13 **Abstract**

14 Deep Seated Gravitational Slope Deformations are characterized by low deformation rates although they can
15 experience partial-collapse phases or more rapid movements, especially in presence of active tectonic
16 structures. In the Central Italy, considering the high seismicity rate, seismic activity must be considered to be
17 an important trigger of deep slope movements. We aim to contribute to the research in this field by reporting
18 the results of a monitoring program on a Deep Seated Gravitational Slope Deformation in this region that
19 involves marly calcareous rocks. We documented the pre-seismic evolution of the phenomenon and measured
20 its seismically induced displacements during the earthquake sequence in 2016 and 2017 in Central Italy, which
21 largest events were magnitude 5.0-to-6.5.

22 A multidisciplinary approach that combines a field geomorphological survey, installation of permanent GPS
23 stations, and InSAR elaborations was adopted for this study.

24 The average ground motion rate of the slope deformation before the earthquakes was very low (<3 mm/y) and
25 not spatially homogenous, as detected by GPS and InSAR. In detail, the uppermost area of the slope instability
26 likely moves faster than the lowest sector.

27 On the other hand, GPS and InSAR recorded significant step-like movements, one to ten times higher than the
28 normal activity rate, triggered by the magnitude 5.0-to-6.5 earthquakes. In detail, the movement mainly
29 depended on the magnitude of the earthquake and the distance from the epicenter, and only secondarily on
30 the number of large magnitude earthquakes on a given day.

31 In conclusion, we furnished monitoring data on the activity rate of a Deep Seated Gravitational Slope
32 Deformation in seismic context, we indicated two sectors of the investigated deformation that resulted more
33 unstable and we proved that the combination of InSAR and GPS data is a useful monitoring system for
34 earthquake-activated, slow-moving slope instabilities.

37 **1.1. Introduction**

Deep-seated Gravitational Slope Deformation (DGSD) is a generic term indicating rock-mass movements that encompass entire hillslopes or valley flanks (Dramis and Sorriso-Valvo, 1994; Agliardi et al., 2001) and that show diagnostic geomorphic features such as double ridges, trenches, and counterslopes (Goguel, 1978; Dramis and Sorriso-Valvo, 1994; Crosta and Zanchi, 2000; Crosta et al., 2013; Pánek and Klimeš, 2016). DGSDs are usually characterized by low deformation rates (few millimetres to 1-2 cm per year) and their activity is related to many factors, including seismic activity, erosional processes, rainfall, and post-glacial *debuttressing* (Radbruch-Hall, 1978; Bovis, 1982; Miller and Dunne, 1996; Crosta and Zanchi, 2000; Crosta et al., 2013). In spite of their low deformation rates, DGSDs can also experience acceleration and/or partial-collapse phases, which represent a significant hazard to people and infrastructures (Dramis and Sorriso-Valvo, 1994).

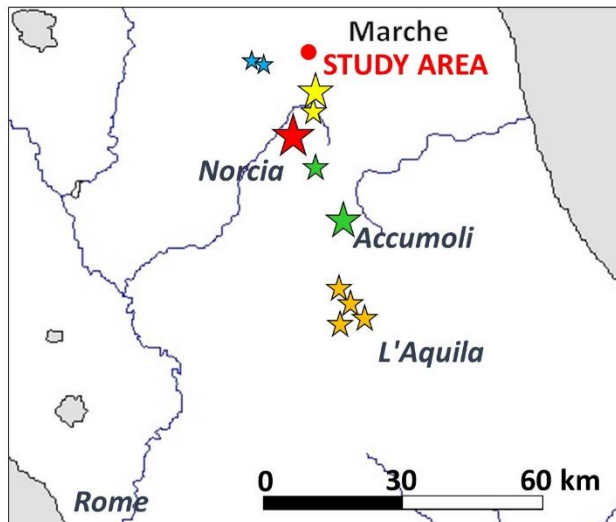

As highlighted by Pánek and Klimeš (2016), research on DGSDs has substantially increased in the past decade, with a focus on the application of monitoring techniques, the characterization of long- and short-term evolution, and the susceptibility to catastrophic collapses. However, there are still outstanding issues, including the need to better determine triggers and characterize changes in the movement rate of DGSDs. Before the first monitoring and dating studies, creep was considered to be the dominant mode of DGSD motion (Varnes et al., 1990). Although recent studies confirm that creep is the main mechanism (McCalpin and Irvine, 1995; McCalpin et al., 2011), in many cases data documented episodic and more rapid movements, especially in presence of active tectonic structures (McCalpin and Hart, 2003; Gutiérrez et al., 2008; Moro et al., 2012).

