Supporting Information

ABSTRACT: Tuberculosis, caused by Mycobacterium tuberculosis (Mtb), is the infectious disease responsible for the highest number of deaths worldwide. Herein, 22 new N-oxide-containing compounds were synthesized followed by in vitro and in vivo evaluation of their antitubercular potential against Mtb. Compound 8 was found to be the most promising compound, with MIC90 values of 1.10 and 6.62 μM against active and nonreplicating Mtb, respectively. Additionally, we carried out in vivo experiments to confirm the safety and efficacy of compound 8; the compound was found to be orally bioavailable and highly effective, leading to a reduction of Mtb to undetectable levels in a mouse model of infection. Microarray-based initial studies on the mechanism of action suggest that compound 8 blocks translation. Altogether, these results indicate that benzofuroxan derivative 8 is a promising lead compound for the development of a novel chemical class of antitubercular drugs.

INTRODUCTION

Mycobacterium tuberculosis (Mtb), the causative agent of tuberculosis (TB) in humans, is considered to be responsible for the highest number of deaths caused by an infectious disease worldwide in 2015. The World Health Organization (WHO) reported 9.6 million new cases and 2 million deaths worldwide in the same year. The high mortality rate of TB has even surpassed the number of deaths caused by human immunodeficiency virus. According to an estimate, one-third of the world’s population is infected with a latent form of TB, for which treatment is often ineffective owing to a lack of drugs with the ability to act on mycobacteria in the dormant state. Furthermore, the increased dissemination of multidrug-resistant (MDR), extensively drug-resistant, and totally drug-resistant strains has posed a huge challenge throughout the world in the fight against TB. For treating TB, the WHO recommends a combination of isoniazid (INH), rifampicin (RMP), ethambutol, and pyrazinamide for 6 months. For cases involving resistance, the treatment can be extended up to 28 months and include the use of second-line drugs, such as fluoroquinolones, aminoglycosides, D-cycloserine,
and linezolid, among others.9−11 The current treatment suffers from several limitations, including the prolonged standard regimen, the high rate of treatment discontinuation, adverse effects, toxicity, drug−drug interactions, and a lack of effectiveness against the latent mycobacteria.12−16

Over the past few years, limited but significant progress in the development of drug candidates against TB has been achieved. After a gap of more than 50 years without new drugs approved for TB, the United States Food and Drug Administration approved bedaquiline (Bdq, SIRTURO, Janssen; Beerse, Belgium) in 2012 for the treatment of MDR-TB. The literature over the past 5 years has indicated significant advances in the development of other compounds with potent antitubercular activity.17−20 In this regard, several drug candidates were moved toward clinical trials, such as sutezolid, posizolid, delamanid, and pretomanid.21,22 Nevertheless, Mtb strains resistant to the new compounds have already been reported,23−25 reinforcing the urgency to develop more potent and a larger number of novel drugs for the treatment of TB.21

We previously reported a series of furoxan derivatives with potent activity against Mtb, including MDR strains. Specifically, the compound (E)-4-(4-((2-isonicotinoylhydrazone)methyl)(phenoxo)-3-(phenylsulfonyl)-1,2,5-oxadiazole 2-oxide (Figure 1) inhibited the growth of Mtb strain H37Rv by 90% at a concentration of 1 μM. In addition, we determined that the antitubercular activity of this furoxan derivative was related to its ability to generate nitric oxide (NO) following biotransformation.26

Motivated by preliminary promising results obtained with the furoxan derivatives, we designed new heterocyclic analogues containing the N-oxide subunit, including amide-furoxans (series 1), benzofuroxans (series 2), and quinoxaline 1,4-di-N-oxide (QdNO) (series 3, Figure 1). Furoxans, benzofuroxans, and QdNO derivatives represent important scaffolds in medicinal chemistry due to their wide spectrum of biological activities, including antitubercular activity.27 The antimycobacterial activity of these compounds is attributed to the generation of reactive oxygen species (ROS) following their biotransformation.28−30 For quinoxalines specifically, earlier studies have reported that these compounds lead to increased levels of ROS under hypoxic conditions, which could contribute to interesting properties against latent TB.31−33

