DEVELOPMENT OF THE IOP-29

Abstract

This article describes the development of the Inventory of Problems-29 (IOP-29), a new, short, paper-and-pencil, self-administered measure of feigned mental and cognitive disorders. Four clinical comparison, simulation studies were conducted. Study 1 ($n = 451$) selected the items and produced an index of potential feigning. Study 2 ($n = 331$) scaled such index to produce a probability score, and examined its psychometric properties. Study 3 tested the generalizability of Study 2's findings with two additional samples ($ns = 128$ and 90). Results supported the utility of the IOP-29 for discriminating bona fide from feigned psychiatric and cognitive complaints. Validity was demonstrated with mild traumatic brain injury, psychosis, PTSD, and depression. Within the independent samples of studies 2 and 3, the brief IOP-29 performed similarly to the MMPI-2 and PAI, and perhaps better than the TOMM. Classifications within these samples with base rates of .5 produced sensitivity, specificity, positive predictive power, and negative predictive power statistics of about .80. Further research is needed testing the IOP-29 in ecologically valid field studies.

9
10 Malingering of mental and cognitive disorders costs millions of dollars each year
11 (Chafetz & Underhill, 2013). Undetected cases of malingering are costly to taxpayers, as
12 funds, for example, are allocated to provide malingering criminals with housing and
13 unnecessary psychiatric treatment in hospitals rather than prisons. Insurance companies and
14 businesses fund treatment for malingered neuropsychological and psychological complaints,
15 as well as pay awards in malingered workman's compensation cases. To some degree,
16 malingering compromises the efficacy of the mental health system, as practitioners may not
17 be able to provide accurate diagnoses, recommendations, or effective treatment to those
18 malingered psychological complaints. Also, true patients may be viewed with a suspicious
19 eye and have more difficulty accessing treatment and compensation.

22
23
24
25
26
27
28
29
30

31
32 Reported rates of malingering vary greatly, because malingering involves both
33 "situation-specific and issue specific" (Rogers & Salekin, 1998, p.148), there is a strong
34 motivation to avoid detection, and different detection methods are used. In a review of
35 literature, Rogers (1997) cited two large surveys estimating malingering prevalence rates to
36 range between 15.7% and 17.4% among forensic settings. Nevertheless, these rates are in fact
37 highly variable in forensic practice, with a standard deviation of 14.4% (Rogers, Salekin,
38 Sewell, Goldstein, & Leonard, 1998). More recently, Larrabee (2003) grossly estimated the
39 average rate of neuropsychological malingering from research publications to be 41%,
40 although estimates in the individual studies differed by as much as 50%.

50

51
52 Given the importance of the phenomenon, it is not surprising that research on the
53 detection of malingering in the form of feigning on psychological tests, has dramatically
54 increased during the past few decades, and a number of instruments and scales to detect
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 feigning¹ of mental disorders, cognitive impairment, and medical complaints have been
4
5 proposed (Rogers, 2008). Multiscale personality inventories such as the Minnesota
6
7 Multiphasic Personality Inventory (MMPI-2; Green, 1991; MMPI-RF; Ben-Porath &
8
9 Tellegen, 2008) and Personality Assessment Inventory (PAI, Morey, 1996) include validity
10
11 indices aimed at detecting atypical response styles and exaggeration. Some interview-based
12
13 and multi-method assessment procedures specifically focus on detecting feigning of mental
14
15 disorders also have been described. Among them, Rogers and his coworkers (Rogers, Gillis,
16
17 Dickens, & Bagby, 1991; Rogers, Gillis, Bagby, & Monteiro, 1991; Rogers, Sewell, &
18
19 Gillard, 2010) have developed the Structured Interview of Reported Symptoms (SIRS), an
20
21 instrument to detect feigning of mental disorders that has received widespread acceptance in
22
23 the forensic community (Archer, Buffington-Vollum, Stredney, & Handel, 2006; Lally,
24
25 2003).

26
27
28
29
30 Because these instruments require either extended administration time or trained
31
32 examiners, several brief and easy to use instruments to detect feigning of mental disorders
33
34 have also been introduced. For example, Miller (2001) developed the Miller-Forensic
35
36 Assessment of Symptoms Test (M-FAST), a 25-item structured interview for feigned
37
38 psychopathology which has demonstrated good scale characteristics. As another example,
39
40 Beaber and his associates (Beaber, Marston, Michelli, & Millis, 1985) developed the M Test,
41
42 a short, self-administered, self-report measure, designed to expose false psychotic complaints.
43
44 Along the same lines, Smith and Burger (1997) developed the Structured Inventory of
45
46 Malingered Symptomatology (SIMS), a 75-item self-report tool aimed to detect commonly
47
48 feigned conditions such as psychosis, neurological impairment, and affective disorders.
49
50
51
52
53
54

55
56 ¹ Consistent with Rogers and Bender (2013), here we refer to *malingering* to indicate the “deliberate fabrication
57 or gross exaggeration of psychological or physical symptoms of the fulfillment of an external goal” and *feigning*
58 to indicate the “deliberate fabrication or gross exaggeration of psychological or physical symptoms (Rogers &
59 Vitacco, 2002) without any assumptions about its goals.” (p. 518)

DEVELOPMENT OF THE IOP-29

1
2
3 In addition, a number of brief measures also have been developed with the purpose to
4 detect feigned cognitive impairment. These instruments, sometimes referred to as “tests of
5 effort” or “performance validity tests,” generally include cognitive tasks that may appear
6 difficult at a first sight, but are in fact relatively simple. Thus, by exerting inadequate or
7 suboptimal effort, feigners often perform more poorly than individuals with genuine
8 cognitive impairment. Examples of these instruments include the Test of Memory
9 Malinger (TOMM; Tombaugh, 1996), the Victoria Symptom Validity Test (VSVT; Slick,
10 Hopp, Strauss, & Thompson, 2005), and the Word Memory Test (WMT; Green, Allen, &
11 Astner, 1996).

