25

26 **ABSTRACT**

27 *Background.* Human cytomegalovirus (HCMV) is the leading cause of congenital infections
28 resulting in severe morbidity and mortality among infected children. Although the virus is
29 highly polymorphic, particularly in genes contributing to immune evasion, the mechanisms
30 underlying its genetic variability and pathogenicity are only partially understood.

31 *Objectives.* We aimed to characterize different HCMV clinical strains isolated from 21
32 congenitally- or postnatally-infected children for *in vitro* growth properties and genetic
33 polymorphisms.

34 *Study design.* The growth of various HCMV isolates was analyzed in different cell culture
35 models. Genetic polymorphism was assessed by genetic and phylogenetic analysis of viral
36 genes involved in virulence (UL144, US28, and UL18), latency (UL133-138), or drug
37 resistance (UL54 and UL97).

38 *Results.* Here, we report a high degree of genetic and phenotypic diversity in distinct HCMV
39 clinical isolates, as shown by their *in vitro* growth properties. In particular, HCMV isolates
40 displayed the highest degree of genetic variability in the UL144 gene, where we were able to
41 define four distinct genotypes within the cohort based on UL144 heterogeneity. Lastly, among
42 all isolates we were able to identify 36 mutations in UL54 and 2 in UL97.

43 *Conclusions.* Our findings indicate that surprisingly high levels of genetic HCMV variability
44 correlate with a high degree of phenotypic polymorphism, which in turn might differentially
45 influence the growth, fitness, and drug susceptibility of HCMV.

46

47 **Keywords:** human cytomegalovirus (HCMV), congenital infection, clinical isolates, genetic
48 variability, viral phenotypes.

49

50

51 **HIGHLIGHTS**

- 52 • HCMV clinical isolates possess different *in vitro* replication properties
- 53 • They all share the same cell tropism, albeit showing different morphological patterns
- 54 • For the most variable gene, UL144, four distinct genotypes were defined
- 55 • In each HCMV isolate, we identified 36 mutations in UL54 and only 2 in UL97

56

57 **1. Background**

58 Human cytomegalovirus (HCMV), a double stranded DNA herpesvirus, is the most
59 frequent cause of congenital malformations worldwide, resulting in neurodevelopmental delay,
60 foetal or neonatal death, and most frequently sensorineural hearing loss [1–3]. It is
61 characterized by a large genome encoding a wide range of gene products, endowed of effective
62 immunomodulatory activity [4–6]. For instance, different viral genes encoding tumor necrosis
63 factor-alpha (TNF- α) receptor (UL144), α -chemokines (UL146-147), β -chemokine receptor
64 (US28) are potential virulence factors associated with severe congenital HCMV infection [7,8].

65 Mounting evidence suggests that HCMV can be highly polymorphic, among and within
66 hosts [9–13], with a high level of intrahost variability comparable to that of RNA viruses. It
67 has been demonstrated that new mutations occur every time that the virus infects a new host,
68 thereby giving rise to a unique viral strain for each infected individual. HCMV infection
69 triggers indeed a selection event where a new genotype becomes dominant due to the selective
70 pressure of the immune response [10]. Another possible explanation of this gap comes from
71 the observation that both viral and host factors can contribute to the onset of HCMV genome
72 mutations, thus fostering virus genetic drift during infection [14,15].

73 HCMV genetic variability, an emerging issue in drug resistance, represents another
74 major obstacle on the way to predicting clinical outcomes of HCMV congenital infections.
75 Currently, the only antiviral therapy available relies on nucleoside analogs, such as ganciclovir
76 (GCV) and valganciclovir (VAL-GCV) [3,16]. In this regard, evidence from adult transplanted
77 patients has shown that DNA polymerase (UL54) and viral phosphotransferase (UL97), two
78 highly polymorphic HCMV genes, seem to play a role in drug resistance against GCV [17].
79 However, further research is clearly needed to fill the lack of information on congenitally
80 HCMV infected children.

81 **2. Objectives**

82 Against this background, the aim of our study was to characterize the *in vitro* phenotype
83 and the degree of genetic polymorphism of HCMV virions freshly isolated from congenitally
84 or postnatally infected children, focusing on genes encoding potential virulence factors, such
85 as UL144, US28, UL18, or contributing to viral latency, such as UL133-138. In addition to the
86 aforementioned immunomodulatory genes, we also analyzed UL97 and UL54 to assess the
87 emergence of drug resistant strains within the enrolled group of patients. Finally, we
88 investigated a potential association between genotype and viral fitness.