ROS play a crucial role in the pathogenesis of TB. Several studies have demonstrated the relationship between the level of ROS produced by immune cells and the susceptibility of a patient to several species of the Mycobacterium genus.34,35 Furthermore, the effects exerted by ROS during TB are many-fold. For example, increased ROS levels can lead to inhibition of Mtb growth, damage to cellular components, such as lipids, proteins, and nucleic acids, and activation of macrophage-mediated inflammatory activity.36−39 High levels of ROS can also induce apoptosis of macrophages (host for tubercle bacilli), thereby preventing the growth and replication of the bacilli.40 Therefore, the design of new compounds that could act by increasing the levels of ROS and perturbing mycobacterial redox homeostasis seems to be a promising strategy for combating TB.32−34

In a continuing effort to develop new drug candidates for the treatment of TB, we herein describe the design, synthesis, and biological activities of a series of heterocyclic compounds containing N-oxide as antitubercular compounds.

RESULTS AND DISCUSSION

Chemistry. Twenty-two novel compounds containing the N-oxide subunit were synthesized according to the synthetic methodologies presented in Schemes 1, 2, and 3. Amide-furoxan derivatives 1 and 2 were synthesized according to previously described methods.45,46 Furoxan derivative 2 was allowed to react with 2-, 3-, or 4-hydroxybenzaldehyde in dichloromethane, using 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as the base, leading to the formation of furoxan derivatives containing an aldehyde group (3a−c).47 Then, a condensation reaction of the aldehyde derivatives with isonicotinohydrazide was performed in ethanolic medium catalyzed by an acid to generate hybrid furoxan derivatives 4a−c (Scheme 1). The benzofuroxan derivative containing an aldehyde group (7) was obtained according to a previously reported methodology.48

Figure 1. Design of the N-oxide-containing heterocycle derivatives.
The compound was allowed to react with different aromatic hydrazides through the same condensation reaction described above, leading to the formation of benzofuroxan derivatives 8–17 (Scheme 2). The $^1$H and $^{13}$C nuclear magnetic resonance (NMR) spectra of these compounds displayed proton and carbon signals from the benzofuroxan nucleus as broad peaks, indicating benzofuroxan tautomerism.\textsuperscript{27,31}

Dioxolan-benzofuroxan derivative 18 was obtained from the reaction between compound 7 and ethylene glycol.\textsuperscript{49} The quinoxaline derivatives were obtained through a variation of the Beirut reaction,\textsuperscript{50−52} wherein dioxolan-benzofuroxan derivative 18 was reacted with the appropriate nitrile derivatives in dichloromethane. Potassium carbonate (K$_2$CO$_3$) was utilized as a catalyst,\textsuperscript{53} leading to the generation of quinoxaline derivatives 19–26. Compound 28 was synthesized from quinoxaline 19, which was submitted to cyclic acetal hydrolysis followed by its reaction with isonicotinohydrazide through a condensation reaction (Scheme 3).\textsuperscript{54}
All compounds were characterized by elemental analysis, infrared (IR) spectroscopy, mass spectrometry, and $^1$H and $^{13}$C NMR. Furthermore, all compounds were analyzed by high-pressure liquid chromatography (HPLC), and their purity was confirmed to be greater than 98.5%. Experimental logP values and melting points were determined for the final compounds.

**Biological Studies.** The antitubercular activity of compounds containing N-oxide (4a−c, 8−17, 19−26, and 28) was assessed using *Mtbe* strain H$_3$7Rv (ATCC 27294). The Resazurin microtiter assay (REMA) was employed as described previously.$^{26,55}$ The results are expressed as minimum inhibitory concentration (MIC$_{90}$), and compounds showing MIC$_{90}$ values below 10 μM were selected for further characterization. The potential cytotoxicity of the compounds was evaluated using the MRC-S human lung fibroblast cell line according to a previously reported methodology,$^{26,56}$ and the results are expressed as IC$_{50}$ values. The selectivity index (SI) of the tested compounds was calculated through the ratio of IC$_{50}$ to MIC$_{90}$. The compounds that reported SI ≥ 10 were considered promising for further studies according to the cutoff value established.$^{57,58}$ Potential anaerobic activity of the best compounds was evaluated using the method described by Cho et al.$^{58}$

Analysis of the spectrum of biological activities of the compounds was performed through determination of MIC$_{90}$ values against *Escherichia coli* (ATCC 25922) and *Staphylococcus aureus* (ATCC 29213) by measuring the optical density (OD) at 570 nm (OD$_{570}$) after 16 h and against *Candida albicans* (ATCC 10231) at OD$_{570}$ after 48 h.