12
13 All of these instruments vary in their merits, foci, and limitations. For example, some,
14 such as the TOMM or the WMT, only focus on certain, specific cognitive abilities (e.g.,
15 recognition memory) and are less likely to detect feigned affective disorders or psychosis. In
16 contrast, others, such as the M Test, are designed to detect a specific, single diagnostic target,
17 such as feigned psychosis, but may not detect other feigned cognitive or affective problems.
18 Both cases are somewhat problematic, in that individuals attempting to feign mental or
19 cognitive disorders often present with a multitude of symptoms and problems within a
20 specific life predicament or context rather than limiting their efforts to a single, specific
21 diagnostic target. Furthermore, some of these screening tools have mostly been studied using
22 simulators² and honest, non-patient controls, while for the sake of generalizability to real life
23 situations it would be optimal if simulators were contrasted to and matched with genuine
24 patients. Also, many focus on only a single detection strategy, possibly under the influence of
25 internal consistency concerns, so that their items do not vary systematically to provide
26 comprehensive coverage of tactics adopted by malingerers (Rogers, 2008). Perhaps more
27 importantly, all suffer from some errors in prediction, shrinkage from developmental research

² The word *simulators* is used here to characterize research participants in simulation studies feigning any psychiatric disorders or cognitive impairments; in contrast, the word *malingerers* is used to describe individuals presenting disorders or impairments in real life.

DEVELOPMENT OF THE IOP-29

1
2
3 to validation and field research, and uncertainty regarding the cutoff scores across situations
4
5 and studies, the last of which is a routine problem in decision-making in practice.
6

7
8 In an attempt to overcome some of these limitations and to help examiners decision-
9
10 making in the field, we developed the Inventory of Problems-29 (IOP-29), a short, paper-and-
11
12 pencil, self-administered measure to detect feigning of mental or cognitive disorders. With
13
14 this first, IOP-29 study, we intended to provide evidence that such measure can detect
15
16 feigning of both psychiatric and cognitive disorders within simulation studies.
17

Overview

18
19
20 Four guiding principles shaped the development the IOP-29. First, we conceptualized
21
22 *malingering* as a person-situation interaction with a developmental course over a period of
23
24 time, reinforced through powerful incentives (Rogers, 1988). Secondly, since malingerers
25
26 adopt different strategies and situations induce various approaches from individuals (Rogers
27
28 & Bender, 2013; Rogers, Harrell, & Liff, 1993), we concluded that a short, but
29
30 comprehensive feigning measure would necessitate multiple detection strategies. Third, an
31
32 implication of these principles is that test and person interact in a particular context or
33
34 predicament. Within this interaction, malingering behaviors may ebb and flow as a function
35
36 of environmental stimuli. Potentially, a test can induce and measure feigning behaviors that
37
38 otherwise might not be available. Finally, consistent with Arbisi and Ben-Porath (1995), we
39
40 focused on incremental validity in developing items and selecting items and strategies. Thus,
41
42 in the test development we retained items that incremented over the easier to develop keyed
43
44 true, atypical or extreme complaint items. Such descriptions dominate many self-report
45
46 malingering tests.
47
48
49
50

51
52 From the sentiment in the field about the advantages of interviewing techniques and
53
54 the research supporting the validity of complex interviewing techniques (e.g., Rogers, 2008),
55
56 we concluded that we had to create a different type of objective test. Such a test might
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 incorporate “proven” techniques from interviews. Thus, in our test development studies
4
5 leading up to the IOP-29, we investigated a number of different item structures and
6
7 organizational methods. First, we included a variety of cognitive problems along with the
8
9 more conventional test item declarative statements. Problem-solving included memory,
10
11 calculation, and reasoning items (e.g., “Reading is to a Book, as Listening is to a Song”).
12
13 Secondly, we added the response choice of “doesn’t make sense” to the typical true-false
14
15 response selections. We hypothesized that this three response choice structure would allow
16
17 more precise identification of feigned versus true psychopathology. In addition, it potentially
18
19 allowed us to address the simulators’ use of extreme or nonsensical complaints more easily,
20
21 so that honest test takers could answer “doesn’t make sense” to items assuming a malingering
22
23 response set (e.g., “It never stops torturing me”). Alternatively, feigned cognitive deficiency
24
25 and resistance to the evaluation might emerge as frequent endorsement of “doesn’t make
26
27 sense” (Rogers, 1997). Furthermore, responses to problem-solving items were not restricted
28
29 to this “true-false-doesn’t make sense” response choice, allowing us to incorporate
30
31 approximate answers or near-miss phenomena (e.g., “Answer this problem: $165 - 121 = ?$ ”).
32
33 We also attempted to address “test-behaviors” that we might induce (and simulators might
34
35 self-report) during the test itself. For example, we speculated that simulators presenting false
36
37 disorders might note that they are shaking uncontrollably or that they might report concerns
38
39 about the test not surveying all of their problems.
40
41
42
43
44

45 An extensive series of studies and three prior versions of the instrument (Viglione &
46
47 Landis, 1994) contributed to the development of the IOP-29. This long developmental period
48
49 adapted concepts, techniques, and statistical procedures derived from the literature and
50
51 empirical experience with the versions of the scale. Our focus was on ecological validity and
52
53 utility by focusing on helping examiners in the field in forming an opinion about whether the
54
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 presenting complaint is bona fide or feigned³. In each stage of our research, strategies,
4
5 techniques, items, and item combinations were revised, trimmed, and enhanced based on the
6
7 empirical findings. We concerned ourselves with discriminating simulators from patients,
8
9 with little emphasis on honest, non-patient controls, as they are very easy to identify. To
10
11 maximize generalizability of our findings, our research studies utilized adult, non-college,
12
13 community samples and included instructions not to overdo feigning roles.
14
15

16
17 Initially, based on our review of the literature and experience, we developed 27
18
19 potential feigning strategies and 245 items (Viglione & Landis, 1994). These strategies
20
21 included concepts such as: (a) endorsement of atypical symptoms, that do not occur or are
22
23 very rare even with significantly disturbed individuals; (b) failure of easy cognitive problems,
24
25 which bona fide patients and non-patient controls almost always answer correctly; (c)
26
27 externalization or minimization of one's own responsibility concerning his or her own
28
29 psychological condition or situation; (d) criticism or nervousness of or problematic reactions
30
31 to the evaluation context, the test itself, or the testing condition; and (e) refusal to admit
32
33 qualified positive attributes or experiences, which bona fide patients and non-patient controls
34
35 almost always endorse. Thus, using Rogers and Bender's (2013) words, we combined both
36
37 *unlikely* and *amplified* mental disorder detection strategies with both *excessive impairment*
38
39 and *unlikely presentations* strategies to feign cognitive impairment within a single instrument
40
41 to maximize prediction. Moreover, many items were worded in ways to capture a variety of
42
43 disorders, and each item corresponded to one or more feigning detection strategies to serve
44
45 our goal of using the test to address a wide variety of disorders. This initial research was an
46
47 attempt to determine which of these detection strategies might work in identifying feigning. It
48
49 included 226 simulators, a few suspected, malingerers in vivo, and patients.
50
51
52
53
54

55
56
57 ³ In practice, of course, this decision is complicated by both multiple, related response styles, and the fact that
58
59 motivation, i.e. malingering, cannot be deduced from test findings. Also, findings from individual tests are often
60
indeterminate regarding the likelihood of feigning (Rogers & Bender, 2013).

