1   **Abstract**

2   We have prepared and evaluated ~~about their~~ the physico-chemical and biological properties of four
3   different hyaluronated mesoporous silica nanoparticles (MSNs) samples (MSN/HA). Hyaluronic
4   acid (HA) with two different molecular weights (200 and 6.4 kDa) was used for the conjugation of
5   aminopropyl-functionalized MSN (NH₂-MSN), following two different procedures. Namely,
6   samples HA200A and HA6.4A were prepared by reacting activated HA with NH₂-MSN (method
7   A), while samples HA200B and HA6.4B were obtained carrying out HA activation in the presence
8   of the nanoparticles (method B). The four samples showed similar hydrophilicity, but clear
9   differences in the HA loading, textural properties, surface charge and stability of the suspensions.
10   More in detail, conjugation using low molecular weight HA with method A resulted in low HA
11   loading, with consequent scarce effects on dispersity and stability in physiological media. The
12   highest yield and corresponding best performances were obtained with method B using high
13   molecular weight HA. HA loading and molecular weight also influenced in a concerted way the
14   biological response towards the MSNs of CD44 target cancer cells (CD44+) and control cells
15   (CD44-): MDA-MB-231 and A2780, respectively. The absence of cytotoxicity was assessed.
16   Moreover, the targeting ability of the best performing MSN/HA was confirmed by cellular uptake
17   studies.

1. Introduction

Nanoparticles-based targeted therapy has emerged in recent years as an innovative strategy to maintain a drug therapeutic dose at the target site, while reducing systemic drug toxicity and adverse side effects to healthy tissues [1-3]. This approach is particularly important in relation to cancer therapy, where the differences in biochemistry between cancerous and normal tissues can be exploited for the selective targeting of over-expressed tumour specific receptors [4-7]. To this aim, nanomaterials are an ideal playground, thanks to their intrinsic properties such as high surface area, tuneable size and shape coupled to ease of synthesis and functionalization. Nanoparticles may be loaded with a plethora of bioactive molecules (*e.g.*, small molecules, peptides, nucleic acids, etc.) to protect them from cleavage by external agents, thus the encapsulated drugs do not participate in the control over pharmacokinetic and biodistribution. Moreover, nanosize ~~allows for~~ **permits** passive transport in biological fluids and for establishing molecular interactions at the cellular and subcellular level [1].

Liposomes [8-10] and biodegradable polymeric nanoparticles [11-13] are among the most versatile biocompatible systems to encapsulate active ingredients. Mesoporous silica nanoparticles (MSNs) can be considered as their inorganic counterparts, with intrinsic features such as a huge available inner volume, inertness and chemical stability [14-17]. The ease of surface functionalization makes them ideal materials to develop “pharmaceutically adapted platforms” [18, 19], with great potentiality in relation to **stimuli responsive** applications [20-26]. One of the major drawbacks for the systemic application of these nanosystems is their poor dispersity in biological fluids, which can be however improved by appropriate surface functionalization [19]. Functionalization **(often carried out to optimize the interaction with the guest drug molecules)** can be obtained with a variety of organosilanes, ~~to optimize the interaction with the guest drug molecules~~ [27]. This has important consequences on the surface properties, such as charge and hydrophilicity [28], which ~~in turns~~ can profoundly affect **influence** the nanoparticle cytotoxicity [29], cellular uptake, transport and/or fate **in biological**

1 fluids of the nanoparticles [30, 31].

2 Surface modification of nanocarriers through macromolecules is particularly relevant in the

3 field of cancer treatment [32], where the conjugation of cytotoxic drugs with macromolecules is

4 designed to improve their pharmacokinetic profile, prolonging the distribution and elimination

5 phases [33]. The most employed are N-(2-hydroxypropyl) methacrylamide (HPMA),

6 polyglutamate, human serum albumin, dextrans, heparin, chitosan, dendrimers, multi-arm

7 polyethylene glycol (PEG), and hyaluronic acid (HA) [32, 33]. HA is a naturally-occurring

8 glycosaminoglycan and a major component of the extracellular matrix. The HA receptor CD44

9 is overexpressed in many cancer cells, and in particular in tumor-initiating cells. HA has thus

10 attracted considerable interest in for the development of nanoplatforms for actively targeting

11 drugs, genes, and diagnostic agents [34, 35].

12 In recent years, HA-conjugated MSN systems have been proposed in the literature, with the double

13 effect aim to improve the MSNs dispersity and obtain a targeted delivery to CD44 overexpressing

14 cancer cells [36-38]. Zhang *et al.* recently proposed biotin-modified HA coupled to MSN to enable

15 controlled drug release at cancer cells expressing CD44 HA receptor CD44 [39]. Moreover, Chen *et*

16 *al.* exploited used HA as both capping and targeting agent. In their work, the entrapped guest

17 molecules were released from the inner pores of MSNs upon HA degradation in response to

18 hyaluronidase-1, which occurred after receptor-mediated endocytosis into targeted cancer cells [40].

19 The potentiality of HA-conjugated MSN systems was further investigated by developing dual-

20 stimuli responsive systems. To this aim, the polysaccharide was conjugated to MSNs through a

21 disulfide bond, which was cleaved in the presence of the high glutathione concentration

22 characterizing cancer cells [23, 24]. Additionally, multifunctional “theranostic” materials where

23 developed, coupling the above-mentioned properties to those of a gadolinium based bovine serum

24 albumin complex for a concomitant simultaneous redox-responsive targeted drug delivery and

25 magnetic resonance imaging [41].

~~This work reports about~~ In this work, the synthesis and characterization of hyaluronated MSNs (MSN/HA), which have been developed with the double aim to improve their dispersion in physiological media and their targeting ability. ~~Here~~ For the first time we compare different synthetic approaches, and the use of HA of different molecular weights (6.4 kDa and 200kDa), to identify the optimal strategy to obtain the better performances, both in terms of biological response and potential pharmaceutical application. A full physico-chemical description of the produced hybrid materials is given, including routine characterization, hydrophilicity analysis assessment, molecular and quantitative analysis of the HA external shell. Finally, the biological effects in cultured cells were studied and the results correlated to the materials properties.

