesha et al., 2000; Ji et al., 2013). Low inclusion levels (5-12%) were successfully achieved for the carnivorous chum salmon, *Oncorhynchus keta* (Akiyama et al., 1984) and for the olive flounder, *Paralichthys olivaceus*, when supplementary AAs Lys and Met were added to the SWP-containing diet (Lee et al., 2012). The omnivorous snakeskin gourami, *Trichopodus pectoralis*, was fed a diet containing 15% of SWP, without it affecting fish growth, but higher levels than 22% decreased both protein digestibility and fish growth (Jintasatapom et al., 2011). In several studies on
rohu, *Labeo rohita*, common carp or rainbow trout, positive results have even been obtained for inclusion levels of 30-50% (up to 100% FM replacement) of defatted or not-defatted SWP (Jayaram and Shetty, 1980; Rahman et al., 1996; Hossain et al., 1997; Nandeesh et al., 2000; Dheke and Gubhaju, 2013). Successful total FM replacement has also been achieved in common carp or in Japanese sea bass, *Lateolabrax japonicus*, but the control diets were deficient in protein (11% FM, 21% CP) and the diets were not isonitrogenous (Jeyachandran and Raj, 1976), or no details on the reference diet were available (Ji et al., 2010). SWP has not been so successful in tilapia, where a low inclusion level (5%) significantly reduced fish growth, compared to FM-fed fish (Boscolo et al., 2001). Similarly, a study on Jian carp (*Cyprinus carpio* var Jian) has shown significantly reduced fish growth, accompanied by decreased superoxide dismutase, intestinal protease activities and increased heat shock protein, even for very low inclusion levels (6-9%) of SWP (Ji et al., 2013). The authors suggested that low levels of SWP caused oxidative stress in Jian carp (Ji et al., 2013). However, walking catfish, fed 58% SWP, showed the same level of protease activity as fish fed FM (Venkatesh et al., 1986). Overall, SWP seems to be a very good potential protein source for use in fish diets, except, according to a few studies, for Nile tilapia, Jian carp and gourami.

### Table 5

#### 3.2.5. Use of Diptera as an FM replacement in fish diets

Protein replacement in fish diets has also been investigated using meals obtained from the larvae of two species of Diptera: the housefly and BSF (Table 5). Both flies have been extensively described (distribution, rearing, environmental impact, nutritional attributes) in a published review (Makkar et al., 2014).

#### 3.2.5.1. Common house fly larva (maggot) meal (magmeal)

Most studies on fish fed common house fly larva (maggot) meal, have not shown any improved fish growth, except when maggots were fed live to fish (see section 3.1). However, three studies showed improved fish growth when maggot meal was included in the fish diet: 50% FM replacement improved the growth of Nile tilapia, but the inclusion levels were not mentioned in the publication (Ajani et al., 2004). The supplementation of the basal diet with 2.5% of maggot meal improved fish growth and the fish immune status and resistance to diseases in the mostly carnivorous black carp, *Mylopharyngodon piceus*, but the composition of the basal diet was not given and may have been low in FM (Ming et al., 2013). Hybrid catfish fed 7.5% maggot meal also showed improved growth compared to a control diet containing 30% of FM (isonitrogenous diets containing 40% CP) (Sogbesan et al., 2006). In other studies, African catfish fed 12.5 or 25% of maggot meal (corresponding to 50 or 100% of FM
replacement, respectively) for 10 weeks grew well and showed good protein efficiency values (Nsofor et al., 2008). Many other studies have shown the potential of maggot meal for use as an FM replacement in African and vundu catfish (7.5 to 32% inclusion) (Fasakin et al., 2003; Idowu et al., 2003; Aniebo et al., 2009; Adewolu et al., 2010), in common and Gibel carp (30-39% inclusion) (Ogunji et al., 2009; Dong et al., 2013) and in Nile tilapia (15-68% dietary inclusion) (Ogunji et al., 2007; Ogunji et al., 2008a; Ogunji et al., 2008b; Omoyinmi and Olaoye, 2012), without affecting fish growth (Table 5). A study using a low-protein maggot meal (29% CP) showed a reduction in growth of Nile tilapia for a 15-30% dietary inclusion (Ogunji et al., 2008c), but the different Protein/Energy ratios in the diets may have biased the results. Higher inclusion levels or similar levels of non-defatted maggot meal have been shown to affect fish growth in African catfish (Fasakin et al., 2003; Idowu et al., 2003; Oyelese, 2007). When the maggot meal diet was supplemented with AAs, an inclusion level of 81% compared favourably with a soybean meal diet, but no FM control diet was included in this study (Ossey et al., 2012). Moreover, an increased cannibalism of the fish larvae was observed in fish fed the maggot meal diet (Ossey et al., 2012), which could have significantly improved the balance of the diet. Maggot meal has also been tested in rainbow trout, but was not very successful, as a 9.2% dietary inclusion significantly affected fish growth, and the fish fillets were poorer in n-3 FA than the control fish fed 36% of FM (St-Hilaire et al., 2007b). Although studied under the same conditions, dietary maggot meal was shown not to affect the growth of Gibel carp, Carassius gibelio, but to significantly reduce the growth, FCR and PER of darkbarbel catfish, Pelteobagrus vachelli; this reduction was linked to a decreased antioxidant activity of the latter fish (Dong et al., 2013). It is therefore not possible to generalise the positive results to other fish species, as fish requirements may vary from one fish species to another, and this may explain the high interspecies variability of the results.