DEVELOPMENT OF THE IOP-29

1
2
3 Based on the findings, we retained those strategies, items, and item and response
4 structures that discriminated well, we eliminated those that did not, and modified others. We
5 added items for empirically supported detection strategies, modified items so that they
6 accessed multiple strategies, and added items according to the emerging research in the field.
7 Thus, we created a second, developmental version of the instrument (IOP-Developmental
8 Version-2; IOP-DV2), which consisted of 162 items intermixing a minority of cognitive
9 items with self-report items. Noteworthy, the great majority of these 162 items had already
10 demonstrated validity in identifying simulators, with a smaller number of new items being
11 based on generalizations from strategies and item types that had demonstrated validity in our
12 first pilot research.

The Current Studies

25
26
27 The main goal of the current group of studies was to develop, scale, and cross-validate
28 the IOP-29, a brief, self-administered measure of feigning. Its main application is to serve as
29 a decision-making tool to discriminate bona fide patients from feigners. We present three test
30 development, simulation studies with various independent samples. The first study was
31 conducted to select a small subset of items which together best discriminate feigning from
32 bona fide disorders. We thus selected the 29 items of the IOP-29. The second study was
33 conducted to scale the IOP-29 and produce a feigning probability score. The third study
34 cross-validated the probability score obtained from Study 2. All studies included clinical
35 comparison samples.

Study 1: Scale Construction**Method**

47
48
49 To select the best subset of the 162 items, which as a group would optimize the
50 validity of the scale, we retrieved archival data from eight studies. Each study used specific
51 procedures and measures, and investigated different samples with different purposes.
52
53
54
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 Nevertheless, all included data on the IOP-DV2 and followed relatively similar procedures in
4
5 terms of inclusion and exclusion criteria, diagnostic status verification, and simulation task
6
7 presentation. For the purpose of this study, we only extracted from each study the IOP-DV2
8
9 data and only included patients' and simulators' data.
10

11 **Sampling procedures and participants.** The sample utilized for Study 1 combined
12
13 data ($n = 451$) from six dissertation studies (Green, 1999; Jansak, 1996; Landis, 1996;
14
15 McDougall, 1996; Mellin, 1996; Schaich, 2000) and two unpublished studies, for a total of
16
17 160 bona fide patients and 291 simulators. Most of the data, 76%, were collected with a
18
19 computerized version of the IOP-DV2 (e.g., Landis, 1996) with 24% being collected with a
20
21 paper-and-pencil version (e.g., Jansak, 1996). In most of the cases, simulators and to a lesser
22
23 degree patients were recruited from the general community through newspapers,
24
25 advertisements, and flyers. Most of the patients (e.g., Mellin, 1996; Schaich, 2000) were
26
27 instead recruited through inpatient hospitals, outpatient clinics, day treatment centers, or
28
29 criminal investigation units. In most cases (i.e., Green, 1999; Jansak, 1996; Landis, 1996;
30
31 McDougall, 1996; Mellin, 1996; Schaich, 2000) participants were compensated for their
32
33 participation with a small amount of money.
34
35
36
37

38 All diagnoses of the patient group were verified either by the chief evaluator of the
39
40 referring site, or by the hospital records, or through some consolidated assessment
41
42 instruments such as the Structured Clinical Interview for the DSM-IV (SCID-IV; First,
43
44 Spitzer, Gibbon, & Williams, 1995), or the PTSD Interview (Watson, Juba, Manifold,
45
46 Kucala, & Anderson, 1991). In almost all cases, criteria for inclusion in the simulator group
47
48 included no evidence of severe psychopathologies or active substance abuse disorder. For
49
50 some of the studies, additional inclusion criteria for the simulator group also included no
51
52 evidence of a specific "target" diagnosis. Landis' (1996) study, for example, aimed at
53
54 contrasting bona fide PTSD patients to PTSD simulators, and also excluded potential

simulators if they exceeded the PTSD severity criteria. In all cases, simulators were given a brief scenario with descriptions of symptoms to provide a life-like motivation to malingering. For example, simulators of depression were asked to imagine that they had had an accident at work, that such accident was caused by their boss' negligence, that their boss decided to unreasonably limit their recovery time (thereby cutting their disability payments), and that their only chance to remain on disability would be to fake depression. To limit extreme, unrealistic portrayals of disorders by simulators and to minimize an artificially large effect size that might limit generalization to real life situations, simulators were warned that if they presented their symptoms too dramatically, their performance would not be believable (Rogers & Bender, 2013; Viglione, Wright, Dizon, Moynihan, DuPuis, & Pizitz, 2001). Finally, in most of the cases simulators were also told that the most "successful feigners," that is those who were not detected, would be put in a lottery and could win additional financial rewards.

Most of the patient group had a diagnosis of depression ($\approx 46\%$), a diagnosis in the schizophrenia spectrum ($\approx 27\%$), or a diagnosis of PTSD ($\approx 18\%$). However, a small proportion ($\approx 9\%$) also included other diagnoses (e.g., $\approx 7\%$ had a bipolar disorder). Similarly, most of the simulator group were non-patients who faked depression ($\approx 25\%$), schizophrenia ($\approx 39\%$), or PTSD ($\approx 20\%$). The rest of the simulator group consisted of incarcerated inmates simulating incompetence to stand trial ($\approx 10\%$) or non-patient simulators faking other disorders ($\approx 6\%$).