2. Experimental section

2.1 Materials

Cetyltrimethylammonium bromide (CTAB), tetraethyl orthosilicate (TEOS), sodium hydroxide (NaOH), (3-aminopropyl)-triethoxysilane (APTS) and all the other reagents and solvents were purchased from Sigma-Aldrich (Milan, Italy) and employed as received. Sodium hyaluronate (HA, of molecular weights MW 6.4 and 200 kDa) was purchased from Lifecore Biomedical (Chaska, MN). Fluorescein-5-isothiocyanate (FITC) was provided by Invitrogen (Life Technologies, Monza, Italy). MilliQ® water was used in all synthetic steps.

2.2 NH₂-MSN synthesis

MSN samples were prepared following a slightly modified literature procedure [42, 43]. CTAB (1 g, 2.74 mmol); employed as Structure Directing Agent (SDA), was dissolved in 480 ml of water under stirring and heating. At the stable temperature of 80°C, NaOH (2.0 M, 3.5 ml) was slowly added to the mixture. TEOS (5 ml, 22.4 mmol) was then added dropwise drop-wise over 10 min under vigorous stirring. After 2 h of stirring at 80 °C the milky reaction mixture was cooled to room temperature (RT) and the white precipitate was filtered off and washed with abundant water and

methanol. The SDA was removed from the as-synthesized material by calcination at 550 °C, heating to the desired temperature under N₂ flow and switching to O₂ for a 6 h isotherm.

Aminopropyl-functionalized MSN (NH₂-MSN) sample was prepared with APTS by post-synthesis grafting with a procedure modified from the literature [44, 45]. Namely, 1 g of MSN (overnight dried at 100°C) were suspended in 30 ml of anhydrous toluene. The particles suspension was heated at 130°C under stirring. Next, 0.6 ml of APTS were added drop-wise and the mixture was allowed to reflux for 17 h. The modified NH₂-MSNs were filtered off and washed with toluene, ethanol, water and at last finally methanol. Subsequently, the sample was dried at 110°C for 3 h to favor the for curing, and at 80°C overnight [46].

2.3 Hyaluronic acid conjugation: MSN/HA samples

Conjugation with HA was carried out starting from NH₂-MSN, to exploit the aminopropyl functionality for covalent linking of the targeting agent. We followed three different procedures proposed in the literature [36, 37, 40]. The protocol described in Ref [40] was discarded since the prepared samples resulted in the lowest derivatization yield. This is probably ascribable to the low concentration of the coupling agent 1-ethyl-3-(3'-dimethylaminopropyl)carbodiimide (EDAC), notwithstanding the excess of HA with respect to MSN. The methodologies proposed by Yu et al. and by Ma et al. [36, 37], briefly described below, are hereafter mentioned as method A and B, respectively. HA of MW of 6.4 and 200 kDa were used with each method for both preparations.

2.3.1 Samples HA200A and HA6.4A

This approach requires activation of HA through N-hydroxysuccinimide (NHS) and EDAC as coupling agent, before nanoparticles conjugation [37]. To this aim, 56 mg of NHS and 30 mg of EDAC were separately dissolved in 1.5 ml water, each. 17 mg of HA were suspended in 9 ml water, before adding the NHS and EDAC solutions previously prepared. The mixture was left under magnetic stirring at RT for 1 h. 150 mg of NH₂-MSN were suspended by sonication in 15 ml of

water, before adding the activated HA solution. pH was then adjusted to 9 with trimethylamine (TEA). The mixture was heated to 38 °C and left under stirring overnight. After cooling down to RT, the supernatant was separated by centrifugation (60 rpm, 20 min). The solid powdered product was washed thrice with water; and suspended in few ml of water before freeze-drying. This procedure was carried out with HA 200kDa and 6.4 kDa, resulting in samples HA200A and HA6.4A, respectively.

2.3.2 Samples HA200B and HA6.4B

~~With this method,~~ Following method B, activation of HA was carried out directly in the presence of the nanoparticles. 150 mg of NH₂-MSN were sonicated in 30 ml of 2-(N-morpholino)ethanesulfonic acid (MES) buffer 0.01 M, at pH 6. 150 mg of HA were dissolved in 15 ml of MES and added to the nanoparticles suspension. 15 mg of EDAC and 15 mg of NHS, each dissolved in 7.5 ml of MES, ~~are~~ were added to the MSN suspension. The reaction was kept under magnetic stirring at RT for 4 h and successively centrifuged (60 rpm, 20 min). After removal of the supernatant, the solid powdered product was washed thrice with water and re-suspended in few ml of water for freeze-drying [36]. The procedure was carried out with HA 200kDa and 6.4kDa, resulting in samples HA200B and HA6.4B, respectively.

2.3.3 Fluorescent labelling

FITC labelled NH₂-MSN and MSN/HA samples were prepared as reported in Ref. [37] with minor modifications. Briefly, 250 µl of FITC ethanol solution (0.3 mg/ml) were added at to a suspension of 1 mg of MSN in 150 µl of water ~~250 µl of FITC ethanol solution (0.3 mg/ml) were added.~~ The mixture was maintained at RT for 6 h under stirring in the dark and then the nanoparticles were centrifuged (60 rpm, 10 min) and washed with ethanol thrice until the supernatants were colorless.

2.4 Physico-chemical characterization

1 ~~High Resolution~~ Transmission Electron Microscopy (HRTM) analyses were performed by means
2 of measurements were carried out with a JEM 3010-UHR microscope (JEOL Ltd.) operating at 300
3 kV. ~~For the measurements, p~~ Powders were dispersed on a copper grid coated with a perforated
4 carbon film. The size distribution of the samples was obtained by measuring a statistically
5 representative number of particles (*ca.* 250 particles). ~~and the~~ The results are indicated as mean
6 particle diameter (dm) $\pm$ standard deviation (STD) (dm $\pm$ STD).

7 Specific surface area (SSA), cumulative pore volume and pore size distribution of samples were
8 calculated by gas-volumetric analysis measuring N₂ adsorption-desorption isotherms at liquid
9 nitrogen temperature (LNT) using an ASAP 2020 physisorption analyser (Micromeritics). The SSA
10 was calculated by the Brunauer-Emmett-Teller (BET) method and the average pore size was
11 determined by means of the Barrett-Joyner-Helenda (BJH) method, employing Kruk-Jaroniec-
12 Sayari (KJS) equations on the adsorption branch of nitrogen isotherms. Before the measurement,
13 the samples were outgassed at RT overnight.

