(Article begins on next page)
We report for the first time the formation of a metal amide-hydride solid solution. The dissolution of KH into KNH₂ leads to an anionic substitution, which decreases the interaction among NH₂⁺ ions. The rotational properties of the high temperature polymorphs of KNH₂ are thereby retained down to room temperature.

The amides of alkaline and alkaline-earth metals were discovered and independently investigated by J. L. Gay-Lussac and H. Davy in the early 19th century. Further studies on their properties were performed towards the end of the same century, most systematically from A. W. Titherley. The determination of their crystal structures was possible only after the 1930s with the studies of Juza et al., later continued by Jacobs et al. At that time this class of compounds was mostly used for organic synthesis. However, more recently, metal amides – metal hydrides mixtures have been proven to be suitable for reversible hydrogen storage. Furthermore, metal amides – metal borohydrides systems are regarded as potential solid state ionic conductors.

The structural and thermal properties of light-weight amides prepared by reaction of metal hydrides with ammonia have been systematically examined by in situ diffraction experiments. While the reaction mechanism and products reported in previous studies were confirmed for the amides of lithium and sodium, the formation of new K-N-H based intermediates was suggested for potassium amide. The same intermediates were proven to play a role in the desorption reactions of the K-Mg-N-H system. These intermediates are isolated here in the KNH₂-KH system and, to the best of our knowledge, identified as the first metal amide-hydride solid solution.

The crystal structures of pristine potassium amide and potassium hydride have already been investigated by X-ray and neutron diffraction. Potassium hydride is known to crystallize in a cubic rock-salt type structure with space group (s.g.) Fm̅3m and no polymorph changes are expected in the temperature range from room temperature (RT) to 390 °C. For potassium amide, the stable polymorph at RT is monoclinic with s.g. P2₁/m. Upon heating this phase transforms into a tetragonal structure with in P4/nmm at 54 °C. The latter phase is stable only in a narrow temperature range; and already above 75 °C the stability of a cubic phase (Fm̅3m) prevails. An increase of symmetry is therefore reached with the two phase transitions at higher temperature. The explanation of the symmetry changes resides in the increasingly high orientational disorder of the amide anions, as proven by powder neutron diffraction (PND), quasielastic incoherent neutron scattering and orientation-dependent deuterium spin lattice relaxation. If the maximum temperature upon heating is kept below the decomposition temperature of KNH₂ (ca. 340 °C), the two phase transitions and the associated rotational dynamics should be reversible on cooling.

This is in agreement with the present in situ synchrotron radiation powder X-ray diffraction experiment (SR-PXD) on KNH₂ (ESI). When a 0.5 KNH₂ + 0.5 KH mixture was investigated, the expected phase transformations of KNH₂ took place, but the interaction of KNH₂ and KH in the temperature range between 100 °C and 270 °C led to the formation of a new cubic structure (Figure 1 a). PND at 270 °C of a potassium deuteramide - potassium deuteride mixture confirmed the presence of a single cubic phase at this temperature (Figure 1 b).
The structure was solved assuming an ionic crystal with unaltered positions for the potassium cations and partially occupied sites at the original positions of amide and hydride anions. Indeed the formation of a solid solution is highly favorable due to the structural similarities between the two cubic polymorphs of KNH₂ and KH (same space group, same cation, same charge for the anions, similar lattice constants). The local symmetry of the deuteramide groups is compatible with the s.g. Fm̅3m only assuming rotational dynamics and orientational disorder. In this case the restrictions imposed from both the s.g. and rigid amide groups resulted in partially occupied sites (multiplicity = 192) for the deuterium atoms of each amide group (Figure 1 c).

The final Rietveld refinement²⁵, ²⁶ of the PND pattern (Figure 1 b) confirmed the structural model, i.e. the formation of a potassium amide-hydride solid solution. To the best of our knowledge, no similar cases have been reported so far for other alkaline metal amides-metal hydrides mixtures.