89 **3. Study design**

90 *3.1. Patients and samples*

91 Twenty-one children diagnosed with congenital or postnatal HCMV infection were
92 recruited at the Neonatal Unit of the University of Turin from 2015 to 2017. Infection diagnosis
93 was based on RT-PCR HCMV DNA detection in patients' urine and blood samples. Urine
94 samples were collected during the admission medical examination. The Neonatal Unit created
95 a detailed database on clinical and pathological characteristics of recruited patients (indicated
96 as P), summarized in Table 1. All patients were evaluated for neurobehavioral development,
97 growth parameters, cerebral ultrasound, sight and hearing, antiviral and supportive therapy
98 [18]. In addition, they were subjected to a follow up of one year of clinical and neurobehavioral
99 tests for asymptomatic patients, and two years for symptomatic patients along with 6 years of
100 audiology tests.

101 *3.2. Cells and viruses*

102 Primary human foreskin fibroblasts (HFF, American Type Culture Collection, ATCC
103 SCRC-1041™), human retinal pigment epithelial cells (ARPE-19, ATCC CRL-2302™), and

human umbilical vein endothelial cells (HUVEC) were cultured as previously described [19]. For HFF infection with HCMV clinical isolates, urine samples were primarily inoculated in HFF in order to boost the infected cell population. The isolates were then propagated until approximately 60% of cells demonstrated a cytopathic effect. All isolates were used before passage 3 in order to avoid cell culture adaptation [20,21].

3.3. Viral replication analysis

The replication of cell-associated isolates was quantified by focus expansion assay (FEA), as previously described [22]. Plaque area was calculated using ImageJ software. Statistical analysis was performed using GraphPad Prism version 5.00 for Windows.

3.4. Immunofluorescence microscopy

Indirect immunofluorescence analysis was performed at 72h pi as previously described [23]. The following primary antibodies were used: rabbit polyclonal anti-human von Willebrand factor (vWF) (Sigma-Aldrich), anti-IEA (immediate early antigen; produced in Santo Landolfo's laboratory, University of Turin [24]), mouse monoclonal anti-IEA, UL44 (Virusys Corporation), and pan cytokeratin (Sigma-Aldrich). Signals were detected using goat anti-rabbit or goat anti-mouse conjugated secondary antibodies (Life Technologies). Images were taken with a 40× objective by fluorescence microscope Olympus IX-70, equipped with cellSens Standard - Microscopy Imaging Software (Olympus), and ImageJ software was used for image processing.

3.5. DNA sequencing

Genomic DNA was extracted from infected cells by heating the cell with lysis buffer (1.25 M NaCl, 62 mM Tris-Cl pH 8.0, 9 mM EDTA pH 8.0, 0.5% SDS) for 15 min, followed by ammonium acetate/chloroform treatment, and the target genes were amplified using Q5

High-Fidelity DNA Polymerase (New England BioLabs). Primers designed on human herpesvirus 5 strain Merlin sequence (NC_006273.2) and PCR conditions are listed in Table 2. The amplified products were purified and used for Sanger sequencing (Eurofins Genomics).

3.6. Phylogenetic analysis

Nucleotide sequences were multiple-aligned to match homologue regions along Merlin reference genome (NC_006273) or along the most similar reference genomes. The alignment was performed using Clustal W, included into Geneious software 9.1, and each gene evolutionary model was selected using jModelTest 2.1.7 [25]. Gene sequences were concatenated, and the phylogenetic tree was reconstructed using a Bayesian approach (MrBayes 3.2.5) [26]. The tree was visualized with FigTree 1.4.2 software (Tree Figure Drawing Tool Version 1.4.2 2006-2014, University of Edinburgh). Robustness of the internal nodes was reported as a posterior probability calculated on the consensus of all the equally probable topologies obtained by the heuristic search. Recombination events were evaluated by using DualBrother plugin in Geneious software [27], SpliTree [28] and SimPlot [29], considering both single genes and concatenated alignments. Association between concatenated tree topology and clinical parameters was investigated using BaTS algorithms evaluating Association Index (AI), Parsimony score (PS) and monophyletic clade (MC) size statistics.