The compounds were also tested against isogenic *Mtbe H$_3$7Rv* strains monoresistant to RMP (ATCC 35838), INH (ATCC 35822), streptomycin (SM, ATCC 35820), capreomycin (CAP), moxifloxacin (MOX), and BDQ (strains were from the University of Illinois at Chicago Institute for Tuberculosis Research) by the multiple antigen blot assay (MABA) microdilution technique.$^{59}$ Following this step, we selected the best compound (compound 8) for further studies.

Due to the ability of *Mtbe* to survive inside macrophages, we decided to investigate whether compound 8 could inhibit the growth of *Mtbe* strain H37Rv in the J774A.1 macrophage cell line. Furthermore, time-kill experiments were performed for up to 15 days to evaluate the bactericidal profile of compound 8.

Some earlier reports$^{60,61}$ indicated that the growth of mycobacteria can be affected by the presence of ions and nutrients as well as by the pH of the medium. For this reason, different culture medium conditions were analyzed by MABA. These included (a) adjusting the culture medium to pH 6.0, (b) including 4% bovine serum albumin (BSA), and (c) supplementing with 10% fetal bovine serum (FBS). The slightly acidic pH (pH 6.0) was selected because it is compatible with the growth of *Mtbe* and corresponds to that at the time when *Mtbe*-containing phagosomes fuse with lysosomes. One of the physiological functions of albumin (synthesized in the liver) is to transport poorly soluble molecules of both endogenous and exogenous origins.$^{62}$ Albumin binding constitutes an essential pharmacological parameter that affects the mechanism of action (MOA) of antibiotics in humans.$^{63}$ We utilized FBS, as it serves as a growth factor for mammalian cells and might interfere with the antitubercular action of some compounds.

Preliminary ADMET (absorption, distribution, and metabolism) studies were performed for compound 8 using the following in vitro assays: chemical stability, plasma protein binding, caco-2 permeability, cytochrome P450 inhibition, and hepG2 cytotoxicity. Additionally, we characterized the mutagenicity of compound 8 through a micronucleus assay using mouse peripheral blood reticulocytes.

To ensure greater stability and improved solubility, compound 8 was evaluated in an in vivo assay using a pharmacological formulation. The nanostructured lipid system (ME) was synthesized as described by our group previously.$^{64}$ The compounds were incorporated at the desired concentration for the in vivo experiments by mass solubilization at the respective volume and sonicated for 3 min in batch mode at 15% amplitude. The ME-containing compound 8 was analyzed for tolerability and oral bioavailability following the treatment of female BALB/C mice infected with *Mtbe*.

Microarrays have been used to successfully define the MOA of antitubercular compounds.$^{65}$ Therefore, a microarray analysis was performed to obtain an unbiased view of the MOA of compound 8.

**In Vitro Antimycobacterial Activity.** The ability of *Mtbe* to remain dormant serves as the predominant factor that contributes to precluding sterilization with antibiotic therapy and promotes the development of antibiotic resistance.$^{66,67}$

Therefore, an ideal antimycobacterial drug should (i) reduce the duration of treatment, (ii) be active against resistant strains, (iii) not interfere with other TB drugs and antiretrovirals, and (iv) be active against “dormant” bacilli.$^{10}$

Recently, our research group identified the compound (E)-4'-((2-isonicotinoylhydrazono)methyl)phenoxo)-3-(phenylsulfonyl)-1,2,5-oxadiazole 2-oxide as a promising antitubercular drug candidate.$^{28}$ To optimize its antimycobacterial activity, we designed novel heterocyclic compounds containing N-oxide analogues of the parent compound, which comprised the following heterocyclic moieties: amide-furoxan (series 1, 4a−c), benzofuroxan (series 2, 8−17), and quinoxaline 1,4-di-N-oxide (series 3, 19−26 and 28). The amide-furoxan derivatives (4a−c) were selected to evaluate whether the replacement of the phenylsulfonyl group from the parent compound by an amide group would increase the antitubercular activity and/or decrease the cytotoxicity. The three amide-furoxan regioisomers (4a−c) displayed improved antitubercular activity compared to that of the parent compound.$^{28}$ The compounds from series 1 exhibited MIC$_{90}$ values around 0.4 μM against actively growing *Mtbe* strain H$_3$7-Rv (Table 1).