14 Powder X Ray Diffraction (PXRD) patterns were collected with a PW3050/60 X'Pert PRO MPD
15 diffractometer (Panalytical) working in Bragg-Brentano geometry, using Cu K α radiation (40 mA
16 and 45 kV), with a scan speed of 0.0167° min⁻¹ and a measure time of 200 s/step. The measure was
17 carried out at low angles, in the range of 1.5-12°.

18 Thermogravimetric analysis (TGA) was carried out on a Q600 analyzer (TA Instruments) heating
19 the samples at a rate of 10 °C/min from RT to 1000°C in air flow. Before starting measurements,
20 samples were equilibrated at 30°C.

21 Fourier Transform Infrared (FTIR) spectra were recorded using an IFS28 spectrometer (Bruker
22 Optics) equipped with a MCT detector, working with a resolution of 4 cm⁻¹ over 64 scans. The
23 spectra were obtained in transmission mode, with the samples pressed in the form of self-supporting
24 pellets, mechanically protected with a pure gold frame. Samples were placed in quartz cells
25 equipped with KBr windows, allowing *in situ* activation and measurement. Before spectra
26 measurement the samples were outgassed at RT for 4 hours to remove adsorbed water and

1 impurities. Spectra were normalized with respect to pellet thickness for direct comparison, by using
2 the silica overtone modes in the 2100-1500 cm^{-1} interval.

3 Colorimetric carbazole test was carried following the procedure described in [47]. Briefly, a
4 suspension of 4 mg/ml in water was prepared for each sample. Two aliquots (60 and 180 μl) were
5 diluted to a final volume of 1 ml in water. 3 ml of a 0.025 M $\text{Na}_2\text{B}_4\text{O}_7$ in H_2SO_4 96% solution were
6 added to each tube. The suspensions were then shaken and heated at 100°C for 10 min. After
7 cooling down, 100 μl of a carbazole solution 0.1% p/v in absolute ethanol was added, before
8 mixing and heating again at 100°C for 10 min. After cooling down, absorbance was measured at
9 530 nm using a DU-70 Beckman spectrophotometer.

10 Microgravimetric H_2O adsorption/desorption isotherms were measured with an intelligent
11 gravimetric analyzer (IGA-002, Hiden Analytical), based on an ultrahigh-vacuum (UHV)
12 microbalance (weighing resolution of 0.2 μg) with integrated temperature and pressure control.
13 Temperature control was based on a thermostated water bath/circulator, while pressure control was
14 achieved with a Baratron capacitance manometer (accuracy ± 0.05 mbar). Buoyancy corrections
15 were carried out using the weights and densities of all the components of the sample (including
16 adsorbed phase) and counterweight sides of the balance, and the measured temperature. The mass
17 uptake was measured as a function of time, and the approach to equilibrium of the mass relaxation
18 curve was monitored in real time using a computer algorithm (real time processor, RTP). For each
19 isotherm point the time origin of real-time analysis was set at 75% of the pressure change, while the
20 minimum and maximum data collection time were set to 5 and 60 mins, respectively. RTP uses last-
21 squares regression of a linear driving force (LDF) model in order to extrapolate a value of the mass
22 relaxation asymptote and assess the time-scale of interaction. The samples were loaded in a sealed
23 stainless steel reactor, where they were outgassed at 50°C overnight prior to H_2O dosage, in order to
24 measure the sample dry weight. Two consecutive adsorption/desorption isotherms were measured
25 varying the water equilibrium pressure in the 0-20 mbar interval (step of 3 mbar) at 28 °C. This
26 corresponds to a maximum p/p^0 value around 0.55 ($p^0 \cong 38$ mbar at the measurement temperature).

1 The experimental isotherms were analyzed with a Langmuir model, which assumes a monolayer
2 adsorption onto the surface and is expressed by the equation:

$$3 \quad q = \frac{q_m K p}{1 + K p} \quad (1)$$

4 where q is the equilibrium water uptake, q_m is the adsorption capacity (corresponding to the
5 monolayer saturation) and K the Langmuir constant, which corresponds to the adsorption
6 equilibrium constant [48]. q_m and K were calculated via the linearization of the Langmuir equation,
7 as follows:

$$8 \quad \frac{p}{q} = \frac{1}{K q_m} + \frac{p}{q_m} \quad (2)$$

9 Calculations were carried out expressing the equilibrium pressure as p/p^0 , so that the K values
10 reported in Table 4 are dimensionless.

11 The mean hydrodynamic size was determined at 25°C by Dynamic Light Scattering (DLS) using a
12 nanosizer (Nanosizer Nano Z, Malvern Inst., Malvern, UK). The selected angle was 173° and the
13 measurement was ~~taken~~ **carried out** after dilution of the nanoparticle suspensions in water and in
14 phosphate buffered saline (PBS 0.1 M, pH = 7.4). The particle surface charge was investigated by
15 zeta potential measurements at 25°C in water and PBS solution applying the Smoluchowski
16 equation and using the ~~Nanosizer Nanoseries~~ **Zetasizer Nanoseries** ZS 90 (Malvern Instruments-). In
17 both cases, measurements were carried out in triplicate by diluting 80 µl of a 1mg/ml particles
18 suspension in water with the selected medium, to reach a final volume of 1 ml.

19 For the dispersity test 2 mg of NH₂-MSN and MSN/HA samples were added to 1 ml of different
20 medium [PBS 0.1 M or Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% of
21 fetal bovine serum (FBS)] and bath sonicated for 30 min. ~~then dispersity~~ **The stability of the**
22 **dispersions was evaluated** after 0, 4, 8, 24 and 30 h ~~was evaluated~~.

23

24 2.5. Tumour cell lines culture

MDA-MB-231 (human breast adenocarcinoma) and A2780 (human ovarian carcinoma) cells were used. MDA-MB-231 cells were grown in DMEM supplemented with 10% of FBS, 0.03% of L-glutamine and 2% penicillin and streptomycin. A2780 cells were cultured in RPMI 1640 medium containing 10% FBS, 0.03% of L-glutamine, 2% penicillin and streptomycin, and 50 g/ml of gentamicin sulfate. Cells were maintained in a humidified incubator at 37°C in 5% CO₂.