3.7 Identification of mutations associated with antiviral drug susceptibility in HCMV clinical strains

To ascertain whether the *in vitro* growth variability of HCMV clinical isolates correlated with different degrees of drug susceptibility, we used the web-based search tool mutation resistance analyzer (MRA) is a platform linking identified HCMV drug resistance mutations to specific phenotypes (<http://www.informatik.uni-ulm.de/ni/mitarbeiter/HKestler/hcmv>) [30]. Detected mutations are then run through a

regularly updated database containing previously published UL97 and UL54 mutations and the corresponding *in vitro* drug susceptibility phenotypes.

4. Results

4.1. Phenotypic characterization of HCMV clinical strains

First, we carried out phenotypic characterization of HCMV isolates from all patients (P), with the exception of P13 and P19, in HFF. Interestingly, we observed a remarkable variation of fibroblast growth properties among the various isolates, with a high value range of infected foci per well (Table 3).

Since cell-free virus transmission is typified by a comet tail phenotype, while cell-associated transmission is characterized by plaques with well-defined edges [22], we sought to determine the transmission pattern of different HCMV clinical isolates by defining plaque morphology. Furthermore, to quantify HCMV replication, we calculated the relative plaque area in HCMV infected HFF. We found that among all isolates, P14 and P15 were those displaying the most aggressive/fast-replicative behavior (Fig. 1A upper panel). These results were also supported by virus plaque morphology analysis showing that P14 displayed larger and comet shaped plaques compared to P9 (Fig. 1A, lower panel). We observed the same infection pattern in HUVEC and ARPE-19 (Fig. 1B and C). Accordingly, in these two cell lines, plaque morphology and area analysis revealed a great heterogeneity (Figure 1B, C) even though the extent of viral growth in HFF did not exactly mirror that seen in HUVEC and ARPE-19. Indeed, in HUVEC P12 and P18 showed a statistically significant larger plaque area compared to that of P9, albeit to a lower extent with respect to P14 and P15, indicating that HCMV replication not only depends on its genetic background, but also on cell environment.

Fig. 1. Replication properties of HCMV clinical isolates. Viral replication was analyzed by focus expansion assay (FEA). Serial dilutions of HFF (A), HUVEC (B), and ARPE-19 (C) infected by clinical isolates were cocultured with an excess of uninfected HFF for 5 days. Monolayers were then fixed, and infected cells were traced by antibodies against HCMV immediate early antigen (IEA), followed by immunoperoxidase assay. Infectious foci were defined as clusters of at least three infected cells, starting from single late-stage infected cells. *Upper panel.* Plaque areas were calculated using ImageJ software. The red bars represent mean values. Differences were considered statistically significant for *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$ (one-way ANOVA followed by Bonferroni's post-tests, GraphPad Prism version 5.00 for Windows, for comparison of all isolates *versus* P9). *Lower panel.* Representative infectious foci of clinical isolates 9 (P9) and 14 (P14) are shown.

4.2. Definition of the endothelio- and epithelio-tropic phenotype of different HCMV isolates

Next, we assessed HCMV isolates for viral growth. The FEA in HUVEC and ARPE-19 revealed that all isolates retained their endothelial and epithelial tropism (Fig. 1 B, C). To rule out the possibility that inoculated infected HFF could overgrow to form infected foci within HUVEC and ARPE-19, we performed an immunofluorescence double staining for von

189 Willebrand factor (vWF) and pan cytokeratin (Fig. 2 A and B). Based on HCMV
 190 aggressiveness, epithelial cell infection resulted in two distinct morphological phenotypes (Fig.
 191 2). Whereas fast-replicative isolates, such as P14, formed enlarged flower-shaped syncytial
 192 foci, slow-replicative isolates, such as P9, were only visible as single mononucleated infected
 193 cells (Fig. 2A). These dual phenotypes were not observed in HUVEC, suggesting a distinct
 194 replication pattern among different cell lines and viral isolates (Fig. 2B).

195

196 **Fig. 2. Definition of the endothelio- and epithelio-tropic phenotype of different HCMV clinical**
 197 **isolates.** ARPE-19 (A) and HUVEC (B) were cocultured with an excess of HFF infected with
 198 representative HCMV clinical isolates (P9 and P14) or mock infected. Cells were fixed 72 h later for
 199 immunofluorescence analysis to detect HCMV immediate early antigen IEA (red) and the inherent cell
 200 markers: endothelial vWF (green) or epithelial keratin (green). Cell nuclei were counterstained with

201 4',6-diamidino-2-phenylindole (DAPI) (blue). Images were taken with a 40× objective by fluorescence
202 microscopy. The most representative infectious foci are shown.