3.2.5.2. BSF larvae meal

Another species of Diptera that has been widely studied in fish is the BSF larva. The fish nutrition experiments were not as successful as expected (Table 5). They have already been described extensively (Makkar et al., 2014), and are therefore only described briefly hereafter: no inclusion level of BSF has led to a better fish performance than fish fed FM-rich control diets. However, some inclusion levels of BSF prepupae have shown a similar WG to that of fish fed FM: 6% dietary inclusion in channel catfish (Newton et al., 2005), 15% (St-Hilaire et al., 2007b) or 18-36% inclusion in rainbow trout (Sealey et al., 2011), with improved n-3 HUFA and PUFA contents in the fillets of fish fed BSF (Sealey et al., 2011), 5-25% inclusion in Atlantic salmon, Salmo salar, where the BSF diets were supplemented with AAs (Lys and Met) (Lock et al., 2014). Higher inclusion levels (12-30%) reduced fish
growth significantly in channel catfish, in rainbow trout, and in turbot, *Psetta maxima*, (Newton et al., 2005; St-Hilaire et al., 2007b; Kroeckel et al., 2012). Juvenile turbot accepted diets containing up to 33% defatted BSF prepupa meal, without any significant effects on FI or feed conversion. However, the specific growth rate was significantly lower for all the inclusion levels tested. At inclusion levels higher than 33%, the palatability of the diet and protein digestibility decreased, and resulted in a reduced FI and lower growth performance (Kroeckel et al., 2012). The protein and lipid digestibility results have been shown to be very good in Atlantic salmon (Lock et al., 2014).

3.3. Quality of the fish fed insects

Since marine fish richness in n-3 HUFA is associated with a health benefit for human consumers, modifying their FA profile could affect the perception of consumers and subsequently the market value of fish cultured for human consumption (Amberg and Hall, 2008). Moreover, the modification of fillet lipids and FA composition directly affects the total volatile compounds, and thus affects the aroma and flavor of the fish (Turchini et al., 2003). The replacement of FM with insect meal can increase the amount of fat or change the nature of lipids in fish, and could therefore change the taste of the fish fillets. Thus, less preference has been shown for catfish and tilapia fed solely with whole BSF larvae, due to the different aroma and texture from that of fish fed a commercial diet or fed partly with BSF larvae (25 or 50%) (Bondari and Sheppard, 1981). On the other hand, despite the differences in the FA profiles, no significant difference was obtained in a blind comparison of rainbow trout fed the FM-containing control diet with fish fed normal BSF or fish offal-enriched BSF pre-pupa diets (Sealey et al., 2011). Similarly, no difference in organoleptic properties was found in African catfish fed maggot meal (Aniebo et al., 2011), in Atlantic salmon fed defatted BSF (Lock et al., 2014), in cyprinids fed SWP oil (Jayaram et al., 1980; Nandeesh et al., 1999; Nandeesh et al., 2000) or non-defatted SWP meal (Nandeesh et al., 2000) compared to control fish. These results suggest that the partial inclusion of insect meal (10-50%) in the diet of fish does not affect the FA profiles, aroma or flavor enough to be detected by consumers.