The benzofuroxan moiety (series 2, 8−17) was selected due to its possible ability to generate ROS after its metabolism.$^{30}$ The structural design of the series under study was based on the isosteric replacement of substituents attached on the phenyl ring. These included hydrogen, nitro, tert-butyl, amino, and hydroxyl groups. Furthermore, we evaluated the substitution of the phenyl ring by a pyridine ring owing to the presence of a heterocyclic pyridine ring in the structure of several antitubercular drugs and bioactive compounds, such as INH, BDQ, and ethionamide.$^{68}$ As expected, the replacement of the phenyl ring of compound 9 by a pyridine ring in compound 8 led to a 7-fold increase in the antituberculosis activity (MIC$_{90}$ = 1.1 μM; Table 1).

Among the benzofuroxan series, our group identified the compound (E)-6-((2-isonicotinoylhydrazono)methyl)benzo- [c]1,2,5-oxadiazole 1-oxide (8) as the lead benzofuroxan derivative with MIC$_{90}$ values of 1.1 and 6.6 μM against actively growing and dormant *Mtbe*, respectively. The nearly equimolar
effects observed against replicating and nonreplicating Mtb, suggested by the small difference in MIC$_{90}$ values, is considered to be an attractive characteristic. Such differences are rarely observed but highly desired and beneficial.

Moreover, our data revealed that the presence of bulky groups, such as tert-butyl (10, MIC$_{90}$ = 3.9 μM), and electron-withdrawing groups, such as nitro (11, MIC$_{90}$ = 5.3 μM), led to an improvement in antituberculosis activity of the analyzed compounds. Compound 9 (unsubstituted phenyl) presented an MIC$_{90}$ value of 8.3 μM, whereas the hydroxyl regioisomers (12–14) presented MIC$_{90}$ values greater than 62 μM. Amino derivatives 15–17 also exhibited a reduction in antitubercular activity in comparison to that of unsubstituted compound 9; however, these compounds reported MIC$_{90}$ values (12.3–27.9 μM) lower than those containing a hydroxyl substitution (Table 1).

With respect to the quinoxaline 1,4-di-N-oxide series, we evaluated the influence of electron-withdrawing and electron-donating groups on the phenyl ring on antituberculosis activity. We also performed an isosteric substitution of the phenyl ring by furan (25) and thiophen (26) moieties. For quinoxaline-phenyl derivatives 19–24, the MIC$_{90}$ values ranged from 12.0 to 30.8 μM, implying a contribution of the presence of substitution at the para position of the phenyl ring to the antituberculosis activity. Since compound 19 was devoid of any substituents, it displayed a lower potency among the phenyl quinoxaline derivatives with an MIC$_{90}$ of 30.8 μM. On the other hand, compound 22, with a methoxyl group in the para position, displayed the lowest MIC$_{90}$ value among the phenyl quinoxaline series. Nevertheless, we could not observe a clear and accurate structure–activity relationship with regard to the electronic properties of the substituents.

For compounds 25 and 26, the isosteric replacement of the phenyl group by a furan or thiophen ring led to a significant increase in the antituberculosis activity. Compounds 25 and 26 exhibited MIC$_{90}$ values of 5.2 and 12.1 μM, respectively. Furthermore, we synthesized a quinoxaline derivative containing an N-acylhydrazone subunit (28); the antitubercular activity of this compound decreased in comparison to that of the previous quinoxalines, exhibiting an MIC$_{90}$ value of 39.7 μM.

**Further in Vitro Biological Profiling of Selected Compounds.** We evaluated the cytotoxicity of the final compounds against the MRC-5 cell line. This cell line is derived from healthy human lung fibroblasts and is widely utilized for the phenotypic screening of antituberculosis drugs.

The data obtained in the cytotoxicity studies of the amidefuroxan series (4a–c) indicated a high selectivity of these compounds against Mtb. All three regioisomers exhibited high IC$_{50}$ values (>854.0 μM), thereby leading to high SI values, which ranged from 2033 to 3205 (Table 1).

Regarding the cytotoxicity studies of the benzofuroxan series, we observed IC$_{50}$ values ranging from 25 to 841 μM against the MRC-5 cell line. The most active benzofuroxan derivative (8) presented an IC$_{50}$ value of 519 μM; however, compound 17 was found to be less cytotoxic among the benzofuroxan series with an IC$_{50}$ value of 841 μM. Compounds 11–14 did not display promising antituberculosis activity (MIC$_{90}$ > 62 μM) and consequently were excluded from the cytotoxicity studies. Rather, compound 8 was selected for further experiments as it possessed the highest potency against Mtb and the lowest cytotoxicity.