203 4.3. Genetic characterization of HCMV clinical strains

204 To determine whether phenotypic changes were accompanied by alterations at the DNA
205 level, we performed comparative analysis of a set of genes encoding potential virulence factors
206 (i.e. UL144, US28, UL18), or contributing to viral latency (i.e. UL133-138), or associated with
207 drug resistance (i.e. UL54, UL97) (Table 2). For each region/gene, the sequences were aligned
208 and, based on the best GTR+ Γ evolutionary models, the Bayesian trees were drawn (Fig. S1-
209 S6). Given that HCMV often shows recombination events [31], the alignment was used to
210 create a split network (Fig. 3A), and a set of reference sequences was included. Statistically
211 significant evidence of recombination was identified along the concatenated alignment ($\Phi p <$
212 0.05) (Fig. 3A). Moreover, the SimPlot showed a great heterogeneity (Fig. 3B), reaching the
213 highest variability within the UL144 gene (Fig. 3C), found exclusively in clinical HCMV
214 strains.

215 Remarkably, UL144 amino acid sequence alignment from all HCMV isolates defined
216 four prevalent subgenotypes, namely A, B, C, and A/B (Fig. 4B). The majority of sequences
217 matched with genotype B, whereas those from the isolates P1, P12, and P20, closely related to
218 the Merlin reference strain, were classified under genotype A. Furthermore, sequences derived
219 from the P5, P18 and P21 isolates matched with genotype C, whereas only the P3-derived
220 amino acid sequence was listed under genotype A/B. Interestingly, we noticed that both the
221 P14 and P15 fast-replicative strains belonged to genotype B, indicating that the viral genetic
222 background can indeed determine viral fitness.

223 Noteworthy, considering both nucleotide (Fig. 3C) and amino acid sequences (Fig. 4A),
224 the most important finding deriving from the SimPlot is that the 5' region is the key to

discriminate the four genotypes. However, despite having a different genotype, we observed that almost all cysteines were conserved along the alignment, suggesting that distinct HCMV isolates may share a similar viral protein folding.

Finally, no statistically significant associations were found between the concatenated tree topology and any clinical parameter reported in Table 1, considering both global (AI and PS) and local (MCs) association parameters.

GenBank accession numbers of all sequences are reported in Table S1.

Fig. 3. Genetic analyses on HCMV clinical isolates. (A) Split network; (B) SimPlot of concatenated alignment; (C) SimPlot of UL144 alignment; mean nucleotide diversity among samples = 86.59% (range 73.0% - 100.0%). For both the SimPlots, Merlin strain was used as reference sequence.

Fig. 4. UL144 gene analysis. Amino acid alignment (A) and neighbor joining tree (B), based on amino acid sequence alignment, are reported. Dots indicate identical residue. Genotypes are indicated for each tree clade.

4.4. Antiviral drug susceptibility of HCMV clinical strains

Complete sequences of UL54 and UL97 from HCMV isolates were uploaded in MRA and compared to the wild-type sequence of the drug-sensitive HCMV strain TB40-BAC4 [32,33]. MRA identified 36 mutations in the UL54 gene associated with genetic polymorphism previously published [34–39], whereas only two mutations were detected in UL97, probably due to a major gene stability (Figure 5A and B) [35,40–43].

246 Interestingly, drug resistance-associated mutations varied among patients, especially in
 247 UL54 and to a lesser extent in UL97 (Figure 5A and B).

248

249 **Fig. 5. Antiviral susceptibility testing.** The heterogeneity of UL54 (A) and UL97 (B) genes is reported.

250 *Left panel.* The heat maps show the presence and the positions of amino acid changes, and the

251 histograms show the frequency of each modification. *Right panel.* The Bayesian tree describes the

252 genetic relationship among samples based on nucleotide alignment.