4. Potential hurdles and solutions

The many studies using insects in the diet of fish have underlined potential problems and suggested some solutions, which are discussed hereafter.
4.1. Mass rearing to avoid toxicity of insects through bioaccumulation

Potential hurdles, such as the bioaccumulation of insecticides, heavy metals and natural toxins in insects harvested from the wild can be monitored more easily in mass rearing setups through controls of their rearing substrates (van der Spiegel et al., 2013), especially when organic by-products are proposed as diets for the insects. A study using high dietary levels of maggot meal (>35%), obtained from larvae fed on poultry droppings, has shown increased levels of liver Glutathione S-transferase (GST) in Nile tilapia, suggesting the presence of pesticides, medical drugs or toxic residues in the hen manure (Ogunji et al., 2007). As large quantities of insect meal should be available before aquafeed companies envisage their inclusion in the feed of fish (I. Karakostas, Biomar, Greece, Personal Communication), the supply chain would need to rely on the mass rearing of the insects on quality-controlled substrates in order to avoid any potential toxicity problem. The mass rearing of insects has spread worldwide, especially for the production of silk, fishing bait and pet food (for fish, birds and reptiles) and for the biological control of pest species (Schabel, 2010; FAO, 2013). Small production units of BSF, mealworms, locusts, house crickets and grasshoppers are currently being set up in Europe and in the rest of the world (Ynsect, France; Protix, Netherlands; Hermetia, Germany; Insagri, Spain; Enviroflight, USA; Next Millennium farm, USA; Enterra Feed, Canada; Entologics, Brazil) (Kroeckel et al., 2012; Rumpold and Schluter, 2013), and a very large production unit of maggot meal has already been set up in South Africa (AgriProtein; 7t maggot meal/day, 3t magoil/day). Moreover, the production of mealworms is already very important in China (HaoCheng: 50t mealworms and superworms/month) and in India (Veldkamp et al., 2012; Ji et al., 2013; van Huis et al., 2013). The production of silkworms in China accounts for approximately 80% of the world’s production, with the annual capacity for dry pupa production being approximately 200 000 mt (Dong and Wu, 2010). Producers throughout the world are becoming organized (VENIK, IPIFF) in order to raise interest in the use of insects as feeds or food. As FM prices regularly increase (FAO, 2013), the price of insect meal obtained from large production units could very rapidly become competitive (Drew et al., 2014).

4.2. Mixture of dietary proteins or dietary supplementation in order to better satisfy fish requirements

On the basis of studies on FM replacement with plant proteins, it appears that the use of a mixture of dietary proteins may help to prevent the deficiencies caused by the use of a single ingredient (Hansen et al., 2007; Torstensen et al., 2008; Hansen et al., 2011; Zhang et al., 2012a; Zhang et al., 2012b; Hu et al., 2013). Some
insects, such as *Z. variegatus* and *M. bellicosus*, show deficiencies in AAs (Met, Lys, threonine or tryptophan, Trp). The use of a mixture of insect meals may equilibrate the AA profiles of the diet. A species slightly deficient in Trp, such as BSF, could be mixed with the housefly or with SWP, both of which are richer in Trp. Insect meals may also be mixed with other protein sources. Nutritional studies have shown that combining superworm meal with 10% of a prebiotic mushroom in a fish diet further improves the performances of tiapia (better Specific Growth Rate, Feed Conversion Ratio, Protein Efficiency Ratio and fish survival) (Mohd Din et al., 2012), possibly due to a balancing of the AA composition of the diet (Kim et al., 2009) or to the prebiotic properties of the mushroom. The total replacement of dietary FM protein with a mixture of SWP (43% inclusion) and clam meat (31% inclusion) protein showed improved feed utilization in rohu fingerlings, compared to fish fed 54% of FM (Begun et al., 1994). Mineral dietary supplementation may also be necessary to cover the basic needs of the fish, particularly for freshwater species that require more minerals than seawater species (Hasan, 2001). Salt and mineral supplementation made ot possible to overcome the growth depression of broilers, caused by 50% FM dietary replacement (Reddy et al., 1991), but, to the best of the authors’s knowledge, no trial has been performed on freshwater fish.