The similarity of chemical environment between the starting materials and the x KNH₂ + (1- x) KH samples at different compositions (x = 0.1, 0.5, 0.9) after annealing was verified by ¹H magic angle spinning solid-state NMR (MAS SSNMR), see Figure 2 b. Direct evidence of the solid solution formation is provided by the ¹H double-quantum (DQ) MAS SSNMR experiment (Figure 2 b). Indeed, the observed DQ correlation between the KNH₂ (-3.2 ppm) and KH (4.8 ppm) signals implies that they are in close spatial proximity each other (less than 5 Å). This is only possible if they are intimately related as in a solid solution.²⁸, ²⁹ Similar correlation, although much weaker, is observed for the sample before annealing (Supporting Information), which can be explained with the formation of a small fraction of solid solution due to the fast rotation and slightly increased temperature during the NMR experiment.

The effect of the starting composition of the mixtures on the final structure was studied by means of in situ SR-PXD. A linear relationship was found between the unit cell parameter of the cubic phase at T = 270 °C and the molar fraction of amide anions (Figure 3 and Table 1) as expected from Vegard’s law.³⁰ This indicates volumes of mixing close to zero and, therefore, an almost ideal behavior for the solid solution (ΔH_mix = 0).

It is noteworthy that, for the compositions x = 0.1, 0.3, 0.5, 0.7, the structure did not change during the cooling process down to RT, except for the thermal contraction of the unit cell volume (more details in Table 1 and in Supporting Information).

It appears that the addition of potassium hydride can stabilize the cubic geometry, which retains the rotation of the amide anions even at RT. A similar behavior was previously reported for the sodium borohydride - sodium chloride systems, at different temperature (T = - 81 °C).³¹ Ex situ PXD of annealed samples (x = 0.3, 0.5, 0.7, 0.9) collected with a Bragg Brentano diffractometer proves the coexistence of at least two different cubic structures. The composition x = 0.1, however, presented unchanged cubic phase (see Supporting Information). At the
composition $x = 0.9$, coexistence of the cubic and monoclinic phases was found. These results suggest the presence of a two phase field at RT. Nevertheless, even in the cases where phase segregation occurred, both cubic structures were proven to be unchanged even after several months, hence a complete transformation back to the pure monoclinic phase of $\text{KNH}_2$ and cubic phase of $\text{KH}$ did not occur.

Noteworthy, the same structures are formed simply by mechanochemical treatments of the starting reactants. In some cases ($x = 0.1, 0.3$ and 0.9) manual grinding is enough to promote the formation of detectable amounts of $\text{K(NH}_2)_x\text{H}_(1-x)$ solid solution. These species are therefore easily formed and are expected to be possibly identified as reaction products or intermediates in future studies of amide-based systems containing potassium.

[a] Nominal composition and [b] Refined composition (molar fraction) of $\text{KNH}_2$ [c] Refined cell parameters at 270 °C [d] Calculated linear thermal expansion coefficients [e] Calculated cell parameters at 20 °C. Estimated standard deviations are given in parentheses.

To the best of our knowledge, amide/hydride solid solutions were not reported so far. In this sense, the chemistry of the K-based amide/hydride system is interestingly peculiar and differs substantially from the one of the other alkaline metal amides/hydrides.

The research leading to these results has received funding from the European Marie Curie Actions under ECOSTORE grant agreement no. 607040. The help of the beamline scientists Francisco Martinez Casado, Dorthe Haase, Olivier Balmes, (MAX-lab – Lund, Sweden), Martin Etter and Jozef Bednarcik (DESY – Hamburg, Germany) is thankfully acknowledged. A.S. thanks the research groups of Turin University, Sassari University and IFE for the fruitful discussion and Dr. Klaus Taube, coordinator of the ECOSTORE project, for providing the essential networking opportunities.

Notes and references

† The in situ SR-PXD experiments were performed at the diffraction beamline I711, MAX Lab (Lund, Sweden) and at the diffraction beamline P02, DESY (Hamburg, Germany).
Germany) (monochromatic beams of $\lambda = 0.99 \, \text{Å}$ and $0.2 \, \text{Å}$ were employed respectively). In the situ cells and the procedure used are described elsewhere. Neutrons with $\lambda = 1.5539 \, \text{Å}$ were provided by a focusing Ge(511) monochromator at 90° take-off angle. Data was collected in the range 20 ° = 10-130 (2θ = 0.05 °) by 2 detector banks each with 7 vertically stacked position sensitive detectors. The sample was contained in an argon-filled quartz tube with a 6 mm diameter placed inside an in-house built furnace. The structure solution was carried out using the software “FOX” and the Rietveld refinement was performed by means of the software GSAS and the EXP(GUI graphic interface).

