(Received 20 March 2015; published 16 June 2015)

If dark matter (DM) is composed by particles which are nongravitationally coupled to ordinary matter, their annihilations or decays in cosmic structures can result in detectable radiation. We show that the most powerful technique to detect a particle DM signal outside the Local Group is to study the angular cross-correlation of nongravitational signals with low-redshift gravitational probes. This method allows us to enhance the signal to noise from the regions of the Universe where the DM-induced emission is preferentially generated. We demonstrate the power of this approach by focusing on GeV-TeV DM and on the recent cross-correlation analysis between the 2MASS galaxy catalogue and the Fermi-LAT γ-ray maps. We show that this technique is more sensitive than other extragalactic γ-ray probes, such as the energy spectrum and angular autocorrelation of the extragalactic background, and emission from clusters of galaxies. Intriguingly, we find that the measured cross-correlation can be well fitted by a DM component, with a thermal annihilation cross section and mass between 10 and 100 GeV, depending on the small-scale DM properties and γ-ray production mechanism. This solicits further data collection and dedicated analyses.

Introduction.—The origin of cosmic structures is well understood in terms of evolution of matter perturbations arising after the inflationary period. Inhomogeneities starting off with higher-than-average density grow through gravitational instability. Dark matter (DM) is a necessary ingredient to the process, as it provides the potential wells where standard matter is accreted after decoupling and protohalos form. As structure formation evolves, DM halos of increasing size form in a bottom-up fashion.

If DM is in the form of particles which exhibit nongravitational couplings to ordinary matter, a certain level of emitted radiation is expected. Photons can be produced from interactions of DM with the ambient medium (e.g., through scatterings) or from DM annihilation or decay by means of direct emission or through the production of intermediate particles. The nongravitational signal associated to decay is proportional to the DM density: it is stronger at low redshift, because the produced radiation is diluted by the expansion of the Universe more rapidly than its source, i.e., the DM particle density. The DM annihilation signal, which is proportional to the density squared, is also peaked at low redshift since the density contrast associated to cosmic structures grows nonlinearly.

DM constitutes the backbone of all cosmic structures and DM halos represent, collectively, a potential source of DM decay or annihilation signals. This means that even if the radiation originating from DM annihilations or decays in a single halo is too faint to be detected, their cumulative signal and its spatial coherence could be. In addition, since the DM signal is expected to peak at $z < 0.3$, it can be separated by more mundane astrophysical processes that typically trace the star formation history and peak at higher redshifts.

To increase the sensitivity to nongravitational DM sources, one needs to isolate the annihilation or decay signal produced at low redshift. An effective way to filter out any signal that is not associated to DM-dominated structures or that is originated at high redshift is to cross-correlate the radiation field with bona fide low-redshift DM tracers [1–6]. In the following, we adopt this approach in the specific and yet very relevant framework of weakly interacting massive particles (WIMP) that may either annihilate or decay. We will use the results of the cross-correlation analysis between γ-ray maps from Fermi-LAT [7] and the 2MASS catalogue of relatively nearby galaxies [8] presented in [9].

Data and models.—The cross angular power spectrum (CAPS) between the unresolved γ-ray sky observed by Fermi-LAT and the distribution of 2MASS galaxies can be written as [3]

0031-9007/15/114(24)/241301(6) 241301-1 © 2015 American Physical Society
\[ C_\ell^{(\gamma)} = \int \frac{d\chi}{\chi^2} W_1(\chi) W_9(\chi) P_{\gamma g}(k = \ell/\chi, \chi), \]  
where \( \chi(z) \) denotes the radial comoving distance, \( W_1(\chi) \) represents the window functions described below, \( P_{\gamma g}(k, z) \) is the three-dimensional cross power spectrum (PS), \( k \) is the modulus of the wave number, and \( \ell \) is the multipole. Indices \( \gamma \) and \( g \) refer to \( \gamma \)-ray emitters and \( \gamma \)-ray annihilation, respectively. In Eq. (1) we used the Limber approximation [10], since \( P_{\gamma g} \) varies (relatively) slowly with \( k \).