4.3. Improving insect lipids to better satisfy fish requirements

4.3.1. Manipulation of lipids in the insect diet to improve the FA profile for use in aquafeeds

The quality of the FA profile of terrestrial insects is usually thought to be poor in HUFA for use in the feeds of marine fish, but it may be enhanced by manipulating the diet of the insects in order to increase the n-3 and n-6 FAs (Ogunji et al., 2008b). For example, the lipids of BSF larvae fed on cow manure consisted mainly of saturated or monounsaturated FAs and low levels of omega-3 FA (0.2%), whereas larvae fed cow manure and 22% fish offal for only 24h contained 4% n-3 FA (St-Hilaire et al., 2007a). Feeding BSF prepupae partly (25 or 50%) with fish offal for a month led to a 25 to 50% increase in FM replacement in the diet of rainbow trout, without any growth reduction (Sealey et al., 2011). However, it seems more economically viable to use n-3 HUFA rich components (by-products of the fish filleting industry, microalgae, phytoplankton…) to feed the fish directly rather than enriching insects in order to feed them to the fish.

4.3.2. Use of aquatic insects to supply marine fish with adequate amounts of n-3 FA
Since aquatic insects are more predatory than the usually herbivores or omnivores terrestrial insects (Yen, 2014), and because they eat aquatic organisms richer in n-3 FA, aquatic insects are usually richer in n-3 HUFA (mainly EPA) (Bell et al., 1994; Yang et al., 2006; Fontaneto et al., 2011). This makes them better candidates to feed marine fish, which are more dependent on HUFA than freshwater fish (see section 2.2). There are numerous aquatic insects (McCafferty, 1981). They were already semi-cultivated in Mexico in the pre-Hispanic era (Van Itterbeeck and Van Huis, 2012), by means of environmental manipulation, through the arrangement of bundles of aquatic weeds to host the eggs of Neopomorpha Hemiptera aquatic tree bugs (Parsons, 2010). Lion water bugs and aquatic bees are used for medicinal purposes in Zaire (Tango, 1994; Srivastava et al., 2009; Yen, 2014). The intensive harvesting of insect delicacies, such as giant water bugs in Thailand (Clutterbuck, 1993), lake fly, Chaoborus, adults in Uganda, the larvae of dragonflies in Papua New Guinea (Srivastava et al., 2009) or diving, backswimmer and water scavenger beetles in China and Laos, can occasionally lead to a decline in wild insect populations (Hanboonsong and Durst, 2014; Yen, 2014). To the authors’ knowledge, mass rearing of aquatic insects is restricted to the larvae of mosquitoes, which are mainly used for biological controls, and only one bibliographical reference is available about their use in fish nutrition (Ostaszewska et al., 2011) (Table 5). It would be interesting to study the use of aquatic insects in marine fish diets.