Solid-state NMR experiments were run on a Bruker AVANCE II 400 instrument operating at 400.23 MHz for $^1$H and equipped with a 2.5 mm probe. The $^1$H MAS spectra were acquired at the spinning speed of 32 kHz with the DEPTH sequence and the EXPGUI graphic interface.

The H sample was contained in an argon-filled quartz tube with a 6 mm diameter placed inside an in-house built furnace. The structure solution was carried out using the software “FOX” and the Rietveld refinement was performed by means of the software GSAS and the EXP(GUI graphic interface).

**Experimental details.**

Synthesis. KH (30 wt% dispersion in mineral oil) was purchased from Sigma-Aldrich. Before usage the oil was removed by washing 3 times with hexane in vacuum filtration. KNH₂ was synthesized by reactive ball milling of the dry potassium hydride powder in a Fritsch Pulverisette 6, at 400 RPM, with a BPR ca. 20:1, under 7 bar of ammonia atmosphere. The reaction vessel (a high pressure vial from Evicomagnetics) was evacuated and refilled with ammonia 4 times, for a total milling time of 18 h. Both the starting materials (KH and KNH₂) were then independently ball milled in a SPEX 8000 mill for 600 minutes to obtain a finer powder. The mixtures of KNH₂ and KH were prepared grinding the two reactants for 5 minutes in an agate mortar. The annealed samples were prepared in a thermal reactor from Parr Instruments, heating at 270 °C under Argon atmosphere for 1 h.

The ball milled samples were prepared using a SPEX 8000 Mill, milling the powder for 5h with a BPR of 10:1. Hardened steel vials and balls were used.

Potassium deuteramide (KND₃) was synthesized by thermal treatment of metallic potassium under 5 bar of deuterated ammonia (ND₃) for 16 h at 300 °C in an autoclave from Parr Instruments. The reaction can be written as: K + ND₃ → KND₂ + 1 / 2 D₂

Potassium deuteride was synthesized by ball milling pure potassium under 50 bar of deuterium (D₂) for 36 h with a rotational speed of 600 rpm and a ball to powder ratio of 60:1. Potassium (98 % purity) under mineral oil was purchased as commercial product from Sigma Aldrich. A cube of 1.1 g approximately was cut. Before use, the oil was removed washing with hexane. In addition the material surface was polished with a sharp blade.

The diffractograms on the ball milled samples (Figure S2) were collected with a Bruker D8 Advance diffractometer in Bragg-Brentano geometry using a General Area detector and a Cu X-ray source. The sample was investigated using an airtight sample holder from Bruker. The incoherent scattering of the Poly (methyl methacrylate) dome is responsible for the bump observed between 1 and 2 Å⁻¹ in all the diffracograms (Figure S2).

The diffractograms on the annealed samples (Figure S3) were performed in the 2θ range 2° – 90° (step size of 0.017°, time per step 200 s) using a laboratory diffractometer (Panalytical X’Pert Pro Multipurpose Diffractometer) equipped with Ni filtered Cu source in Debye-Scherrer geometry. Samples were sealed into boron silica glass capillaries of internal diameter 0.8 mm in a protected atmosphere.

The sample handling was performed in an Argon circulation glove box, with oxygen and moisture concentrations lower than 2 ppm.

The scattering images obtained by in situ synchrotron X-ray diffraction were integrated with the program Fit2D. Rietveld refinement was performed by means of MAUD program (Material Analysis Using Diffraction)⁴ on the diffractograms selected for phase identification and determination of the cell parameters (Figures S5, S6, S7, S8, S9). In any case structural models from the literature were used for the known phases of KNH₂ and KH. For the new KNH₂(1−x)KH₃ₓ phases a general structural model was obtained using FOX software⁵ on the pattern obtained by in situ powder neutron diffraction on the sample with nominal composition x = 0.5 and then adapted for the other different compositions. The occupancies for the amide and hydride anions were calculated and fixed in order to be in agreement with the refined composition of the room temperature pattern. The Rietveld refinement of the neutron diffraction pattern was performed with GSAS software.⁴

**Linear expansion coefficients and related structural properties.**

The linear thermal expansion coefficients reported in Table 1 were calculated according to the following formula: αₜ = ( aₜ – a₁ ) / { a₁ ( T₂ – T₁ ) }, where T₂ > T₁ and a₂ > a₁.