The (differential in energy) window function for \( \gamma \)-ray emission from DM annihilation \( W_\gamma(z) \) is [3]

\[ W_\gamma^a(z) = \frac{(\Omega_{\text{DM}} \rho_\gamma)^2 \langle \sigma v \rangle}{8\pi m_{\text{DM}}^2} (1 + z)^3 \Delta^2(z) \frac{dN_\gamma}{dE_\gamma} e^{-\tau_{\gamma;E}(z)}, \]  
where \( \Omega_{\text{DM}} \) is the DM mean density in units of the critical density \( \rho_c \), \( \Delta^2(z) \) is the clumping factor, \( m_{\text{DM}} \) is the mass of the DM particles, and \( \langle \sigma v \rangle \) denotes the velocity-averaged annihilation rate. A six-parameter flat \( \Lambda \) cold dark matter cosmological model is assumed with the value of the parameters taken from Ref. [11]. \( dN_\gamma/dE_\gamma \) indicates the number of photons produced per annihilation and determines the \( \gamma \)-ray energy spectrum. The exponential damping quantifies the absorption due to extragalactic background light [12].

The window function for DM decay is [3]

\[ W_\ell^d(z) = \frac{\Omega_{\text{DM}} \rho_\gamma \Gamma_d}{4\pi m_{\text{DM}}^2} \frac{dN_d}{dE_\gamma} e^{-\tau_{\gamma;E}(z)}, \]  
where \( \Gamma_d = 1/\tau_d \) is the DM decay rate.

The window function of 2MASS galaxies is \( W_\gamma(z) \equiv H(z)/c dN_g/dz \) and their redshift distribution \( dN_g/dz \) is [13]

\[ \frac{dN_g}{dz}(z) = \frac{\beta}{\Gamma((m+1)/\beta)} z_0^{m+1} \exp \left[ -\left( \frac{z}{z_0} \right)^\beta \right], \]  
with \( m = 1.90, \beta = 1.75, \) and \( z_0 = 0.07 \).

We employed the 2MASS catalogue instead of other compilations because the galaxy distribution in Eq. (4) is peaked at very low redshift as for the DM emission of Eqs. (2) and (3). This enhances the cross-correlation signal. The picture for astrophysical components would be different and other catalogues might be more informative (see Sec. S2 in the Supplemental Material [14]).

The PS \( P_{\gamma g} \) in Eq. (1) is computed within the halo-model framework, as the sum of one-halo plus two-halo terms. For more details, see [3]. Both the PS and the clumping factor \( \Delta^2(z) \) in Eq. (2) depend on a number of DM properties: the halo mass function, that we take from Ref. [22], the halo density profile, for which we assume a Navarro-Frenk-White model [23], the minimum halo mass, that we set equal to \( 10^{-6} M_\odot \), and the halo mass-concentration relation \( c(M, z) \), that we adopt from Ref. [24]. The theoretical uncertainty of these quantities is rather small for halos larger than \( 10^{10} M_\odot \), because they can be constrained by observations and simulations. Since the DM decay signal is mainly contributed by large structures, the theoretical predictions are relatively robust. This is not the case for the annihilation signal which is preferentially produced in small halos and in substructures within large halos. Consequently, theoretical uncertainties on the annihilation signal are larger. For the subhalo contribution we consider two scenarios (LOW and HIGH) to bracket theoretical uncertainty. The LOW case follows the model of Ref. [25] [see their Eq. (2), with a subhalo mass function \( dN/dM_{\text{sub}} \propto M_{\text{sub}}^{2-2} \)]. The HIGH scenario is taken from Ref. [26], with the halo mass-concentration relation extrapolated down to low masses as a power law. Further uncertainties in the concentration parameter and in the value of the minimum halo mass can introduce an extra factor of \( \sim 2 \) of uncertainty, that we quantify only in the Supplemental Material [14], for the sake of definiteness.

In our CAPS model [Eq. (1)], we add a constant term \( C_{1h} \) \((\text{one-halo correction term})\) to correct for possible unaccounted correlations at very small scales, within the Fermi-LAT point spread function. The value of \( C_{1h} \) will be determined by fitting the data, and we anticipate that we find a \( C_{1h} \) value compatible with zero. Thus, the inclusion of this term does not change significantly the results. For a discussion on this term, see Ref. [5].

The measured CAPS \( \tilde{C}_\ell^{(\gamma)} \) is a convolution of the true CAPS and the effective beam window function \( W_\nu^g \) that accounts for the point spread function of the instrument and the pixelization of the \( \gamma \)-ray map. Both quantities depend on energy. We use the \( W_\nu^g \) derived in Ref. [9] and model the observed spectrum as \( \tilde{C}_\ell^{(\gamma)} = W_\nu^{\ell} C_\ell^{(\gamma)} \).

In the following, we shall consider the angular cross-correlation function (CCF) rather than the spectrum. To model the CCF, we Legendre transform the CAPS:

\[ \text{CCF}^{(\gamma)}(\theta) = \sum_\ell 2\ell + 1 4\pi \tilde{C}_\ell^{(\gamma)} P_\ell(\cos(\theta)), \]  
where \( \theta \) is the angular separation and \( P_\ell \) are the Legendre polynomials.