Compounds from the quinoxaline series were significantly more cytotoxic against MRC-5 cells, with IC$_{50}$ values ranging

The percentage of inhibition was determined as the mean of six independent experiments ±SD. Bars: mean ± SD.

In terms of cross-resistance, compound 8 displayed equipotent activity (<2-fold change in MIC<sub>90</sub>) against all drug-sensitive and monoresistant strains of *Mtb* tested, suggesting a novel MOA or inhibition of a shared target containing a distinct binding site by the compound (Table 3). In contrast, the amide-furoxan series (4a–c) was inactive against half of the monoresistant strains tested and therefore was not selected for further studies.

We utilized J774A.1, a macrophage cell line, to study the intracellular inhibition of *Mtb* using the drugs under analysis. We observed that compound 8 exhibited high intracellular inhibition at all concentrations tested (around 90%). However, similar to RMP, we could not verify the dose-dependent inhibition at different concentrations (Figure 2). In time-kill kinetic experiments, compound 8 was observed to be bactericidal with an early bactericidal effect. Noteworthy, compound 8 could sterilize the cultures after 48 h of exposure (about of 6.7 log<sub>10</sub> Figure 3).

**Preliminary ADMT Studies of Compound 8.** On the basis of the promising biological results described above for compound 8, we conducted stability and ADMT studies to assess its drug-like properties, such as absorption, distribution, and metabolism. To analyze the chemical stability of the compound, we conducted an *in vitro* assay under two pH conditions (5.5 and 7.4) to mimic the environment of a macrophage phagolysosome (pH 4.5–6.2) and that of neutral plasma (pH 7.4). At pH 5.5 and 7.4, compound 8 exhibited good stability (Figure 4); however, a reduction of 20% was detected at both pH values after 10 h. Interestingly, the concentration of compound 8 was 76 and 7% at pH 5.5 and 7.4, respectively, after 24 h. The degradation rate of compound 8 was calculated by HPLC-UV; however, we did not characterize the degradation products. These results indicated that compound 8 exhibited high stability in the physiological pH range in the target areas of bacteria, namely, blood and phagolysosome.

The *in vitro* ADMT properties of compound 8 are listed in Table 4. The benzofuroxan derivative demonstrated a 46.5% unbound fraction when an *in vitro* plasma protein binding assay was conducted. The findings from the study of compound 8 on the inhibition of cytochrome P450 isozymes indicated no potential for inhibition, presenting IC<sub>50</sub> values greater than 15.0 μM. From 13 to 67 μM, thereby resulting in low SI (<6.8) values and making them less attractive candidates as antitubercular agents.56
against all isoforms tested. The studies in the Caco-2 cell line demonstrated a good permeability profile. The cytotoxicity study conducted in HepG2 cells reported an IC_{50} of 16.0 μM and an SI of 14.5. We also performed the micronucleus assay using mouse peripheral blood reticulocytes for compound 8 to evaluate its intrinsic mutagenic activity. The results indicated that compound 8 was not genotoxic at any concentration tested (Figure 5).

**Tolerability, Oral Bioavailability, and Efficacy of Compound 8 in Mice.** In vivo oral bioavailability, toxicology, infection, and treatment studies were performed to ensure the safety and efficacy of compound 8.

**For toxicity studies, mice were monitored daily for 10 days, receiving one daily oral dose (by gavage, 200 mg/kg body weight), and their behavior parameters (hippocratic screening) were evaluated. No significant variation in the behavior of mice was observed during the period of 10 days. Changes in the weight of organs (heart, lungs, spleen, kidneys, and liver) were evaluated using analysis of variance (ANOVA) and Dunnett’s test, establishing a p-value < 0.05 as the significant level. No statistically significant difference was observed between the drug-treated and control groups. To probe for potential liver damage, the levels of liver transaminases were checked in the plasma and indicated no significant differences for alanine aminotransferase (Figure 6a), aspartate aminotransferase (Figure 6b), and alkaline phosphatase (Figure 6c) between the treated and control groups. Similarly, we evaluated the levels of urea in blood samples to assess potential changes in kidney function. Here, a significant difference was observed for the group treated with RMP-ME when compared to the control group (Figure 6d). The study of the oral bioavailability of compound 8 displayed an inhibition of Mtb growth in mouse plasma (Table 5).