2.6. Receptor expression analysis

Flow cytometry was used to determine the presence of CD44 on the cell surface by indirect immunofluorescence. Cells were washed twice with PBS and incubated 30 min in the dark at 4 °C with CD44 primary antibody, washed twice with PBS and then incubated 30 min in the dark at 4 °C with a phycoerythrin (PE) conjugated goat antibody (Dako Italia, Milan, Italy). Samples were analyzed on a flow cytometer instrument (FACSCanto, Becton Dickinson, San Jose, CA). Dead cells and debris were excluded on the basis of forward-scatter and side-scatter. Flow cytometry data were analyzed using the FlowJo software (TreeStar, Ashland, OR). CD44 expression was measured by calculating the ratio between median fluorescence intensity of cells labelled with antibodies versus unlabelled cells (Relative Median Fluorescence Intensity, RMFI).

2.7. Incubation with MSN and cytotoxicity evaluation

MDA-MB-231 and A2780 cells were seeded at 1×10^4 cells/well in 96 wells microtiter plates and incubated overnight to allow cellular adhesion. Various dilutions of NH₂-MSN and MSN/HA samples (1.5-25 µg/ml) were added in triplicate, and incubated for 24, 48 and 72 h.

Cell growth inhibition was evaluated by sulforhodamine B (SRB) colorimetric proliferation assay, modified by Vichai and Kirtikara [49].

2.8 Confocal analysis of fluorescent MSN

1 After 24 h incubation with either FITC labelled NH₂-MSN or MSN/HA, MDA-MB-231 and A2780
2 cells were fixed for fluorescence microscopy with 4% (v/v) paraformaldehyde in PBS, pH 7.4, for
3 30 min at room temperature. The samples were stained for DNA with Hoechst 33342 (1 µg/ml in
4 PBS for 5 min; Sigma), counterstained with 0.1% Trypan blue in PBS for 30 sec to visualize the
5 cytoplasm, rinsed in PBS, and mounted in a 1:1 mixture of glycerol:PBS (Calbiochem, Inalco,
6 Milan, Italy). For confocal laser scanning microscopy (CLSM), a Leica TCS SP5 AOBS system
7 (Leica Microsystems Italia, Milan, Italy) was used with a 40x oil immersion objective. For
8 fluorescence excitation, a diode laser at 405 nm for Hoechst, an Ar laser at 488 nm for FITC and a
9 He/Ne laser at 543 for Trypan blue were employed. Z-stack of 1.5 µm step sized images (each
10 image in the 1024x1024 pixel format) were collected and processed by the Leica confocal software.
11 The RGB channels of the images presented here are the gray intensity images obtained with 405 nm
12 (B), 488 nm (G) and 533 nm (R) excitation wavelengths respectively.

13

14 *2.9 Cellular uptake*

15 A quantitative determination of the cellular uptake was performed on a fluorescence-activated cell
16 sorter (FACS). MDA-MB-231 and A2780 cells seeded in 6-well culture plates (5X10⁵ cells/well),
17 were exposed for different length of time (15 min, 30 min or 1 h) to FITC labelled NH₂-MSN and
18 MSN/HA with equivalent fluorescence. After removal of the free FITC-NH₂-MSN and FITC-
19 MSN/HA, cells were washed twice with PBS, collected by tripsynization and finally re-suspended
20 in 1 ml of PBS. Then the intracellular uptake of MSNs was analyzed using a FACScan. Detection
21 of FITC-MSNs green fluorescence (FL-1) was performed on at least 5,000 events per samples,
22 using the CellQuest software (Becton-Dickinson, Milano, Italy). Cells incubated in the absence of
23 MSN were used as control.

24

25 **3. Results and discussion**

1 ~~All samples were characterized about their general properties,~~ The general properties of all samples,
2 including textural and morphological features, ~~were analyzed.~~ Sample HA6.4A was discarded due
3 to low derivatization yield and to scarce dispersity (see later), and will thus not be described in
4 detail in the following. The NH₂-MSN sample used for HA conjugation was measured for
5 comparison. Corresponding results are hereafter discussed only when relevant.

7 3.1 Effect of conjugation on porous structure

8 MSN/HA samples are composed by spherical nanoparticles (particle size 94 ± 20 nm, see
9 corresponding histogram as Figure S1), which are characterized by an ordered pore structure with
10 the typical hexagonal array of MCM-41-like materials. This can be appreciated in the high
11 resolution TEM picture of sample NH₂-MSN, reported in Fig 1a, showing two superimposed
12 particles with pores parallel and perpendicular to the image plane (circle and hexagon shapes,
13 respectively). The same particle size, morphology and ordered porosity is preserved after HA
14 conjugation, as shown in Figures 1b-d. However, in this case an amorphous-like external layer is
15 clearly observed, which can be attributed to the formation of a shell of HA, covering the particles.
16 The formation of a HA shell is supported by both qualitative and quantitative characterization
17 results, described in the following.

18 The ordered pore structure of the materials is also reflected in the typical XRD pattern,
19 characterized by low angle peaks at 2.3, 4.0 and 4.7° (Figure S2). These can be labelled as (100),
20 (110) and (200) in the P6mm symmetry group, corresponding to the hexagonal pore-array of
21 pores. After HA conjugation, in all samples the peaks decrease in intensity and move to slightly
22 higher 2 θ values in all samples. The change is in the order HA200A < HA6.4B $\cong$ HA200B. Both
23 phenomena are usually observed in MCM-41-like materials after functionalization and/or drug
24 encapsulation, and are interpreted in terms of molecules filling/lining the pores [50, 51].
25 Particularly, the d_{100} parameter, which is the distance between planes passing through the pores