The cell parameters "a₁" and the temperatures "T₁" are referred to the diffractograms collected during the cooling process, since in that interval only one KNH₂(1−x)KH₃ₓ was present. T₂ = 270 °C for all the samples. For the compositions x = 0, 0.1, 0.3, 0.5, 0.7 the calculations are referred to T₁ ≈ RT while for the compositions x = 0.9 and x = 1, the diffractograms corresponding to T₁ = 48 °C and T₁ = 82 °C were selected respectively, due to the phase transformations occurring at lower temperatures.
The obtained linear expansion coefficient was then used to calculate the cell parameter expected at $T_1 = 20 \, ^\circ\text{C}$ for the cubic polymorph of each composition (also reported in Table 1). Even though for the pure KNH$_2$ the cubic polymorph does not exist at room temperature (in normal pressure conditions), the cell parameter calculated with the linear expansion coefficient of the cubic form of KNH$_2$ is in good agreement with the values expected by the linear behavior (Figure 4 – Main article). The explanation most probably resides in the structural similarities between the different polymorphs of KNH$_2$. Indeed, considering the cubic structure highlighted in Figure S1, an element of pseudo-cubic symmetry with comparable interatomic distances can be easily identified also in the monoclinic and tetragonal polymorphs.

![Figure S1. Structural similarities between the different polymorphs of KNH$_2$. The hydrogen atoms of the NH$_2$ groups were omitted for clarity.](image)

**Effect of ball milling**

The interaction between KNH$_2$ and KH under mechanochemical or thermal input was studied for different compositions. The mechanical energy transfer induces a chemical reaction of the compounds already after 5 h. *Ex situ PXD* on the ball milled samples (Figure S2) shows a complete disappearance of the monoclinic polymorph of potassium amide. For all the compositions two different cubic structures coexist, namely an “amide rich” and a “hydride rich” structure. Noteworthy, the formation of a monoclinic polymorph is not observed even after several months.

![Figure S2. Diffractograms on the x KNH$_2$ + (1-x) KH samples collected after mechanochemical treatment.](image)
**Effect of annealing**

The compositions 0.1, 0.3, 0.5, 0.7, 0.9 were studied promoting the reaction by thermal treatment up to 270 °C. *Ex situ* PXD on the annealed samples (Figure S3) confirmed that, also by thermal input, KNH$_2$ and KH mutually reacted to form at least two cubic phases (compositions $x = 0.3, 0.5, 0.7$) and only close to the lower extreme of the compositional range ($x = 0.1$) one single cubic phase was found, probably stabilized by the high relative amount of potassium hydride. For the composition $x = 0.9$, coexistence of the cubic and monoclinic phase was found. Due to the fact that amide anions can be hosted in a single cubic lattice only for certain compositions (approximately $x = 0.1$), these results suggest a two phase field at room temperature.

*In situ* synchrotron radiation powder X-ray diffraction (SR-PXD)

*In situ* synchrotron X-ray diffraction experiments were performed on five selected compositions ($x = 0.1, 0.3, 0.5, 0.7, 0.9$), to investigate the behaviour of the K-N-H system upon heat treatment. The pure phases of KH and KNH$_2$ (indicated as $x = 0$ and $x = 1$ respectively) were also measured as reference (Figure S4). For all the samples with intermediate compositions ($x = 0.1, 0.3, 0.5, 0.7, 0.9$) the phase transformations of KNH$_2$ takes place in the expected temperature region. At about 100 °C KNH$_2$ ($Fm-3m$) and KH ($Fm-3m$) are present. At higher temperatures, the change of the diffracted intensities together with the different shift of KNH$_2$ peaks reveals the starting point of the reaction between the two phases. This reaction continues until ca. 270°C, with a gradual convergence of the two starting structures (an amide-rich- and a hydride-rich phase) to the single phase composition.