To compare model and observed CCFs, we estimate the \( \chi^2 \) difference defined as

\[ \chi^2 = \sum_{n=1}^3 \sum_{\delta, \delta_j} [d_{\ell n}^{\gamma} - m_{\ell n}^{\gamma}(A)] [C^{\gamma}_{\ell n}]^{-1} [d_{\ell n}^{\gamma} - m_{\ell n}^{\gamma}(A)], \]  
where \( m \) and \( d \) indicate model and data, \( n \) identifies each one of the three overlapping energy ranges considered...
FIG. 1 (color online). Cross-correlation above 500 MeV for the best fitting annihilating and decaying DM scenarios, compared to the measured CCF. The curves are for DM particles of 100 GeV (200 GeV) annihilating (decaying) into $b\bar{b}$. We show the two annihilation models, HIGH and LOW, with annihilation rates $\langle \sigma_v a \rangle = 2 \times 10^{-26}$ cm$^3$ s$^{-1}$ (blue-dashed curve) and $2.4 \times 10^{-25}$ cm$^3$ s$^{-1}$ (blue-solid curve), respectively, and a decay model with lifetime $\tau = 1.6 \times 10^{27}$ s (red-dotted curve). The green curve shows the CCF of the one-halo correction term $C_{1h}$. We show the sum of this component and the DM CCF (in the LOW scenario) with the black curve. The inset shows that these DM models provide a dominant contribution to the observed IGRB spectrum [27].

($E > 0.5$, 1, and 10 GeV), and the indices $\theta_i$ and $\theta_j$ run over 10 angular bins logarithmically spaced between $\theta = 0.1^\circ$ and $100^\circ$. $C_{\theta_i\theta_j}$ is the covariance matrix that quantifies the errors of the data and their covariance among the angular bins. Data and covariance matrix are taken from Ref. [9]. The parameter vector for annihilating DM is $A = (m_{DM}, \langle \sigma_v a \rangle, C_{1h})$, whereas for the decaying DM it is $A = (m_{DM}, \tau, C_{1h})$.

**Results.**—In Fig. 1 we show a comparison between the measured CCF in one of the considered energy bins ($E > 500$ MeV) and the best fitting annihilating and decaying DM models obtained from the analysis discussed below. Error bars are given by the diagonal elements of the covariance matrix. DM models fit the measured CCF remarkably well (for the best fitting model, $\chi^2_{BB} = 16.7$ with 26 d.o.f.). It is also noteworthy that the level of annihilation or decay rate provides a minor contribution to the isotropic gamma-ray background (IGRB) measured by the Fermi-LAT [27], as shown in the inset of the figure. This implies that the cross-correlation technique can detect DM signals too faint to show up in the total intensity measurement (for a review of the IGRB properties, see Ref. [28]).

In Fig. 2, we show the 1$\sigma$ and 2$\sigma$ C.L. contours (obtained marginalizing over $C_{1h}$) for DM mass and annihilation or decay rate for various final states. Note that, although we use only three energy bins, they are sufficient to constrain the DM mass which induces a small but characteristic signature in the energy spectrum. In the LOW scenario the 1$\sigma$ region lies just above the thermal annihilation rate $\langle \sigma_v a \rangle = 3 \times 10^{-26}$ cm$^3$ s$^{-1}$. In the HIGH case, the DM signal increases by a factor of $\sim 10$ and consequently regions shift down by 1 order of magnitude. Therefore, given the current uncertainty in modeling DM structures we conclude that the thermal cross section is well within the allowed regions for $m_{DM} \lesssim 200$ GeV.

We stress that the confidence contours in Fig. 2 are drawn under the assumption of no contribution from astrophysical sources. While their purpose is mainly illustrative, they may not be unrealistic since astrophysical sources, which are indeed required to account for the IGRB thanks to their medium-to-large redshift emission, can indeed provide a negligible contribution to the cross-correlation signal between Fermi-LAT and 2MASS galaxies that, as we point out, has a rather local origin (see the discussion in Sec. S2 of the Supplemental Material [14]). On the other hand, given the current uncertainty on the astrophysical components of the IGRB, an astrophysical model that can explain the measured cross-correlation signal with no additional contribution from DM can be found [9]. Future data and analyses will help distinguishing between these two options.