Individual demographic information was available, albeit with some missing values, for 282 out of 451 cases. By supplementing these data with group and sample demographic descriptions reported by Green (1999), Jansak (1996), Landis (1996), McDougall (1996), Mellin (1996), and Schaich (2000), in their doctoral dissertations, we were able to produce a relatively accurate characterization of the entire sample: Within the patient sample, ages

DEVELOPMENT OF THE IOP-29

1
2
3 ranged from 20 to 79 years old, with a mean age of 38.8 ($SD = 11.5$); within the simulator
4
5 sample ages ranged 16 to 80 years old, with a mean age of 33.8 ($SD = 10.7$). Although such a
6
7 difference is statistically significant, $t_{(449)} = 4.6$, $p < .01$, $d = .45$, it consists of merely five
8
9 years, which in adulthood is likely to not affect the IOP-DV2 data. Gender did not differ, Φ
10
11 = $-.01$, $p = .89$, with about 52% males and about 48% females in the patient sample and about
12
13 51% male and 49% female among simulators. Within the patient sample, about 26%, were
14
15 non-Caucasians, with about 12% of African-Americans, about 8% of Hispanics, about 3% of
16
17 Asian-Americans, and about 3% of other ethnicities. Within the simulator sample, a similar
18
19 proportion, i.e., about 24%, of non-Caucasians was observed, with about 12% of Hispanics,
20
21 about 4% of Asian-Americans, about 3% of African-Americans, and about 5% of other
22
23 ethnicities. The percentage of Caucasians vs. non-Caucasian within the patient and simulator
24
25 samples, thus, did not statistically differ, $\Phi = -.01$, $p = .77$. Within the patient sample about
26
27 53% had at least attended some college, whereas such percentage within the simulator sample
28
29 was about 75%. Thus, the simulator group was more educated than the patient group, $\Phi = -$
30
31 $.23$, $p < .01$. Finally, about 14% of the patient sample was married, while about 23% of the
32
33 simulator sample was married. This difference, again, is statistically significant, $\Phi = -.10$, p
34
35 = $.03$, although the small effect size was small.

40
41 **Item selection.** Aiming at developing a brief, paper-and-pencil self-report measure, a
42
43 sub-set of the initial 162 IOP-DV2 items was selected. To do so, we followed a three-step
44
45 procedure. First, we excluded all items that were not suitable for a paper and pencil self-
46
47 administration. For example, we excluded some memory items in that they required images
48
49 to be shown on a computer screen. This initial screening yielded 126 items to be further
50
51 examined. Secondly, we calculated the Phi correlations between each item (1 = response in
52
53 the key direction; 0 = response not in the key direction) and group (dummy code 1 =
54
55 simulator; 0 = bona fide patient). Item/response combinations with significant Phi values ($p \leq$
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 .05) and in the expected direction were retained for the third step of our item selection
4
5 procedure. Thus, a given keyed true item was retained only if the response “true” (1 = true; 0
6
7 = not true) produced a positive and significant Phi correlation with group, and, similarly, a
8
9 given keyed false item was retained only if the response “false” (1 = false; 0 = not false)
10
11 produced a positive and significant Phi correlation with group. Although the item selection
12
13 process focused on the true vs. false options, the additional “doesn’t make sense” choice
14
15 option effects this process. Potentially, this third response option allows for a more refined
16
17 and less ambiguous understanding of the meaning of the true and false response selection by
18
19 eliminating its forced choice character and reducing error.
20
21

22
23 We found 114 significant item/response Phi correlations among the 126 items, a
24
25 testament to the validity of the item development and validity of our procedures to this point.
26
27 We implemented a relatively complex algorithm to extract a small subset of items that
28
29 together would maximize the IOP-29 correlation with group while minimizing redundancy
30
31 among the items. The first item selected is the item/response combination with the highest
32
33 Phi value, i.e., the best predictor. Subsequent items were those with the best incremental
34
35 validity. To select those items one-by-one, we partialled out previously selected item(s) from
36
37 the remaining item/response-group correlations, and selected the item with the highest partial
38
39 Phi correlation. This procedure was stopped after selecting 29 items, when the highest
40
41 remaining partial Phi correlation approached zero.
42
43
44

45 **Item weights.** With these 29 items, an initial feigning index (Single Weight Score)
46
47 was produced by summing them with one point for each item/response combination. We then
48
49 selected all item/response combinations from these 29 items that demonstrated incremental
50
51 validity – operationally defined by a significant Phi correlation in the expected direction after
52
53 partialling out the Single Weight Score. This procedure resulted in multiple weighting for the
54
55 subset of items with strong validity and involved the “doesn’t make sense” response more
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 directly in the scaling. For example, a given item keyed false may have a +1 weighting for
4
5 “false”, a 0 weighting for “doesn’t make sense” and a -1 weighting for “true.” The resulting
6
7 index was named Multiple Weight Score.
8

Results

9
10
11 The point bi-serial correlations between group (dummy code 1 = simulator; 0 = bona
12
13 fide patient) and the two feigning indexes under investigation were respectively .687, $p <$
14
15 .001, for the Single Weight Score, and .714, $p <$.001, for the Multiple Weight Score. The
16
17 difference between these two correlations was significant ($z = 2.7 p <$.001), using procedures
18
19 described by Meng, Rosenthal, and Rubin (1992) for comparing correlations obtained from
20
21 the same sample that share a common variable. The receiver operator characteristic curve
22
23 (AUC) for the Single Weight Score was .913 ($SE = .014$), the AUC for the Multiple Weight
24
25 Score was .932 ($SE = .012$). Cohen’s d values were 1.97 for the Single Weight Score and
26
27 2.13 for the Multiple Weight Score.
28
29
30
31

Study 2: Probability Scaling

32
33
34 Study 2 utilized the Multiple Weight Score derived from Study 1 to produce and to
35
36 cross-validate a False Disorder Probability Score. That is, a second, independent sample was
37
38 used to generate the transformations of raw scores to the scale used for the IOP-29, a
39
40 probability of feigning score. The independence of the samples in Study 1 and 2 prevents
41
42 distortions of the normative scaling. Similar to Study 1, data were retrieved from a number of
43
44 studies that used a variety of procedures and measures. Again, all included studies followed
45
46 relatively similar inclusion and exclusion criteria, diagnostic status verification, and
47
48 simulation task presentation. Also consistent with Study 1, for the purpose of Study 2 only
49
50 the IOP data were utilized and data from non-patient, honest participants was excluded. Half
51
52 of this dataset was randomly selected to produce the False Disorder Probability Score, and
53
54 the other half was used to cross-validate this score.
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