Some authors have recently investigated the correlation between seismic activity and DGSDs movement (Moro et al., 2007, 2011, 2012; Gori et al., 2014; Materazzi et al., 2015; Polcari et al., 2017). These authors documented coseismic displacements of DGSDs during magnitude (M_w)>5.0 earthquakes using Synthetic Aperture Radar Interferometry (InSAR) data and performing paleoseismological analysis. All of these studies were conducted in the central Apennine, a seismically active mountain chain in Italy, where DGSDs and active faults are common. All authors reported evidences of episodic instantaneous DGSDs reactivation. In particular, in two cases, they linked these movements to the Colfiorito earthquake, which happened in Central Italy on September 26, 1997 (Moro et al., 2007; Materazzi et al., 2015) and, in one case, to the L'Aquila earthquake (Moro et al., 2011), which occurred on April 6, 2009, about 80km south of the previous one.

Moreover, after the M_w 6.0 Accumoli earthquake, occurred on August 24, 2016 about 40 km south of Colfiorito, Aringoli et al. (2016) documented DGSDs reactivation in the epicentral area.

The Accumoli earthquake was the first of a series of earthquakes that struck Central Italy between 2016 and 2017, severely damaging tens of villages and causing several fatalities. The seismic sequence includes an M_w 5.4 aftershock, one hour after the M_w 6.0 main shock, and tens of thousands smaller aftershocks, which pursued until the middle of September when the numbers of aftershocks decreased to about 100 earthquakes/day (Michele et al., 2016). Two months later, on October 26, M_w 5.9 and M_w 5.4 earthquakes occurred 20-30 km north of Accumoli, preceding the largest event of the sequence, an M_w 6.5 quake on October 30, 6 km north of Norcia (Fig. 1). All of the earthquakes had hypocenters at about 7-9 km depth along normal fault planes.

A series of earthquakes happened on January 18, 2017, 20 km south of the first event of the seismic sequence, damaging villages in the province of L'Aquila. The four strongest earthquakes of this series happened within four hours and had sources at depths of 9-10 km (Fig. 1).

Earthquake date and related epicenter: August 24, 2016 October 26, 2016
 October 30, 2016 January 18, 2017 February 3, 2017

Fig. 1. Distribution of the epicentres of the largest earthquakes (M_w 5.0-to-6.5) of the 2016-2017 seismic sequence.

Considering the high seismicity of Central Apennines and that only 10% of DGSDs in this area can be explained by post-glacial *debuttressing* of formerly glaciated slopes (Aringoli et al., 2011), seismic activity must be considered an important trigger of deep slope movements in this region. Thus, investigations on the relation between historic earthquakes and DGSD motion is crucial for quantifying: i) the amount of any co-seismic DGSD displacements, ii) the minimum moment magnitudes and iii) the maximum distance of earthquakes capable to trigger movements.

