2. UV-Raman spectra of additional reference compounds

In Figure S1 some compounds useful in the operando experiments interpretation are reported.

Figure S1. UV-Raman (244 nm) spectra of: a) methylated benzenes; and b) other useful compounds.

The spectra have been acquired according to the experimental procedure previously described for polycyclic aromatics compounds.³
3. Simulation of the Raman spectra of selected methylated PAHs

Since their unavailability for measurements, the Raman spectra of some compounds of interest were simulated. The focus was in particular on the effect of methylation over the skeletal vibrational modes of PAHs: naphthalene, anthracene and phenanthrene were selected as representative model since their affordable computational cost. Calculation were performed with the Gaussian09 code (D03 release)\(^4\) at the B3LYP hybrid functional computational level,\(^5,6\) including dispersive forces according to the Grimme D3 scheme.\(^7\) The TZV2P basis set from Ahlrichs was exploited on C atoms, whereas a Pople’s 6-311++G(2d,2p) described H atoms.\(^8,9\) The “ultrafine” pruned integration grid (99 radial shells and 590 angular points per shell) was chosen to guarantee a good numerical precision necessary for a proper description of the flexible methyl groups. Each molecule was geometry relaxed, then a frequency calculation was performed. In order to better estimate the UV-Raman intensities (i.e. trying to account for resonance), the dynamic CPHF evaluation of Raman intensities was performed. The excitation energy was calibrated on the basis of the electronic transitions computed for the bare naphthalene, anthracene and phenanthrene molecules through TD-DFT. The discrepancy between simulated and experimental electronic transition wavelength was determined to be in average -12 nm. Thereby, the excitation wavelength in dynamic CPHF was set to 232 nm to simulate the experimentally exploited 244 nm excitation. The simulated vibrational frequencies have been scaled through the following linear relation, derived from the linear fitting of the \(\nu_{\text{exp}}\) vs \(\nu_{\text{calc}}\):

\[
\nu_{\text{calc,scaled}} = 4.86 + 0.97 \cdot \nu_{\text{calc}}.
\]

The simulated Raman spectra of single methylated naphthalenes, anthracenes and phenanthalenes are reported in Figure S2.
Figure S2. Calculated Raman spectra of a) bare naphthalene (N (calc)), 1-methyl-naphthalene (1-MN), 2-methyl-naphthalene (2-MN); b) bare anthracene (A (calc)), 1-methyl-anthracene (1-MA), 2-methyl-anthracene (2-MA), 9-methyl-anthracene (9-MA); and c) bare phenanthrene (P (calc)), 1-methyl-phenanthrene (1-MP), 2-methyl-phenanthrene (2-MP), 3-methyl-phenanthrene (3-MP), 4-methyl-phenanthrene (4-MP) and 9-methyl-phenanthrene (9-MP). Raman intensities have been computed through a dynamic CPHF approach simulating the 244 nm excitation. The experimental spectra (λ =244 nm) of naphtahlene (N (exp)), anthrace (A (exp)) and phenathrene (P (exp)) are reported for comparison. All the spectra are normalized to the maximum intensity peak for sake of visualization.

As demonstrated in Figure S2, a good agreement in terms of frequency is observed for the experimental and calculated spectra of the bare molecules, testifying the reliability of the computational approach. The dynamic CPHF approach, even being a rough approximation to the description of Raman resonance, is able to give a realistic result in term of intensities. Considering the effect of methylation of PAHs, simulation demonstrates as the high frequency region (above 1400 cm⁻¹) is slightly affected by the insertion of methyl groups in terms of peaks shift. Some variations in the relative intensities of these peaks are observed, however never resulting in a complete quench of the most intense modes. Conversely most of the spectral alterations involve the low frequency region (1200-1400 cm⁻¹), where each molecule exhibits its vibrational fingerprints as a consequence of the different methylation.
4. Full MS data

Figure S3 shows the full MS charts for the five operando experiments reported in this work. The following signals/molecules have been monitored (in brackets, their m/z ratio): methanol (31), dimethylether (45), ethylene (27), propylene (and higher alkenes) (41), xylene (representative for aromatics) (91). The sudden jumps observed in the MS signals in some cases (e.g. Beta, panel b) are ascribed to the loss of fluidization, who altered the flow outgoing the reactor until restored.

Figure S3. MS charts of the products stream analysis for: a) ZSM-5; b) Beta; c) Mordenite; d) ZSM-22; and e) SAPO-34, collected during the Raman experiments.