Development of the False Disorder Probability Score

Sampling procedures and participants. Subsequent to creating the 162 items of the IOP-DV2, we tested some additional items and developed a third, developmental version of the instrument (IOP-Developmental Version-3; IOP-DV3), a 181 item, computer-administered feigning measure. This version of the IOP includes all the 29 items that form the IOP-29⁴. Thus, to produce the IOP-29 False Disorder Probability Score, the current study investigated data from four simulation studies conducted with the IOP-DV3. Each study addressed one of the four disorder categories for which the IOP-DV3 was designed, i.e., neuropsychological deficit (Pizitz, 2001), schizophrenia and psychosis (O'Brien, 2004), Post-Traumatic Stress Disorder (Connell, 2004), and depression (Abramsky, 2005). Moreover, some combination of these four likely addresses a great majority of the malingering forensic clinical practice. All four studies used a simulation design contrasting a clinical comparison group of approximately 40 bona fide patients to approximately 40 individuals feigning the disorder. Participation was on a voluntary basis with prior consent obtained before participating, and in three of the four a small monetary compensation was given to all participants. Procedures used for these four studies are very similar to those described above for Study 1 (for additional details, see Abramsky, 2005; Connell, 2004; O'Brien, 2004; and Pizitz, 2001). As reported in Table 1, patients and simulators in this large ($n = 333$), combined sample did not differ from each other in terms of gender, age, ethnicity, education, and marital status.

As noted above, to produce our feigning probability score, and cross-validate it with an independent sample, we split this $N = 331$, Study 2 sample. Half of each the patient and simulator samples within each study were randomly assigned to the developmental sample or validation sample. Thus, the developmental sample included 168 participants, 84 of which

⁴ Accordingly, both the DV2 and DV3 versions of the IOP contain the IOP29 items. Both also included other items being evaluated for a longer more complex test of feigning.

DEVELOPMENT OF THE IOP-29

1
2
3 were bona fide patients and 84 simulators. Ultimately, missing data reduced this number to
4
5 166 participants, 84 patients and 82 simulators, with approximately 20 patients and
6
7 simulators in the four diagnostic groups: mild traumatic brain injury (MTBI) as an example
8
9 of cognitive or neuropsychological disorders, schizophrenic spectrum-psychosis patients,
10
11 PTSD, and depression.
12

13
14 **Results.** The Multiple Weight Score from Study 1 was investigated with the
15
16 developmental sample of Study 2. The point bi-serial correlation between group (dummy
17
18 code) and the Multiple Weight Score was .625, $p < .001$. The difference in the score of
19
20 simulators and patients corresponded to a Cohen's d of 1.59. The AUC was .868 ($SE = .029$).
21
22

23
24 To produce a feigning probability score, the Multiple Weight Score was then used as
25
26 predictor in logistic regression with group as the outcome. The model was significant, $\chi^2(1) =$
27
28 78.51, $p < .001$, with a Nagelkerke R^2 of .502. The $exp(B)$, or odds ratio of the Multiple
29
30 Weight Score was 258,483. Using a cut-off of .50, which nearly matches the feigning base
31
32 rate in this sample (.494), the resulting, False Disorder Probability Score correctly classified
33
34 81.3% of the cases, with 14 patients erroneously classified as simulators (i.e., 8.4% of the
35
36 total, and 17.7% of those predicted to be malingering), and 17 simulators erroneously
37
38 classified as patients (i.e., 10.2% of the total, and 19.5% of those predicted to be not
39
40 malingering). Sensitivity is .79, specificity .83. Using the base rate observed in our sample
41
42 (i.e., .494), positive predictive power (PPP) is .82, negative predictive power (NPP) is .80,
43
44 and overall correct classification (OCC) is .81. Consistent with findings obtained for the
45
46 Multiple Weight Score, the AUC was .868 ($SE = .029$) also for the False Disorder Probability
47
48 Score.
49
50

Cross-Validation of the False Disorder Probability Score

51
52
53
54 Next, we tested the validity of our feigning indexes with the independent Study 2
55
56 validation sample consisting of 165 participants with 82 bona fide patients and 83 simulators.
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 **Results.** The point bi-serial correlations between group (dummy code) and the
4
5 Multiple Weight Score was .625, $p < .001$; the difference in the score of simulators and
6
7 patients yielded a Cohen's d of 1.67; the AUC was .867 ($SE = .029$). These findings are
8
9 virtually identical to those obtained from the developmental sample, so that no shrinkage was
10
11 shown, thus lending credence to our item development and item weighting procedures. With
12
13 a cut-off of .50, the False Disorder Probability Score correctly classified around 80% of the
14
15 cases, with 17 false positive classifications (i.e., 10.3% of the total, and 20.2% of the
16
17 positives), and 16 false negative classifications (i.e., 9.7% of the total, and 19.8% of the
18
19 negatives), and 16 false negative classifications (i.e., 9.7% of the total, and 19.8% of the
20
21 negatives).

22
23 Sensitivity, specificity, PPP, NPP, and overall correct classification (OCC) statistics
24
25 were calculated. Due to the PPP, NPP, and OCC statistics being highly dependent on the
26
27 prevalence or base rate of the condition being tested (Meehl & Rosen, 1955), in addition to
28
29 the approximately .50 base rate⁵ of our sample, base rates of .25, .10, and .05 were also
30
31 explored by adjusting the PPP, NPP, and OCC formulas accordingly (Streiner, 2003). These
32
33 additional base rates were selected in that they may present a priori base rates or prevalence
34
35 in a variety of clinical, forensic, disability, benefit, or compensation settings. In addition, we
36
37 also surveyed probability score cutoffs, because they influence positive and negative
38
39 predictive power, and false positive and false negative errors are associated with different
40
41 predictive power, and false positive and false negative errors are associated with different
42
43 cost-benefit ratios. Results, reported in Table 2, indicate that when a cut-off of .50 is adopted,
44
45 about 80% of the simulators are detected (sensitivity = .81), and about 80% of the patients are
46
47 correctly labeled as non-simulators (specificity = .79). Also, the OCC is maximized when the
48
49 cut-offs under examination reflect the base rates. For example, when a base rate of .50 is
50
51 considered, the OCC is maximized (OCC = .80) if the cut-off of the False Disorder
52
53