4.4. Chitin

4.4.1. Process to improve chitin digestibility

It is commonly assumed that monogastric animals, including fish, cannot digest chitin (Rust, 2002; Sanchez-Muros et al., 2013). In order to enable the inclusion of chitin in animal feeds, it could be removed from insect meal via alkaline extraction (DeFoliart, 1992; Belluco et al., 2013; Sanchez-Muros et al., 2014), or chitinase and chitinolytic bacteria could be included simultaneously to improve the digestibility of chitin-protein complexes (Kroeckel et al., 2012), as has been shown for tilapia fed diets containing crustacean shell (Zhang et al., 2014). Alternatively, chitin could be degraded by chemical or enzymatic methods before being added to fish diets as chito-oligosaccharides (COS), acetylglucosamine (GlcNAc) or chitosan ((Shiau and Yu, 1999; Se-Kwon and Niranjan, 2005; Lin et al., 2012a; Lin et al., 2012b). Like chitin, low levels of these metabolites have been shown to immunostimulate fish (Hoffman et al., 1997; Lin et al., 2012a). However, these processes could substantially increase the costs of insect meal.
4.4.2. Is chitin really a problem?

Growth experiments on the inclusion of insects in fish diets that lead to a reduction in fish growth and protein and lipid digestibility have very often blamed chitin, without any real evidence (Lindsay et al., 1984; Köprücü and Özdemir, 2005; Balogun, 2011; Longvah et al., 2011; Alegbeleye et al., 2012). The digestion of chitin requires the action of 3 enzymes, chitinase, chitobiase and lysozyme, all of which are present in both carnivorous and omnivorous fish (Lindsay et al., 1984; Fines and Holt, 2010). Chitinase, which has been found in the fish stomach, disrupts the chitinous exoskeletons, whereas chitobiase, which is present in the fish intestine, plays a nutritive role (absorption of nutrients) (Jeuniaux, 1993). The presence of these enzymes has been found in both freshwater (Lindsay et al., 1984; Jeuniaux, 1993) and marine fish (Fänge et al., 1979; Danulat and Kausch, 1984; Kono et al., 1987; Clark et al., 1988; Kurokawa et al., 2004; Fines and Holt, 2010). However, a study on turbot fed BSF larvae failed to detect any chitinase activity, but the study looked at the enzymatic levels in the mid-gut rather than in the stomach of the fish (Kroeckel et al., 2012). Despite the presence of these enzymes in fish, it is commonly assumed that fish cannot digest chitin. Do you need the word “fish” here? (Rust, 2002; Sanchez-Muros et al., 2013).

The chitin found in crustaceans is encompassed in a matrix of proteins and minerals (mostly calcium) (Johnson and Peniston, 1982; No et al., 1989), whereas the cuticle of insects is composed of chitin in a matrix of proteins, lipids and other compounds (Kramer et al., 1995). It has been hypothesized that these matrix forms of chitin may reduce the access of chitinases or proteinases to their substrates and may prevent the absorption of proteins and lipids by the intestine (Tanaka et al., 1997), thus reducing not only chitin digestibility but also lipid and protein digestibility, with a subsequent reduction in nutrient utilization and fish growth performance. Dietary crustacean chitin was shown to reduce digestibility of the diet and the growth of rainbow trout fed 25% chitin (Lindsay et al., 1984) and of tilapia hybrids, O. niloticus×O. Aureus fed 2, 5 and 10% chitin (Shiau and Yu, 1999). However, in contrast to these two studies, many more studies on fish naturally feeding on crustaceans, insects or benthic invertebrates have shown a high digestibility of shrimp and crab meals. In these studies, fish performances were either improved or were not affected by dietary chitin: an increased protein digestibility was obtained in cobia fed crab meal containing 3% chitin or shrimp meal containing 10% chitin (Fines and Holt, 2010); 1% of dietary chitin did not affect the growth of common carp (Gopalakannan and Arul, 2006). Ten percent of dietary chitin stimulated the growth of both Japanese eel (Anguilla japonica) and yellowtail kingfish (Seriola quinqueradiata) (Kono et al., 1987); 5 and 10% of dietary chitin stimulated the growth of red seabream (Pagrus major), while 20% reduced it (Kono et al., 1987). In addition, low levels of dietary chitin have been reported to increase the activity of the innate immune system in seabream (<0.01%) (Esteban et al., 2001) and carp (1%) (Gopalakannan and Arul, 2006).
and to increase the resistance of common carp to bacterial disease (1% chitin) (Gopalakannan and Arul, 2006). Chitin may therefore not be the problem it was first suggested to be.