The histology of the liver (Figure 7) and kidneys (Figure 8) revealed that the morphology of these tissues was the same in all groups, implying that no gross abnormalities were caused by the treatments.

The efficacy of compound 8 was analyzed by infecting the mice with Mtb strain H37Rv followed by subjecting the infected animals to the treatment with compound 8 or vehicle. The homogenized lung samples were plated at dilutions of 1:100 to 1:10000, at which no growth of Mtb colonies was observed. Therefore, the homogenized lung samples were reinoculated on agar plates in undiluted form and at 1:10 dilution; however, again, no colonies were observed (Figure 9). Control experiments with vehicle, RPM, and RPM-CE behaved as expected (Figure 9).

**Mode of Action Studies.** Although the antitubercular activity of benzofuroxan derivative 8 was originally attributed to its potential to generate and release nitric oxide (NO), we no longer believe this to be the case because the compound could not result in the release of NO in the Griess assay (a chemical test to analyze nitrite ions in solution; data not shown). An alternative mechanism was proposed as mentioned below.

Microarray analysis of Mtb treated with compound 8 or vehicle control revealed a significant upregulation in the majority of ribosomal genes as well as all genes encoding subunits of ATP synthase (Table 6).
synthase (Figure 10 and Table S1). This included EF-G, which induces GTP-dependent translocation of nascent peptide chains from the A- to the P-site in the ribosome, and EF-Tu, which promotes GTP-dependent binding of aminoacylated tRNAs to the A-site in ribosomes. No upregulation of heat shock proteins was observed; in fact, a downregulation of hspR was demonstrated (Table S1). Similarly, upregulation of ribosomal proteins was observed upon treatment of Mtb with inhibitors of protein synthesis. Our data indicated an upregulation of a large number of operons as well as single genes encoding ribosomal proteins, which in turn suggested that compound 8 could affect protein synthesis by inhibiting the ribosome. Bosho and co-workers divided protein synthesis inhibitors into two classes on the basis of their effect on the expression of heat shock proteins.

Experiments were carried out in BALB/c mice. Predetermined by the Resazurin microtiter assay (REMA) in vitro. Determined using mouse plasma by REMA in vitro; estimates in plasma are given.
proteins (either no effect or upregulation). Compound 8 did not increase the abundance of transcripts encoding heat shock proteins and, in fact, decreased the levels of three transcripts (hsp, htrA, and hspR). The results of this study of the inhibition of protein synthesis indicated that compound 8 behaves more like an inhibitor of translation initiation, such as tetracyclines, rather than an inhibitor of protein synthesis that leads to mistranslation, such as aminoglycosides. Further studies are required to define the exact MOA of compound 8, including its binding site and inhibition of the Mtb ribosome, ATP synthase, or other targets.

**CONCLUSIONS**

Twenty-two new N-oxide-containing compounds were synthesized followed by in vitro and in vivo evaluation of their antitubercular activity against *Mtb*. The amide-furoxan series (4a–c) was observed to be the most promising compounds, with MIC90 values around 0.40 μM against actively replicating Mtb and SI values ranging from 2033.3 to 3204.7. The benzo-furoxan series (8–17) also presented promising antitubercular activity, especially compound 8, which reported MIC90 values of 1.1 and 6.6 μM against actively growing and nonreplicating Mtb, respectively. Compound 8 also displayed high activity in a macrophage model of infection. In addition, in vivo studies employing a mouse model of infection demonstrated the sterilizing activity of compound 8. No detectable Mtb was observed in the lungs of treated mice, whereas control mice displayed the expected number of CFUs. Altogether, these findings highlight benzo-furoxan derivative 8 as a novel lead compound for designing an antitubercular drug that possesses sterilizing activity superior to that of rifampicin in a mouse model of infection.