54
55
56
57
58 ⁵ The base rate for malingering in Study 3 is .503.
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 Probability Score is .50; similarly, when a base rate of .10 is considered, the OCC is
4
5 maximized (OCC = .92) for a False Disorder Probability Score of .90.
6

7 **Comparative validity.** For about half of the samples utilized for Study 2, we also had
8
9 available data on frequently used feigning scales to address the comparative validity of the
10
11 IOP-29 against the MMPI-2 and TOMM. Specifically, O'Brien's (2004) psychotic sub-
12
13 sample had MMPI-2 data from 43 patients and 45 simulators, and Abramsky's (2005)
14
15 depression sub-sample included TOMM data from 43 patients and 42 simulators. To
16
17 maximize the stability and reliability of the statistics, comparative validity analyses were
18
19 conducted using all the available participants (i.e., 88 for the psychotic sub-sample, and 85
20
21 for the depression sub-sample). Because about half of these data were also included in the
22
23 developmental sample of Study 2 and used to produce the final scaling of the False Disorder
24
25 Probability Score, however, in addition to False Disorder Probability Score also the Multiple
26
27 Weight Score was examined. This latter score is completely independent of the scaling in the
28
29 second study, so could not possibly provide any over-estimation of the effect size.
30
31
32
33

34 As for the MMPI-2, consistent with O'Brien's (2004) work, the F, Fp, and Ds-r2
35
36 scales were selected for these analyses, as they are particularly useful in detecting feigning of
37
38 schizophrenia or psychosis (e.g., Elhai, Gold, & Frueh, 2000; Rogers, Sewell, & Ustad, 1995;
39
40 Viglione et al., 2001). As for the TOMM, consistent with Abramsky's (2005) work as well as
41
42 with previous research (e.g., Rees, Tombaugh, Gansler, & Moczynski, 1998; Tombaugh,
43
44 1996), both the number of correct responses on the first trial (TOMM-1), second trial
45
46 (TOMM-2), and entire test (TOMM-tot) were inspected.
47
48

49 The correlations calculated between each measure and group are presented in Table 3,
50
51 along with the respective AUC values. These data indicate that the IOP-29 performs similarly
52
53 to the selected MMPI-2 scales, and perhaps better than the TOMM. Also noteworthy, the
54
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

IOP-29 performed similarly well for all of the four diagnostic groups taken into consideration for this study, i.e., MTBI, Schizophrenia/Psychosis, PTSD, and Depression.⁶

Study 3: Generalizability of the Findings

The analyses performed with the validation sample of Study 2 provide initial cross-validation of the IOP-29 False Disorder Probability Score. However, because they utilized the randomly excluded half of the subsamples used to develop the feigning probability score, Study 3 was designed to further validate the IOP-29 with independent samples.

Method

Sampling procedures and participants. Study 3 included two additional, independent samples from two dissertations. The first was a forensic sample of 128 volunteer participants on community-based county and federal probation (McCullaugh, 2011); half responded genuinely, half simulated mental health symptoms. The second sample included 90 participants: half were patients with Schizophrenia or Schizoaffective Disorder and half simulators (Wood, 2008). For both samples, the IOP-DV3 and Personality Assessment Inventory (PAI; Morey, 1991, 1996, 2007) were administered. To avoid extreme, unbelievable performances, participants were warned not to “overdo” their presentations, otherwise their performance would not be believable (Viglione et al, 2001).

McCullaugh’s (2011) forensic sample. Participants ($n = 128$) were volunteer offenders on community-based county and federal probation. Twenty-four were recruited from a local, private forensic psychologist’s practice; all were being treated using a mixture of manual-based cognitive behavioral therapy (CBT) treatment for sexual offenders and substance abuse treatment. Confirmation that all these individuals were on probation was provided by the treating psychologist. The remaining 104 participants were recruited via

⁶ As reported in Table 3, AUC was .845 ($SE = .042$) for the psychotic sub-sample and .898 ($SE = .037$) for the depression sub-sample. For the PTSD sub-sample AUC was .903 ($SE = .037$); for the MTBI sub-sample AUC was .840 ($SE = .048$).

DEVELOPMENT OF THE IOP-29

1
2
3 volunteer postings on the internet. To verify that they also were on probation, the San Diego
4
5 Country Court Index website was used.
6

7
8 Half of the sample (randomly selected) was asked to respond genuinely, the other half
9
10 was asked to simulate mental health symptoms. Inclusion criteria required that participants
11
12 were not prescribed anti-psychotic medication, did not experience psychotic symptoms, and
13
14 did not report substance use within the last 30 days. Approximately 80% were men, the mean
15
16 age was about 36 (SD approximately 10), and about 70% were Caucasian. No significant
17
18 differences between the two groups were found for age, gender, ethnicity, education, marital
19
20 or employment status. Following completion of the procedures, all participants were
21
22 debriefed about the aims of the study, provided with \$20.00 incentive for participation, and
23
24 thanked for participating. Two additional raffle winners were drawn after study completion
25
26 and provided with \$100.00 cash prizes.
27
28

29
30 Consistent with Rogers and Gillard's (2011) recommendations, simulators were given
31
32 a vignette to facilitate feigning. Based on details of an actual case of suspected malingerer
33
34 from another study (Weber, 2008), these vignettes were rich in contextual and historical
35
36 detail. Raters judged these vignettes as a group to include diffuse mental health symptoms,
37
38 including post-traumatic stress, neuropsychological impairment, and depressive symptoms,
39
40 but not schizophrenic or psychotic ones. For example, one of the vignettes asked the
41
42 individual to imagine having suffered an injury while working at a horse stable. The injury
43
44 resulted in being laid off without receiving disability income. Faking mental health symptoms
45
46 would be the way to receive compensation benefits for his or her disability. All simulators
47
48 were asked to carefully read these vignettes, and respond to the measures as the individual
49
50 depicted, reflecting history and symptom presentation.
51
52