4.4.3. Quantification of chitin in insects

Until recently, the amount of chitin in insects has been considered to correspond to acid detergent fiber (ADF), but a study has shown that the ADF fraction actually contains high amounts of AAs (6.7 to 32.7% of the ADF), which suggests that previous studies overestimated the chitin content of insects (Finke, 2007). Using ADF, adjusted for its amino acid content, the estimated chitin content of insects ranged from 11.6 to 137.2 mg/kg (DM) (Finke, 2007). Thus, a diet containing insect meal will only transfer a very small amount of chitin to the fish. Moreover, the first suggestions that soft-bodied insects contained less chitin and were more digestible than hard-bodied insects (Frye and Calvert, 1989) were biased, as more recent studies have shown that the chitin content of SWP larvae is similar to that of adult crickets (Finke, 2007). In fact, the hardness of the cuticle could primarily be a function of the degree of sclerotization, a process that links protein to fibers, and could thus be proportional to the AA content of the cuticles rather than to its chitin content (Nation, 2002). Subsequently, the digestibility of the insects may decrease when the proportion of AAs increases in their ADF fraction (Finke, 2007). Thus, the reduction in fish growth is more likely to be related to the proportion of AAs in the cuticle or to a potential AA imbalance, FA deficiency or other inadequacies of the diets than to the chitin content. With a caloric content of 17.1 kJ g⁻¹, chitin could constitute a substantial percentage of the total energy intake of marine fish feeding on crustaceans (Gutowska et al., 2004), and it represents an under-utilized biomass resource, despite the potential commercial benefits of using it as a prebiotic or as a carbohydrate source for aquafeeds (Tharanathan and Kittur, 2003). This ? Laura – what does “This” refer to? may also be applicable to insect chitin, and further studies are needed to determine this potential.

4.5. Processing of insect meal to improve palatability and digestibility

The low palatability of insect meal may be caused by different factors: a potential chemical or microbiological contamination, the presence of anti-nutrient factors, flavonoids and terpenoids in the feedstuff of insects (Finke, 2002) and/or the richness in monounsaturated FAs of terrestrial insects (Barroso et al., 2014), which makes them susceptible to oxidation, with resulting rancidity problems (Finke, 2002). The palatability, nutrient availability,
digestibility and composition of insect meal may be more suitable for fish nutrition after some processing of the meal, such as drying, hydrolyzing, ensiling or defattening (Newton et al., 2005).

4.5.1. Drying of insect meal

The sun- or oven-drying of mealworms, directly or after boiling in water, has improved the palatability of mealworms (Ng et al., 2001). Oven-drying is usually recommended over sun-drying, as the latter usually yields a fattier maggot meal (with an increased risk of lipid oxidation) that is poorer in proteins (Aniebo and Owen, 2010).

4.5.2. Acid hydrolysation or ensilage of insect meal

Although hydrolysation using acids has been shown to successfully increase the protein and decrease the lipid contents of insect (silkworm and maggots) meal (Anon, 1999; Fasakin et al., 2003), it may also partially or totally destroy some EAAs such as cystine, Met and Trp (Castell, 1986). Ensiling with molasses, acids and antioxidants (Rangacharyulu et al., 2003) seems more promising. During fermentation, the bacteria predigest the components of the feed, which may be difficult to digest by the fish. Fermentation converts sugars into acids, thus lowering the pH, and competes with bacteria that might cause spoilage (Manikandavelu et al., 1992). Optimised ensilage can improve palatability, as shown in mammals, but the conditions must be closely monitored (Buchanan-Smith, 1990). Fermented SWP silage has been shown to be nutritionally superior (better nutrient utilization and fish survival, leading to a higher production) than untreated SWP or even FM (Rangacharyulu et al., 2003).