1 centre (see Figure S3), can be calculated from the Bragg equation, as resumed in Table 1. These
 2 data are further discussed hereafter in combination with results from gas-volumetric analysis.
 3 The nitrogen adsorption/desorption isotherms of the three MSN/HA and parent NH₂-MSN materials
 4 are reported in Figure 2 (top panel), with the corresponding pore size distribution calculated with
 5 the BJH method (bottom). Curves a) and b), corresponding to NH₂-MSN and HA200A, can be
 6 classified as type IV, typical of mesoporous materials. Namely, a steep increase of the adsorbed
 7 amount is observed below $p/p^0 = 0.3$, which corresponds to the capillary condensation of the
 8 adsorbate inside the pores. The narrow hysteresis loop present in all samples at p/p^0 reaching 1 is
 9 instead related to condensation of nitrogen in the interparticle porosity. After conjugation, the
 10 nitrogen adsorbed amount decreases in the order HA200A > HA6.4B $\cong$ HA200B, and in the latter
 11 last two the capillary condensation related to mesopores filling is no more present. This is reflected
 12 in the corresponding pore size distribution curves (Figure 2, bottom panel). Parent NH₂-MSN
 13 material shows an intense and relatively narrow peak centred around 30 Å, corresponding to the
 14 pores lined with aminopropyl groups. This peak is weaker and shifted to lower values for HA200A,
 15 very weak and not present for in HA6.4B and HA200B, respectively.
 16 The textural parameters obtained from these data are summarized in Table 1. On the whole, we
 17 observe a major effect of conjugation on samples prepared by method B, where Specific Surface
 18 Area (SSA), pore volume and diameter are sensibly decreased. This suggests that during this
 19 procedure (where HA activation is carried out directly in the presence of the nanoparticles) the
 20 polymer is not only forming an external layer but it is also diffusing inside the pores. This is less
 21 likely in the case of high molecular weight HA, where the polymer could mainly block pores
 22 entrance not allowing nitrogen molecules to diffuse within during BET measurements. On the other
 23 hand, method A, where HA activation is carried out before reaction with NH₂-MSN, results in a
 24 minor diffusion inside the pores, which are less obstructed to the diffusion of the nitrogen adsorbate
 25 used for gas-volumetric analysis. These considerations are in very good agreement with XRD and
 26 TEM observations, showing an apparently thicker HA layer on sample HA200B with respect to the

other two (compare Figure 1b with c and d). Finally, the mean pore diameter calculated by BJH method was combined with the a parameter calculated from XRD (distance between centres of the pores, see Figure S3), to calculate the apparent wall thickness. The values, summarized in last column of Table 1, clearly show an increase in the order HA200A < HA6.4B $\cong$ HA200B, in agreement with the above considerations.

3.2 Quantitative HA analysis

Quantification of HA ~~bonded~~ covalently linked to the NH₂-MSN particles was carried out by two independent techniques, namely TGA and the carbazole colorimetric test.

TGA was carried out from 30 to 1000 °C in air flow, in order to quantify the amount of organic groups anchored to the silica surface. This was calculated on the basis of the observed weight loss, normalized to the dry mass of the sample, *i.e.* after removal of physisorbed water around 100 °C (Figure S4). All MSN/HA samples show a consistent weight loss between *ca* 180 and 650 °C, which is higher with respect to parent NH₂-MSN, in the order HA200A < HA200B $\cong$ HA6.4B. The calculated amounts are summarized in Table 2. More details about the criteria used for quantification can be found in the Supplementary Material. In this context, it is sufficient to mention that samples HA200B and HA6.4B show very similar weight losses and curves slope, while HA200A has an intermediate profile, both in terms of quantity and curve shape, in very good agreement with the trends observed with textural and structural techniques, as described above.

Carbazole colorimetric test was also employed for HA quantification. As mentioned above, HA is a high molecular weight glycosaminoglycan, formed by a repeating disaccharide unit composed by D-glucuronic acid and *N*-acetyl-D-glucosamine. In this test HA is hydrolyzed in acid environment, so that monosaccharide units can form coloured adducts with carbazole through their glucuronic acid residues. This allows the quantification of HA through a simple optical measurement.

The values obtained with both techniques are resumed in Table 2, expressed as HA weight percentage. First of all, we underline the very good agreement between the two techniques.

Secondly, the results show that a definitely higher mass of HA has been linked to MSN with method B, irrespective of its molecular weight. Method A definitely yields a materials with lower (around one third) HA loading. This could be explained by the fact that in the latter case HA activation was carried out before reaction with NH₂-MSN. On the basis of gas-volumetric and TEM results, we infer that this could result in a more difficult diffusion inside the pores, so that mainly external aminopropyl groups were involved in the reaction. Finally, these results contribute to the interpretation of the structural and textural parameters of the MSN/HA samples, which appear to be mainly affected by the HA loading, irrespective of its molecular weight.

3.3 Qualitative HA analysis: infrared spectroscopy

Infrared spectroscopy is a powerful tool to investigate interface interactions in hybrid organic-inorganic materials. It can be used to assess the molecular structure of surface grafted functionalizing groups, and the weak interactions taking place between silica surface and adsorbed/encapsulated drug molecules [28, 50-58]. The spectra of parent NH₂-MSN and HA conjugated samples are reported in Figure 3, in the high and low frequency ranges (top and bottom panel, respectively). All samples were measured in transmission mode on self-supporting pellets, after RT evacuation necessary to remove adsorbed impurities and water, which would influence the spectral analysis (see for instance Refs. [28] and [57]). The spectrum of HA 200 kDa (measured in KBr) is reported for comparison in the Supplementary Material (Figure S5). The bands assignment discussed in the following is resumed in Table 3.

The spectrum of parent NH₂-MSN sample, reported for comparison, is similar to what already reported and discussed in the literature [28, 57]. Namely, it is characterized by a broad signal in the high frequency region (top panel), which is characteristic of hydrogen bonding interactions among surface Si-OH groups (silanols) and between these and the grafted aminopropyl functionalities. The presence of the aminopropyl groups is testified by the ~~components~~ bands (superimposed to the broad band described above) at 3370 and 3300 cm⁻¹ (antisymmetric and symmetric NH₂ stretching

1 modes, νNH_2 , respectively) and at $2930/2870\text{ cm}^{-1}$ (antisymmetric and symmetric νCH_2). The very
2 weak peak at 3734 cm^{-1} is related to hydrogen bonding acceptors and/or ~~geminal~~ geminal -Si(OH)₂
3 silanols, which were not consumed by the grafting reaction [57]. The corresponding fingerprints of
4 aminopropyl functional groups in the low frequency region (bottom panel of Figure 3) are the band
5 at 1595 cm^{-1} due to the NH_2 bending mode (δNH_2) and the weak δCH_2 features between 1500 and
6 1320 cm^{-1} .