**EXPERIMENTAL SECTION**

**Chemistry.** Melting points (mp) were measured using an electro-thermal melting point apparatus (SMP3; Bibby Stuart Scientific) or in a Mettler FP82+FP80 apparatus (Greifense, Switzerland). Infrared spectroscopy (KBr disc) was performed on a FTIR-8300 Shimadzu or a Nicolet Nexus FTIR Thermo spectrometer, and the frequencies are expressed in cm⁻¹. NMR spectra for ¹H and ¹³C of all compounds were recorded on a Bruker Fourier spectrometer with a dual ¹H/¹³C (300 MHz) probe or a Bruker 400 Ultrashield ¹H/¹³C (400 MHz) spectrometer using deuterated chloroform (CDCl₃) or dimethyl sulfoxide (DMSO-δ₆) as solvent; the chemical shifts are expressed in parts per million (ppm) relative to tetramethylsilane. The signal multiplicities are reported as singlet (s), doublet (d), doublet of doublets (dd), and multiplet (m). Elemental microanalysis (C, H, and N) was performed on a PerkinElmer model 2400 analyzer or a CHN-900 Elemental Analyzer (LECO, Tres Cantos, Spain), and the data were within ±0.4% of theoretical values. HRMS (ESI⁺) data were acquired using a Bruker Maxis Impact quadrupole time-of-flight tandem mass spectrometer (Q-TOF MS/MS), and the mass spectra values are reported as m/z. The compounds were purified on a chromatography column with silica gel (60 Å pore size, 35–75-μm particle size), and the following solvents were used as the mobile phase: methanol, ethyl acetate, dichloromethane, hexane, and petroleum ether in a flow rate of approximately 20 mL/min. The reaction progress of all compounds was monitored by thin-layer chromatography (TLC), which was performed on 2.0 × 6.0 cm² aluminum sheets precoated with silica gel 60 (HF-254; Merck) to a thickness of 0.25 mm and revealed under UV light (254 nm). All compounds were analyzed by HPLC, and their purity was confirmed to be greater than 98.5%. HPLC conditions: Shimadzu HPLC model CBM 20-A (Shimadzu) equipped with UV–vis detector (model SPD-20A), quaternary pumping system mobile phase (model LC-20AT), solvent degasser (model DGU-20As), and an Agilent Eclipse XDB C-18 column (250 mm × 27.46 mm; 5 μm). For HPLC, an isocratic flow was used [methanol/water (75:25)]. Reagents and solvents were purchased from commercial suppliers. Compounds 3a–c, 4a–c, 6a, 7a, 18, 19, and 28 were prepared according to previously described methods.

**General Procedure for the Synthesis of Compounds 4a–c and 8–17.** A solution of compound 3a–c or 7 (0.87 mmol) in 10 mL of ethanol and 3 drops of glacial acetic acid was stirred at room temperature for 20 min. Next, the appropriate aromatic hydrazide (0.106 g, 0.87 mmol) was added, and the mixture was stirred for 12 h. The solvent
was concentrated under reduced pressure, and ice was added to precipitate the desired products. If necessary, the samples were further purified by silica gel column chromatography using ethyl acetate/methanol (98:2 v/v) as eluent to give the appropriate compound (4a–c and 8–17) in variable yields.

(E)-3-Carbamoyl-4-((2-isonicotinoylhydrazono)methyl)benzo[c][1,2,5]oxadiazole 1-Oxide (4a). White powder; yield, 51%; mp 226 to 229 °C. IR Vmax (cm⁻¹); KBr pellets): 3439 (NH2 amide), 3203 (N=N aromatic). 1H NMR (300 MHz, DMSO-δ 6): 8.52 (1H; s), 8.39 (2H; d; J = 5.7 Hz), 8.51 (1H; s), 8.03 (3H; m), 7.84 (2H; d; J = 6.0 Hz).13C NMR (75 MHz, DMSO-δ ppm): δ: 162.4, 150.6, 146.6, 140.2, 133.7, 134.4, 130.8, 130.4, 130.1, 129.4, 121.8, 114.3. General Procedure for the Synthesis of Compounds 20–26. Compound 18 (0.3 g, 1.06 mmol) was dissolved in dichloromethane (15 mL) and then cooled by placing it on an ice bath. Next, the appropriate nitrile (0.15 g, 1.06 mmol) and potassium carbonate (0.18 g, 1.34 mmol) were added in portions. The reaction mixture was stirred at 40 °C for 96 h. Afterward, the solvant was evaporated under reduced pressure and the obtained solid was dissolved in 50 mL of ethyl acetate and washed with water. The organic phase was dried with anhydrous magnesium sulfate, and the solvent was evaporated, giving a yellow solid. The obtained solid was purified by silica gel column chromatography using hexane and ethyl acetate (70:30 v/v) as eluent to give the appropriate compound (20–26) in variable yields.