4.5.3. Defattening

Given the presumed good quality of insect EAA profiles and the low quality of insect FA profiles for marine fish, it could be a good idea to defatten insect meal and use the proteins for fish feeds and the lipids for other processes that do not require richness in n-3 HUFA. For example, the lipids extracted from BSF or mealworms have been suggested to be good candidates for use in biofuel (Belforti et al., 2014; Schneider and Llecha, 2014). Defattening insects by cutting the frozen BSF larvae and applying them to a press to enable the leakage of intracellular fat (Kroeckel et al., 2012) or using petroleum ether extraction of the insect meal (Fasakin et al., 2003) has increased the crude protein content of the insect meal (Hossain et al., 1997; Fasakin et al., 2003). Defattening maggot meal has led to an increase in the inclusion level of maggot meal in the diet of African catfish, without affecting fish growth (Fasakin et al., 2003). However, a recent study on Atlantic salmon has shown that highly defatted BSF, dried at a conventional temperature, surprisingly reduced fish growth compared to fish fed lightly
defatted BSF dried at a low temperature (Lock et al., 2014). The problem with lipids may be related more to their oxidation (at a high temperature) than to the actual high dietary lipid content.

4.5.4. Addition of antioxidants

Rancidity has been proposed as a limiting factor to the use of fatty insect meal, but some studies using SWP have shown better results with non-defatted than with defatted insect meal (Hossain et al., 1997). It was suggested that lipophilic growth stimulants may be lost when insect meal is defatted (Tsushima and Ina, 1978; Nandeesha et al., 1999). Adding antioxidants to insect meal could therefore increase palatability and reduce the negative effects of the insect lipid content on fish growth.

The advantages of processing meal (digestibility/palatability) must be weighed against the cost of the processing, as an increase in the price of the final insect meal should not surpass the gains provided by the increase in weight of the commercialized fish.

5. Conclusion

This review has highlighted the good potential of using insects as a replacement of FM in finfish diets, thanks to their high protein content and adequate EAA profiles, which are only deficient in a few AAs. The use of a mixture of different protein sources (different insects or insects with prebiotics, with plants or with animal proteins) or dietary AA supplementation could reduce the potential nutrient deficiencies and better balance the AA profiles. Lipid oxidation or an inadequate FA composition of some insect meals can limit their use in aquafeeds as replacements of FO, and defatted insect meal could be more useful, although this topic needs further research. A total FM replacement with insect meal has usually not been successful, probably because of a dietary unbalance or deficiencies. However, when insects (mealworm, maggots, BSF) were fed whole to fish, they usually compared positively with control fish fed low quality commercial pellets. The partial replacement with insect meal seems possible, mainly for herbivorous/omnivorous species, but also for some carnivorous fish (black carp, rainbow trout, Japanese sea bass, chum salmon, gilthead seabream and European sea bass).

Mealworms, SWP and maggots have been shown to be the most successful insects in fish feeding experiments so far, with good digestibility results and fish growth performances that match and even exceed FM in some cases, even for high dietary inclusion levels or for whole fat insect meal. In order to achieve a positive and significant ecological and economic impact, further studies need to be conducted, preferentially focusing on the use of these insects in the diet of fish species with high protein requirements. Digestibility issues also require further studies,
as the chitin content may not be the only factor responsible for these problems, and may even not be involved at all. In order to enhance the achievable percentage of FM substitution, without compromising fish growth or fish health, different strategies (drying, defattening, ensilage, manipulation of the insect diet and rearing conditions, the addition of antioxidants) could be adopted to enhance the nutritive value, the palatability and/or digestibility of the insect meal, and to reduce the potential toxicity or contamination level of the meal. Defattening insect meal may also be a means of separating the highly proteic insect meal for use in fish feeds, and insect lipids for use, for example, as biofuel. A finishing diet rich in FM and FO could be used in marine fish fed insects, before the commercialization of the fish, in order to restore the richness in n-3 FA of the fillets. Alternatively, aquatic insects could be used in the diet of marine fish, but their mass rearing needs to be mastered first. The sheer multitude of available insect species, with different habitats, developmental stages, and feeding habits as well as the optimal rearing conditions that can affect their composition, portend a great deal of potential future research on this exciting subject in which entomologists and fish nutritionists will have to join forces.