7 The spectra of MSN/HA samples show interesting differences with respect to parent materials.
8 Namely, in the high frequency region an increase in the intensity and spectral breadth of the
9 absorption between 3700 and 2200 cm^{-1} is observed, in the order $\text{HA200} < \text{HA200 B} \cong \text{HA6.4B}$.
10 This can be clearly related to the presence of an extended hydrogen bonding network, both among
11 HA residues and between them and the silica surface. Indeed, the weak band at 3734 cm^{-1} related to
12 Si-OH groups is consumed, confirming the involvement of surface silanols in hydrogen bonding
13 interactions with HA.

14 Moreover, weak components bands can be also observed between 3200 and 3000 cm^{-1} , recalling the
15 typical spectral shape of hydrogen-bonding carboxylic acids. This indicates that not all the D-
16 glucuronic acid residues were involved in the formation of an amidic bond with the amino groups
17 present on silica. In agreement with the structural, textural and quantitative data discussed above,
18 the two samples prepared by method B are very similar and more affected by conjugation, at
19 variance with sample HA200A, showing an intermediate behavior.

20 The same trend is observed in the low frequency range (Figure 3, bottom panel). More in detail,
21 broad absorptions develop in the $1700 - 1500\text{ cm}^{-1}$ and $1450 - 1350\text{ cm}^{-1}$ ranges, with the same
22 order of intensity described above, *i.e.* $\text{HA200} < \text{HA200 B} \cong \text{HA6.4B}$. The δNH_2 signal at 1595 cm^{-1}
23 is clearly evident on sample HA200A, and as while it is only a shoulder in the other samples. This
24 indicates that not all aminopropyl functionalities reacted with HA, as expected for functional groups
25 lining the inner surface of the pores. Interestingly, the intensity of this band is higher on sample

HA200A, where a lower diffusion of HA residues inside the pores was inferred from textural and structural analysis (see above).

Concerning the new ~~spectral~~ features developing in this spectral region after HA conjugation, they can be safely ascribed to the formation of an amidic bond between the NH₂-MSN amino groups and the carboxylic acid functionalities of HA. Namely, the amide I band (ν CO) is observed at 1650 cm⁻¹, the amide II (δ NH and ν CN combination mode) at 1550 cm⁻¹, while the absorption between 1430 and 1350 cm⁻¹ is related to the numerous δ CH and δ OH vibrations of HA.

3.4 Interaction with water molecules

HA is a hydrophilic macromolecule, with interesting applications as wetting agent [59-61] or as polymer for surfaces modification. Indeed, recent studies reported about the use of HA to improve hydrophilicity and biocompatibility of chitosan films or scaffolds [62, 63]. Moreover, HA has been used to increase surfaces hydrophilicity to provide antifouling properties, as a result of reduced nonspecific protein adsorption [64-68]. In this work, the effect of HA conjugation on the hydrophilic character of MSN has been studied by carrying out water vapour sorption microgravimetric experiments. This technique has been recently employed by some of us to investigate the effect of different functional groups on the hydrophilic character of MSN [28].

Water adsorption/desorption isotherms at 28 °C were measured on the three MSN/HA, by gradually increasing the equilibrium vapour pressure in the 0- 20 mbar range (p/p^0 from 0 to ca 0.55). The results obtained on sample HA6.4B are reported in Figure 4 (top panel). Similar trends were observed on samples HA200A and HA200B (see Figure S6) and can be summarized as follows. Both primary and secondary adsorption/desorption cycles are characterized by a hysteresis loop, with higher water uptake measured during the desorption step, for each p/p^0 value. This can be explained by the slow diffusion of water interacting with the external HA layer surrounding the MSN. This implies that the equilibrium is probably not reached in the adsorption step within the time frame of the experiment (timeout of 60 minutes for each p/p^0 dosage). A small water amount is

1 not desorbed after the first desorption step, and in all samples the second cycle results in a slightly
2 higher water uptake. When comparing the secondary desorption curves on the three MSN/HA
3 samples, the following order of water uptake is observed: HA6.4B > HA200A $\cong$ HA200B (Figure
4 4, bottom panel).

5 The obtained results are at first sight surprising, when compared to what measured on the parent
6 NH₂-MSN material, where a maximum uptake of 6.7 wt% (3.7 mmol/g) was measured at $p/p^0 \cong 0.3$
7 and 25 °C [28]. This is sensibly higher with respect to what obtained on the MSN/HA samples (1.3-
8 1.7 wt%, see Table 4), indicating a decrease of in the water uptake of MSN after HA conjugation, in
9 contrast to what expected for the high hydrophilicity of the polysaccharide. However, the
10 explanation of this apparently puzzling results can be found through a more detailed analysis of the
11 measured isotherms. To this aim, the primary and secondary desorption curves of the samples have
12 been fitted with a Langmuir model, assuming that they are closer to the thermodynamic equilibrium
13 with respect to adsorption ones. The results from this analysis are summarized in Table 4, together
14 with the results for NH₂-MSN parent sample (data from Ref. [28]). First, we acknowledge the fact
15 that for all HA conjugated samples the agreement with the Langmuir model is satisfactory ($R^2 >$
16 0.99), which is not the case for NH₂-MSN ($R^2 = 0.9267$ for both cycles). Secondly, the set of
17 calculated K values (corresponding to the equilibrium constant of the adsorption process) are
18 consistent for the set of samples, ranging from 17 to *ca* 23, while for NH₂-MSN a value around 8.5
19 was found for both sorption cycles. These data clearly indicates that on the conjugated samples
20 water is mainly interacting with the external HA layer, where it is strongly adsorbed and cannot
21 freely diffuse inside the MSN pores, at least in the time frame and experimental conditions of the
22 experiment. This picture fits well with the higher K values and smaller uptake with respect to parent
23 NH₂-MSN.

24 Coming back to the comparison among the three samples (Figure 4, bottom panel) the calculated K
25 values are in the order HA200A < HA200B < HA6.4B. The last samples being the one with the
26 highest uptake, we can infer that the polysaccharide molecular weight influences its hydrophilicity.