5. Discussion

The clinical and biological relevance of HCMV genetic variability in congenitally and postnatally infected children has been the focus of intense research over the past few years. In this study, we sought to determine whether and to what extent the differences in gene composition affected viral fitness. For this purpose, we enrolled 21 pediatric patients with confirmed congenital or postnatal HCMV infection. We evaluated the degree of genetic polymorphism of HCMV clinical strains by genetic and phylogenetic analyses, primarily focusing on viral genes involved in virulence, latency, and drug resistance. In parallel, we ran an extensive *in vitro* analysis of all clinical isolates to characterize viral growth properties and viral tropism in fibroblasts, endothelial and epithelial cells. Our results suggest that HCMV clinical isolates possess phenotypic differences as judged by both viral dissemination rate and replication properties, which define the extent of strain aggressiveness. Particularly, the two strains P14 and P15 were the most aggressive and fast-replicative ones because they could give rise to infectious foci characterized by comet-shaped plaques, typically observed in laboratory strains [22]. Altogether, these results support the hypothesis that HCMV heterogeneity may have an impact on viral fitness, influencing both viral dissemination rate and replication properties.

The reliability of such results could be inferred from the different cell lines employed for virus propagation and their low passage number (≤ 3) to ensure that no cell-culture adaptation had occurred [20,21]. All clinical isolates in the recruited group of patients were able to infect both epithelial and endothelial cells displaying no difference in their cell tropism, while they displayed a unique morphological pattern in cells infected with fast-replicative isolates. Interestingly, the enlarged flower-shaped syncytial foci typical of epithelial, but not endothelial, cells obtained with the most aggressive strains were similar to those observed by Tandon and coworkers in HFF infected with UL96-deleted Towne bacterial artificial

chromosome (Δ UL96BAC) [44], which could be partly ascribed to different maturation patterns between isolates.

The analysis of specific HCMV genome regions suggests that genetic variability among HCMV isolates may impact viral fitness. Indeed, here we report enhanced sequence diversity, identified thanks to the 5' region of UL144 alignment used as a discriminatory criterion. Interestingly, the high degree of nucleotide heterogeneity mirrors in the amino acidic sequence, indicating a considerable difference among UL144 genotypes. This is interesting, as UL144 is a potent NF- κ B activator [45] that plays a role in virus-mediated immune evasion [46,47]. This high heterogeneity of UL144 strongly influenced the split tree configuration based on the concatenated alignment, highlighting the role of this gene in the description of genetic relationships between CMV isolates. The same sample clustering has been demonstrated for both UL54 and UL97 genes, known to be involved in antiviral drug resistance. In both cases, the similarity among samples was high even though a number of previously reported mutations were identified in UL54 and to a lower extent in UL97. However, all treated patients so far responded to valganciclovir therapy. Nonetheless, we are not able to fully exclude the possibility that the reported mutations might have an impact on the antiviral therapy over a prolonged time.

It is highly likely that multiple strains of CMV are present in each patient of our group of patients, similar to cases being previously extensively reported in the literature [12]. However, we used an approach based on the Sanger sequencing of PCR products obtained from cell culture. The sensitivity of this method is strongly dependent on the relative frequency of viral variants. In particular, low-abundance viral populations are likely to be missed and the overall viral diversity to be underestimated. Thus, although sequence electropherograms did not show clear evidence of multiple signals (i.e., double peaks and/or high background signal), we can not exclude the presence of mixed infections. Further investigations can be carried out

to evaluate the role of mixed infections in pediatric infected patients, including PCR product cloning strategies or next generation sequencing approaches.

The limits of our study include the small number of the recruited patients, the short collection period (two years) in the limited geographic area. Besides, not all the analysis were available for all the samples, f.i. propagation and isolation of the virus failed for P13 (simultaneous presence of pathogenic bacteria and yeast in the patient's urine, since patient 13 was presented with severe sepsis at admission) and P19 (low viral load in urine sample).

In conclusion, our study may suggest that genotypic variability is associated with *in vitro* phenotypic diversity in HCMV clinical strains isolated from a group of congenitally and postnatally infected patients. In addition, our results indicate that genetic polymorphisms across the UL54 genome might play a role in multidrug resistance HCMV infection, pointing to UL54 as a potential therapeutic target to consider when treating congenital HCMV disease. This is, to our knowledge, the first detailed analysis that tries to associate in the same cohort of patients' genetic polymorphism and viral fitness. Although the results achieved so far do not allow any definitive conclusion, it emerges that a strong genetic HCMV variability is reflected in a remarkable phenotypic polymorphism that could affect virus growth properties and *in vivo* fitness.