53
54 ***Woods' (2008) psychotic sample.*** The second sample included in Study 4 is a
55
56 psychotic sample, derived from a dissertation study (Wood, 2008) conducted with the IOP-
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 DV3. Patients ($n = 45$) were recruited from local day treatment programs, and all had a
4
5 diagnosis of Schizophrenia or Schizoaffective disorder, as confirmed by their treating
6
7 psychiatrists. Simulators ($n = 45$) were matched with patients on gender and level of
8
9 education: In each group there were 34 men and 11 women, 36 had no college education and
10
11 11 did. The mean age within patients was 40 years ($SD = 10$), while the simulators were
12
13 younger, with a mean age of 28 years ($SD = 10$). In both groups of this diverse sample, about
14
15 one third of the participants identified themselves as Caucasian, about one third as African-
16
17 American, and about one third as Latino. Approximately 70%, in each group, were single. All
18
19 patients, but none of the simulators, had a history of psychiatric hospitalization and were
20
21 currently taking psychotropic medication. Prior to taking the IOP, simulators were given ten
22
23 minutes to review the instructions, which included a description of the disorder. In short, they
24
25 were asked to complete the psychological testing as if they were trying to appear psychotic in
26
27 a given real-life scenario (e.g., they were asked to pretend they had been accused of
28
29 committing a crime, and that the only way to avoid incarceration would be to appear
30
31 psychotic). Furthermore, simulators were also told that the best fakers would receive an
32
33 additional \$50.00, in addition to the \$20.00 compensation given to all participants.
34
35
36
37

38 **Measures.** Both McCullough' (2011) and Wood' (2008) also used the PAI, a 334-
39
40 item, self-report, personality inventory widely used in research on malingering. Positive
41
42 findings for the PAI capacity to identify malingering has been reported consistently in the
43
44 literature (e.g., Archer et al., 2006; Blanchard et al., 2003; Sellbom, Bagby, & Rogers, 2008).
45
46 According to a recent meta-analysis (Hawes & Bocaccini, 2009), the Negative Impression
47
48 Management (NIM; Morey, 1996) and the Malingering Index (MAL; Morey, 1996) have
49
50 demonstrated the best overall classification rates for malingering. Specifically, a NIM cut
51
52 score of $T \geq 81$ resulted in an average hit rate of .79 ($SE = .09$), sensitivity of .73 ($SE = .13$),
53
54 and specificity of .83 ($SE = .07$); a cut score of $MAL \geq 3$ yielded an average hit rate of .71
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

($SE = .05$), sensitivity of .58 ($SE = .08$), and specificity of .86 ($SE = .04$). Additionally, the Rogers Discriminant Function (RDF; Rogers, Sewell, Morey, & Ustad, 1996) also has demonstrated some clinical utility in applied settings, even though it does not strongly correlate with the SIRS (Edens, Poythress, & Watkins-Clay, 2007). For the RDF, Morey (2007) suggested that raw scores above zero are indicative of risk of malingering.

Results

The point bi-serial correlation between the IOP-29 False Disorder Probability Score and group is comparable to that obtained with the PAI scales, and AUC analyses similar to for the PAI and IOP-29 (Table 4). Mean IOP-29 differences for simulators and patients yields a Cohen's d of 2.66 in the forensic sample, and a d of 1.95 in the psychotic sample. For the PAI NIM scale (T score), the Cohen's d values are 2.85 within the forensic sample, and 1.69 within the psychotic sample. For the MAL (raw score), Cohen's d was 1.36 within the forensic sample, and 1.78 within the psychotic sample. For the RDF, Cohen's d was 1.82 within the forensic sample, and 1.75 within the psychotic sample.

Using a cut score of .50 for the IOP-29, and cut scores recommended by Hawes and Bocaccini (2009) for the NIM and MAL, and by Morey (1996) for the RDF scales of the PAI, we then calculated diagnostic efficiency statistics for both the forensic and the psychotic samples. Results, reported in Table 5, confirm similar validity findings for both the PAI and the IOP-29, with the IOP-29 False Disorder Probability Score producing OCC rates equal to or greater than .80.

General Discussion

We presented development and psychometric foundation research for a new, brief, self-administered measure of feigning of a variety of disorders, the IOP-29. Study 1 selected the items to be retained from a pool of items of which most had already been validated as a measuring feigning. In addition, it produced a feigning index, the Multiple Weight Score.

DEVELOPMENT OF THE IOP-29

1
2
3 Study 2 scaled this index and produced a probability score, the False Disorder Probability
4
5 Score. Finally, Study 3 cross-validated the False Disorder Probability Score with two
6
7 additional independent samples. What emerged from this series of studies is a 29-item scale
8
9 to measure feigning of psychiatric and cognitive or neuropsychological disorders. It includes
10
11 26 self-report items and 3 cognitive items. We found a way to capture in vivo behavior that
12
13 often is only accessed in interviews: Some of the most effective items are “test behavior”
14
15 items, which refer to reactions to the test itself. Some items are worded in vague ambiguous
16
17 ways with “it” or “problems” so as to capture malingering response style sets and a broad
18
19 array or feigned difficulties. For self-report items, we included a third response alternative,
20
21 namely “doesn’t make sense,” in addition to the standard “true” and “false,” because we
22
23 found it increased validity. Nonetheless, our investigation only focused on clinical
24
25 comparison and simulation studies, therefore further research testing the IOP-29 in
26
27 ecologically valid field studies is needed.
28
29
30
31

32 Taken together, the results of our studies lend initial support to the validity of the
33
34 IOP-29 in discriminating bona fide patients from feigners. Within a number of independent,
35
36 validation samples with base rates of about .50, and an a priori, statistically-determined cut
37
38 score of .50, the IOP-29 correctly classified about 80% of the cases, with sensitivity,
39
40 specificity, PPP, and NPP being around .80. Noteworthy, the samples under investigation
41
42 came from a total of 14 independent studies, 12 doctoral dissertations and 2 unpublished
43
44 studies, and were diverse in terms of age, sex, ethnicity, marital status, and educational
45
46 background. The 29 items are an optimal combination selected from approximately 250 items
47
48 with independent re-validations. Individual items were cross-validated at multiple stages in
49
50 the test development process. Shrinkage in the later stages of development was minimal. In
51
52 fact, the AUC of the False Disorder Probability Score was .87 both in the developmental and
53
54 validation samples of Study 2 (SE’s \approx .03), and reached .94 (SE = .02) and .92 (SE = .03) in
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 the forensic and psychotic samples of Study 3. Thus, it is reasonable to anticipate that the
4
5 IOP-29 will generalize well and perform similarly in different cultural contexts and future
6
7 clinical comparison, simulation studies.
8