1 On the contrary, water uptake on HA200A is almost identical to HA200B, irrespective of the
2 different loading. This supports the idea that, when dosed from vapour phase, water is strongly
3 adsorbed on the external HA layer with limited diffusion within the pores. This effect could limit
4 the diffusion of drugs to and from the material pores, as indicated by preliminary studies on drug
5 loading carried out in our group (not reported). Noticeably, samples HA200B and HA6.4B shows a
6 similar water/HA weight ratio (ranging from 0.07 to 0.09) with respect to the sample prepared by
7 method A (0.21-0.22). These data further support the picture obtained by characterization
8 techniques, indicating that sample HA200A is characterized by a different distribution of HA at the
9 pores entrance, with a consistent amount of unreacted amino groups. This could indicate an easier
10 diffusion of adsorbates (such as water molecules) and host drug molecules within the sample.

11

12 *3.3 Effect of HA on surface charge, aggregation and dispersity*

13 The electrophoretic mobility of the materials was measured to evaluate the effect of conjugation on
14 the particles ζ potential, which gives an indirect information about the surface charge in the Stern
15 layer. This parameter is affected by both the hydrodynamic diameter and the electric double layer
16 thickness, the latter being strongly influenced by the fluid ionic strength and pH. An estimation of
17 the double layer thickness as a function of the ionic strength can be used in the Henry equation, to
18 convert electrophoretic mobility into ζ potential values [69]. However, in this work ζ potential
19 values (summarized in Table 2) were calculated with the Smoluchowski equation (representing an
20 approximation valid for thick double layers), for direct comparison with the literature works in the
21 field [28, 70-73].

22 In aqueous solution, the amine group is positively charged while the carboxylic ones of HA show a
23 negative charge in relation to their pKa. Assessing the pKa of both covalently linked HA external
24 layer and aminopropyl groups is not straightforward, since both systems are intrinsically complex.
25 Indeed the pKa of amino-functionalized hybrid materials is **has been** the subject of extensive
26 research work, since the covalent bond and interactions with the inorganic surface can affect the

1 amino basicity [28, 57, 74-78]. In our work, ζ potential values in water change depending on the
2 amount and on the molecular weight of the conjugated HA. At equal HA molecular weight
3 (compare HA200A and HA200B, 2nd and 3rd lines in Table 2), the ζ potential decreases as the
4 amount of HA increases. Namely, HA200A (HA loading 6.6 wt%) shows a small but positive value
5 ($+14.3 \pm 1.3$ mV), while HA200B, with a HA loading almost triple is characterized by a negative ζ
6 potential (-19.8 ± 1.9 mV). Samples obtained by method B showed a more negative surface charge;
7 in fact, according to TGA and carbazole test, this method allows a more efficient conjugation.
8 Considering the different HA molecular weights of samples obtained by the same conjugation
9 method, HA200B showed a more negative surface charge with respect to HA6.4B, without clear
10 correlation with the HA loading. Measurements were also carried out on sample HA6.4A, which
11 was discarded for a more detailed characterization because of low HA loading (3.1 wt% as
12 measured by carbazole test, see Table 2) and scarce dispersity (see below). Indeed, this sample
13 shows a ζ potential value in water almost identical to NH₂-MSN, in agreement with the low
14 derivatization yield.

15 When the same measurements are carried out in PBS, a different trend is observed, in that almost
16 all samples show more negative ζ potential values. As recently reported, buffer ions can strongly
17 affect adsorption phenomena at the solid-liquid interphase of charged nanoparticles [73, 79, 80].
18 Marucco *et al.* pointed out how adsorption of phosphate ions from the buffer solution can influence
19 the particles surface properties and charge [79]. On the other hand, we cannot exclude the
20 competition of chloride (and Na⁺ and K⁺ cations, although at a lesser extent) in modifying the
21 effective surface charge of MSNs, in agreement with the work by Cugia et al. [73]. Indeed, in our
22 work all the three considered HA conjugated samples show a similar negative ζ potential value
23 (around -16 mV), irrespective of the values measured in water. On the contrary, parent NH₂-MSN
24 still shows a positive (though minor) charge and sample HA6.4A is almost neutral (-1.3 ± 0.5 mV).

1 These results cannot easily be rationalized due to the complex interactions of buffer ions with
2 nanoparticles [73].

3 DLS measurements were carried out to estimate the hydrodynamic sizes of all samples in both
4 water and PBS (Table 2). The average values are always higher than the size of the single particles
5 measured by TEM, indicating agglomeration. A slight decrease in the size is observed after HA
6 conjugation, particularly for high molecular weight and loading, indicating a positive effect of the
7 polymer against the MSNs tendency to agglomeration. Since our attention is focused on the
8 possibility to use these systems for pharmaceutical application, we have followed the evolution of
9 the hydrodynamic size with time. Figure 5 shows the results obtained on the more stable samples in
10 PBS, *i.e.* HA6.4B, HA200A and HA200B. All The samples show a slight increase of dimensions in
11 the first hours, and then reach a stable value, apart from sample HA6.4B which is characterized by
12 larger size and lower stability. These observations are reflected in the dispersity tests described
13 below.

14 The pictures acquired during dispersity tests in PBS are shown in Figure 6. In this case a higher
15 concentration was used (2 mg/ml vs 0.08 mg/ml used for both ζ potential and DLS measurements),
16 for easier visual observation. The samples with HA of higher molecular weight were better
17 dispersed with respect to parent NH_2 -MSN and HA6.4B, which started to precipitate after 4 h. On
18 the contrary, dispersity was dramatically improved after conjugation with high molecular weight
19 HA: HA200A and HA200B formed a stable suspension in PBS for more than 24 h. The enhanced
20 stability of these samples can be explained on the basis of their steric hindrance and of the
21 electrostatic repulsion among the stretched hydrophilic HA chains, reducing the possibility of
22 agglomeration and precipitation. Finally, as concern sample HA6.4A, its precipitation is already
23 complete already after 4 hours, in agreement with a ζ potential value close to zero measured almost
24 zero-charge. The dispersity tests carried out in DMEM +10% FBS showed a similar trend (data not
25 reported).

These data confirm the working hypothesis that HA conjugation is a simple and effective method for improving the dispersity and stability of the nanoparticles, which is in turn beneficial for blood circulation making the further intravenous injection possible. Moreover, our study points out how, irrespective of the similar measured ζ potential, which is influenced by the chemical nature of the buffer medium, the molecular weight of the conjugating macromolecule has a strong influence on dispersity.