This cross-correlation measurement can alternatively be used to derive 95% C.L. upper bounds on the annihilation or decay rate. These bounds are conservative and robust, since we assume here that DM is the only source of the $\gamma$-ray signal, without introducing additional assumptions on astrophysical components which would make the constraints stronger but also more model dependent. The 95% C.L. upper bounds on the WIMP annihilation (decay) rate as a function of WIMP mass are shown in the left-hand (right-hand) panel of Fig. 3. For $b\bar{b}$ and $\tau^+\tau^-$ final states, the thermal annihilation rate is excluded for masses below 10 (100) GeV in the LOW (HIGH) scenario. In the case of $\mu^+\mu^-$, the bounds degrade by about 1 order of magnitude.

In Fig. 4 we compare the sensitivity of our cross-correlation method with that of other extragalactic $\gamma$-ray probes. We focus on these probes since they are similarly affected by uncertainties in modeling DM halo and subhalo properties. This allows us to compare various techniques in a homogeneous and robust way, something that cannot be done with local DM tracers (galactic regions, dwarf galaxies) or early Universe probes, which have different systematic uncertainties (see, however, the discussion in Sec. S1 of the Supplemental Material [14]). For illustrative purposes, we selected the LOW substructure scheme and $b\bar{b}$ final states case. We verified that different choices provide little differences and the results are robust to both the DM clustering model and the annihilation or decay channel. We consider again the simplest case (where most conservative bounds can be derived), in which the astrophysical

Programs (P) are available from the authors.
contribution is set to zero in all observables and only DM is contributing as a $\gamma$-ray source.

The bound corresponding to the IGRB energy spectrum has been derived using the IGRB estimated by the Fermi-LAT Collaboration [27] and adding up in quadrature statistical and systematic errors given in their Table 3. For the autocorrelation bound, we considered the angular spectrum estimated in four energy bins in Ref. [29] as provided in their Table II (DATA:CLEANED) and averaged in the multipole range $155 \leq l \leq 504$. For both probes, the model prediction has been computed using the same DM modeling as in our analysis. Our bounds are compatible with the ones presented in Refs. [30–35] (under the same set of assumptions). Cluster bounds are instead taken directly from the literature. In particular, for annihilating DM, we consider the analysis of 34 clusters using expected sensitivity for the five years of Fermi-LAT data in Ref. [36] which uses the same LOW model adopted here. For decaying DM, we consider the analysis of eight clusters in three years of Fermi-LAT data taking performed by [37].

Figure 4 shows that the cross-correlation technique stands out as the most sensitive one, improving the

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure4.png}
\caption{Left: 1σ and 2σ allowed regions for the DM annihilation rate versus its mass, for different $\gamma$-ray production channels and assuming a low substructure scheme. Crosses indicate the best fitting models. In the high scenario, regions remain similar but shifted downward by a factor of $\sim 12$; see stars indicating the best fitting models. Right: The same as in the left-hand panel but for decaying DM, showing the DM particle lifetime as a function of its mass.}
\end{figure}
We found that in the model prediction, in order to derive conservative constraints by a factor between a few to a hundred over the other techniques. Note that the ratio decreases at high energy because our analysis focuses at low energies (up to $E > 10$ GeV). Since the IGRB is measured up to 820 GeV there is room for further improvements.

Conclusions.—We compared the predicted angular cross-correlation between the $\gamma$-ray emission induced by DM annihilation or decay and the distribution of 2MASS galaxies with the measured CCF between these objects and the Fermi-LAT $\gamma$-ray maps.

The contribution of astrophysical sources to the IGRB is assumed to be subdominant at low redshift and not included in the model prediction, in order to derive conservative bounds on DM. We found that in the LOW [25] and HIGH [26] scenarios the “thermal” annihilation cross section is excluded at 95% C.L. up to DM masses of 10 and 100 GeV, respectively, for the final state of annihilation into $b\bar{b}$ and $\tau^+\tau^-$. We demonstrated that the cross-correlation technique is significantly more sensitive to a DM signal than all other extragalactic $\gamma$-ray probes used so far. This was done by comparing the bounds of our cross-correlation analysis with the most recent results from IGRB, angular autocorrelation, and clusters, finding an improvement of a factor ranging from a few up to 100 for both annihilating and decaying DM.

We showed that a WIMP DM contribution can fully explain the observed cross-correlation. A canonical WIMP with a mass in the 10–100 GeV range, an annihilation rate around the thermal value, and a realistic model for DM halo and subhalo properties reproduce both the size and shape of the measured angular cross-correlation. This intriguing possibility deserves further investigation within a more comprehensive framework that include contributions from astrophysical sources and additional data.

A future investigation employing the Pass8 release from the Fermi-LAT and forthcoming surveys at low and intermediate redshift [38] will therefore provide remarkable insights to the particle DM quest.