9
10 Most of the available feigning scales adopt classic test theory and normative scaling
11
12 approaches and produce, for example, t-score comparisons between simulators (or suspected
13
14 malingerers) and non-patient or patient groups. As a result, selecting optimal threshold scores
15
16 for real life situations might be challenging, at times. The IOP-29 provides examiners with a
17
18 fully cross-validated, easy to use probability score: The higher the False Disorder Probability
19
20 Score, the higher the probability that the tested individual is trying to feign a psychological,
21
22 psychiatric or neurological disorder. The interpretation of this score is simple and
23
24 straightforward, and should contribute to the decision at hand, i.e., whether the presenting
25
26 complaint is bona fide or feigned. However, users should keep in mind that while a cut-off
27
28 score of .50 is likely to work best when the a priori probability is .50, other cut-off scores
29
30 may be more appropriate for different a priori probabilities. For example, if in a given
31
32 environment the expected prevalence rate of malingering is about .10, a cut-off of .90 might
33
34 be more appropriate. Also, the selection of the best cut-off score of the IOP-29 should always
35
36 be based on the purposes of the examination and on the costs and benefits associated with
37
38 false positive and false negative classifications. Thus, if the IOP-29 is used as a screening
39
40 tool, lower probability cut-offs might be preferable so as to maximize NPP.
41
42
43
44

45
46 Despite the IOP-29 consisting of only 29 items, neither the MMPI, the TOMM, nor
47
48 the PAI outperformed the IOP-29 in discriminating between bona fide patients and
49
50 simulators. These findings, again, support the potential utility and validity of the IOP-29 as a
51
52 brief, feigning measure. To further investigate the comparative validity of the IOP-29, future
53
54 studies should also compare its performance to that of other brief instruments, such as the
55
56
57
58
59
60

DEVELOPMENT OF THE IOP-29

1
2
3 SIMS or the M Test. Most importantly, future research should focus on ecologically valid
4
5 field studies rather than simulation studies.
6

7
8 Despite these encouraging findings, some limitations persist. The most obvious
9
10 limitation is that we investigated large archival files but did not test the instrument in its final
11
12 29-item format, and the great majority were administered in a computerized versus paper-
13
14 and-pencil format. In other words, in all cases patients and simulators were administered a
15
16 large number of items that included but were not limited to the final 29 IOP-29 items.
17
18 Although other instruments have been developed in a similar manner (for example, see
19
20 Peters, Sunderland, Andrews, Rapee, & Mattick, 2012), this may have affected our results, to
21
22 some extent. To address this limitation, new data are currently being collected, in various
23
24 countries and cultural contexts.
25
26

27
28 Another limitation of these studies, which is actually shared by all simulation studies,
29
30 is that it is impossible to know whether the behavior of the simulators reflect that of true
31
32 malingerers in actual real-life situations. To maximize generalizability we took several
33
34 methodological cautions, such as providing contexts to facilitate malingering, offering extra
35
36 incentives for the best feigners, cautioning to not exaggerate so as to produce a believable
37
38 profile, etc. (Rogers, 1997, 2008; Rogers & Bender, 2013; Rogers & Gillard, 2011; Viglione
39
40 et al., 2001). Nonetheless, it is still unknown whether true malingerers in real-life situations
41
42 would have obtained the same scores as those produced by our simulator samples. Finally,
43
44 future research might consider investigating samples with base rates different from .50, such
45
46 that different cut-off scores could be investigated.

DEVELOPMENT OF THE IOP-29

Table 4. Point bi-serial correlations and AUCs of the IOP-29 and PAI within the Forensic ($n = 128$) and Psychotic ($n = 90$) Samples.

	Point bi-serial	
	Correlation with Group ^a	AUC (<i>SE</i>)
<i>Forensic Sample (n = 128)</i>		
IOP-29 – False Disorder Probability Score	.80**	.943 (.023)
PAI – Negative Impression Management (T score)	.82**	.966 (.016)
PAI – Malingering Index (raw score)	.57**	.837 (.038)
PAI – Rogers Discriminant Function (raw score)	.68**	.892 (.030)
<i>Psychotic Sample (n = 90)</i>		
IOP-29 – False Disorder Probability Score	.70**	.915 (.028)
PAI – Negative Impression Management (T score)	.65**	.887 (.034)
PAI – Malingering Index (raw score)	.67**	.909 (.031)
PAI – Rogers Discriminant Function (raw score)	.66**	.886 (.037)

^a Dummy Code: 1 = Simulator; 0 = Bona Fide Patient. * $p < .05$; ** $p < .01$.

DEVELOPMENT OF THE IOP-29

Table 5. Hit Rates of the IOP-29 and PAI within the Forensic ($n = 128$) and Psychotic ($n = 90$) Samples.

	Group		Diagnostic Efficiency Statistics				
	Patients	Simulators	Sensitivity	Specificity	PPP	NPP	OCC
<i>Forensic Sample (n = 128)</i>							
IOP-29 – False Disorder Probability Score			.72	1.00	1.00	.78	.86
$p < .50$	64	18					
$p \geq .50$	0	46					
PAI – Negative Impression Management			.75	.98	.98	.80	.87
$T < 81$	63	16					
$T \geq 81$	1	48					
PAI – Malingering Index			.08	.98	.83	.52	.53
Raw < 3	63	59					
Raw ≥ 3	1	5					
PAI – Rogers Discriminant Function			.72	.92	.90	.77	.82
Raw < 0	59	18					
Raw ≥ 0	5	46					
<i>Psychotic Sample (n = 90)</i>							
IOP-29 – False Disorder Probability Score			.82	.80	.80	.82	.81
$p < .50$	36	8					
$p \geq .50$	9	37					
PAI – Negative Impression Management			.82	.73	.76	.81	.78
$T < 81$	33	8					
$T \geq 81$	12	37					
PAI – Malingering Index			.89	.76	.78	.87	.82
Raw < 3	34	5					
Raw ≥ 3	11	40					
PAI – Rogers Discriminant Function			.96	.67	.74	.94	.81
Raw < 0	30	2					
Raw ≥ 0	15	43					

PPP = Positive Predictive Power; NPP = Negative Predictive Power; OCC = Overall Correct Classification. Cut scores for the PAI scales were defined based on Hawes and Bocaccini's (2009) meta-analytic review (NIM and MAL) and on Morey's (2007) PAI manual (RDF). PPP, NPP, and OCC are calculated using the base rate of our sample, which is equal to .50.