3.4 Biological characterization

3.4.1. Analysis of cell surface CD44 expression

The HA receptor CD44, an ubiquitous transmembrane molecule, is expressed at low levels on the surface of several normal cells and overexpressed in many cancer cells [81]. The levels of receptor cell surface expression were preliminary evaluated on a panel of cancer cell lines (MDA-MB-231, JR8, A459, MCF7 and A2780) using anti-CD44 antibody and flow cytometry, with the aim to identify the cell models to be used for further *in vitro* studies. The results show that A2780 cells did not express detectable amount of CD44 whereas MDA-MB-231 cells display a very high expression (Figure 7). Thus, to evaluate the cytotoxic activity and the cellular uptake of the nanoparticles, MDA-MB-231 and A2780 cells were chosen as CD44⁺ and CD44⁻ cancer cells, respectively.

3.4.2 *In vitro* cytotoxicity

The *in vitro* cytotoxicity of NH₂-MSN and MSN/HA was evaluated after treatment of 24, 48 and 72 h in the concentration range of 1.5-25 μ g/ml. and The results showed that the nanoparticles were non-toxic for both cell lines demonstrating the good safety and biocompatibility of the carriers (data not shown). These data are in agreement with the results obtained with other HA decorated MSN [24, 36, 37, 40].

1 3.4.3 *In vitro* targeting analysis

2 Efficient cellular uptake is a major requirement for the therapeutic efficacy of nanoparticles
3 targeting. To test the targeting ability of our MSN we evaluated the cellular uptake of both FITC-
4 labelled NH₂-MSN and MSN/HA on MDA-MB-231 (CD44+) and A2780 (CD44-) cell lines by
5 both CLSM and FACS.

6 CLSM allowed **us to visualize** ~~visualizing~~ the cellular uptake and biodistribution of the
7 nanoparticles ~~by~~ **in** these two cell lines. As shown in Figure 8, in both cell lines MSN occurred in
8 the cytoplasm as clusters of different size; accordingly, previous **TEM** studies ~~at transmission~~
9 ~~electron microscopy~~ demonstrated that these nanoparticles are internalized by the cell via both
10 endocytosis and phagocytosis, and then accumulate into cytoplasmic vacuoles [82]. Moreover,
11 MSNs were never found inside the nucleus of MDA-MB-231 and A2780 cells, consistently with
12 previous observations ~~in the same or in different cell lines treated with these nanoparticles~~ [23, 24,
13 40, 82-85]. Although CLSM does not allow precise quantitation of cellular uptake, the amount of
14 internalized NH₂-MSN was apparently similar in the two cell lines, whereas HA6.4B and HA200B
15 were more abundant in MDA-MB-231 than in A2780 cells. This suggests that MSN/HA possess
16 significant selectivity for cells overexpressing CD44 receptors, ~~consistently~~ **in agreement** with our
17 results obtained with flow cytometry (see below).

18 In addition, microscopic observation of the samples revealed the absence of evident morphological
19 alterations in both cytoplasm (e.g. vacuolization) and nucleus (e.g. pyknosis, apoptosis), thus
20 confirming the high biocompatibility of NH₂-MSN and MSN/HA at the concentrations tested in this
21 study.

22 The morphological images obtained by CLSM are consistent with the flow cytometry analysis
23 performed in order to obtain a quantitative comparison between FITC labelled NH₂-MSN and
24 MSN/HA ~~nanoparticles characterized by different preparation methods and different HA molecular~~
25 ~~weight~~ (Fig. 9). After treating A2780 and MDA-MB-231 cells with the different MSN/HA, their
26 uptake in A2780 cells is moderately increased in a time **dependent** ~~depending~~ manner, but almost

irrelevant in comparison with MDA-MB-231 (Fig. 9A). In particular, the FITC mean intensity of MSN/HA200 (both A and B) was dramatically increased in MDA-MB-231 in comparison to A2780 (Fig. 9A, B). Concerning MDA-MB-231, we observed that the cellular uptake efficiency is increased over incubation time (up to 1h, when the uptake is near plateau, approximately 80%, Fig. 9C). Moreover, the cellular uptake efficiency is also dependent on the amount of HA on nanoparticles surface and on its molecular weight. In particular, we obtained a higher uptake of HA200B versus HA200A, demonstrating that the method B in which the activation of HA was carried out directly in the presence of the nanoparticles, improves cells uptake (Fig. 9B). In contrast, the mean intensity of FITC from the cells incubated with FITC labelled NH₂-MSNs without HA modification is lower and similar for both cell lines. These *in vitro* experiments confirm that MSN/HA can target CD44 over-expressing MDA-MB-231 cancer cells via the HA receptor-mediated endocytosis [84, 86] and phagocytosis [87] pathways, strongly highlighting the potential use of MSNs/HA as ~~more~~ **an** efficient approach for tumor-targeting treatments.

Conclusions

MSN/HA samples were prepared following two different conjugation procedures previously reported [36, 37] and using HA of two different molecular weight (6.4 and 200 kDa). The size of HA strongly affects its biological functions and its physico-chemical characteristics [35]. However, to our knowledge this is the first time that such a comparative study is reported, helping the scientific community working in the field to select the best strategy to obtain hybrid nanomaterials with good biological response and potential pharmaceutical applicability. More in detail, our systematic physico-chemical analysis points to the concerted effect of both HA molecular weight and loading ~~on MSN~~ in improving dispersity **of MSN**. With this respect, we have demonstrated that the ‘one pot’ method - in which HA is directly activated in the presence of the nanoparticles – is the most efficient, also in terms of possible scale-up.

1 Our results are also in agreement with recent reports about the importance of considering the
2 interaction of buffer ions with nanoparticles when assessing surface charge and related interphase
3 phenomena, which are of fundamental importance to rationalize results in physiological media [73].
4 Finally, *in vitro* tests on cancer cell lines demonstrated that MSN/HA are biocompatible and
5 preferentially target cells overexpressing the HA receptor CD44. Also in this context, the best
6 performances are obtained with the ‘one pot’ sample prepared using HA with high molecular
7 weight (HA200B). All these data suggest the potential use of MSNs/HA as ~~a more~~ efficient
8 approach for tumor-targeting treatments.