In the isothermal part, at 270 °C, the reaction is completed and only one cubic phase is present and appears to be stable for the entire isothermal period, since there are no significant changes of the peaks positions and intensities, independently from the composition. The formation of a single phase for all the compositions is a confirmation of the stability of the solid solution at 270 °C. During the cooling process the only noticeable change is the expected contraction of the cell for the nominal compositions $x = 0.1, 0.3, 0.5, 0.7$. Only for the composition $x = 0.9$, a phase transformation to a tetragonal geometry occurs almost at room temperature. Interestingly, since only the tetragonal phase is present, a partial solubility of KH into the tetragonal polymorph of KNH$_2$ is demonstrated. The structural similarities (highlighted in Figure S1) between the cubic and tetragonal polymorphs are probably responsible for the solubility of small amounts of KH in the tetragonal KNH$_2$ phase. Moreover, a comparison of this result with the one obtained by *ex situ* PXD on the same composition measured several days after annealing (Figure S3 – $x = 0.9$) suggests a metastability of the tetragonal phase at room temperature. The solubility of KH in the tetragonal polymorph of KNH$_2$ could be explained considering the structural similarities between the different polymorphs (Figure S1). Concerning the compositions $x = 0.3, 0.5, 0.7$, during the cooling process in the *in situ* experiments the kinetic inertia of the system prevents the single phase from disproportioning into two or more cubic phases, as it should be expected according to the *ex situ* data.

Figure S9. Rietveld refinements of the SR-PXD pattern collected at 270 °C for each composition.
High temperature powder neutron diffraction (PND)

The results obtained by in situ SR-PXD are confirmed also by PND on a deuterated sample of nominal composition x = 0.5. The sample was first measured at RT, then transferred in the high temperature cell and measured again in order to be able to remove the contribution of the sample holder by comparison (Figure S10). The sample was then heated up to 270 °C and kept in isotherm during the acquisition of the diffraction pattern.

![Figure S10](image)

**Figure S10.** Powder neutron diffraction pattern of the samples 0.5 KND2 + 0.5 KD at RT inside of the vanadium sample holder (a), and the same sample at room temperature (b) and at 270 °C (c) when the quartz sample holder was employed. A wavy background and some new Bragg reflections can be noticed. The peaks generated from the quartz sample holder are indicated by the arrows on the dotted lines and their absence can be noticed in the pattern corresponding to the vanadium sample holder (a).

Figure S11 depicts the Rietveld refinement of the RT diffractogram obtained with the in situ cell.

![Figure S11](image)

**Figure S11.** Rietveld refinement of the RT PND pattern of the sample 0.46 KND2 + 0.54 KD. Rwp(%) = 5.52 (corrected for background).
Thermal decomposition

The thermal decomposition behavior of the solid solution was determined by differential thermal analysis (DTA) in a Netzsch STA 409 apparatus (Figure S13). After recording the baseline on an empty alumina crucible, about 8 mg of material were heated up in the same crucible under a flow of purified Argon of 50 mL/min. The temperature was increased at 5 °C / min from RT up to 270 °C, kept constant for 10 minutes and then decreased to RT at the same rate in order to observe the formation of the solid solution. During this process an endothermic signal was recorded at ca. 57 °C which is close to the temperature value for the phase transition from the monoclinic to the tetragonal geometry. A less intense peak can be noticed in the shoulder of the main peak, accounting for the phase transition tetragonal → cubic. An exothermic event took place at 146 °C, most probably due to the formation of the solid solution. Right after the cooling process the temperature was increased up to 350 °C with a rate of 10 °C / min to observe the thermal decomposition. A strong endothermic signal can be noticed with an onset temperature of ca. 285 °C, which is ascribable to the starting of the thermal decomposition of the material. According to the mass spectrometer (HidenAnalytical HAL 201) mainly H₂ was released during this event. However the decomposition was not completed even if the temperature rose to 350 °C, therefore the material was heated again, this time up to 400 °C. The decomposition products were detected with the mass spectrometer, revealing formation of H₂, NH₃ and N₂. The interaction of amide/hydride anions is therefore possible at high temperature, however the
inspection of the sample revealed the formation of a shiny metal, suggesting that the powdered sample decomposed completely to form metallic potassium.

\[ \text{KNaN}_2 \] and \[ \text{KH}_6 \] are reported to decompose above 320 °C and above 400°C respectively. However, the present results show that, when combined, the two materials start to decompose already at 285 °C, indicating a possible interaction of the two anions to form \( \text{H}_2 \), while the nitrogen is released from the crystal structure in form of \( \text{N}_2 \) and \( \text{NH}_3 \).