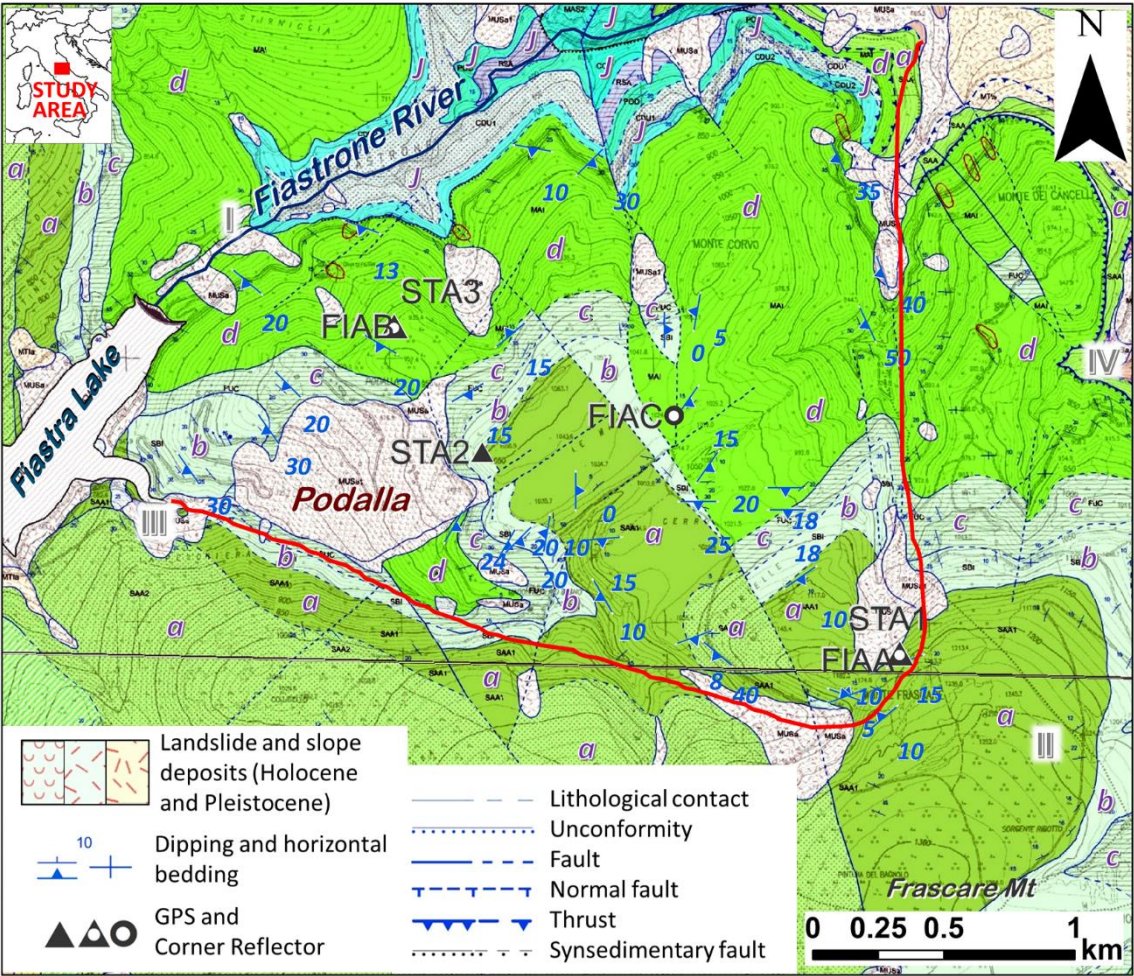

We aim to contribute to the aforementioned issues by reporting the results of a monitoring program of a DGSD in Central Italy. We documented the pre-earthquakes evolution of the phenomenon and measured its seismically induced displacements during the 2016-2017 seismic sequence through GPS permanent stations and InSAR.

1.2. Geological and geomorphological context of the Fiastra DGSD

Our case study is located in Marche region, on the east side of Central Apennines. The investigated slope extends northward from the top of Mount Frascare, about 1300 m a.s.l., to the Fiastrone valley floor at about 600 m a.s.l. The Fiastra hydroelectric reservoir is located on the valley floor, and its dam lies at the foot of the investigated slope (Fig. 2).

The Jurassic and Cretaceous units of the marly-calcareous Umbro-Marchigiana stratigraphic succession (Lower Lias–Upper Eocene) underlie the study area (Calamita, 1994; Deiana et al., 2009). In detail, the following formations widely outcrop in the investigated slope: Maiolica Formation (Upper Tithonian – Lower Aptian), Marne a Fucoidi Formation (Lower Aptian – Upper Albian), Scaglia Bianca Formation (Upper Albian - Lower Turonian) and Scaglia Rossa Formation (Lower Turonian – Lutetian) (Aringoli et al., 2010) (Fig. 2). Maiolica has a total thickness up to hundreds of meters and is made of whitish limestone with concoidal fracturing and gray

103 or black chert (Deiana et al., 2009). The Marne a Fucoidi Formation consists of reddish, green and yellowish
 104 marls and clayey marls, and an overlying unit of whitish marly limestone; it is about 60 m thick (Deiana et al.,
 105 2009) and is the softest rock in the study area. Scaglia Bianca is a whitish limestone and marly limestone with
 106 black to reddish chert, 60-70 m thick (Deiana et al., 2009). Finally, the Scaglia Rossa Formation is composed of
 107 reddish limestone and marly limestone with red chert, and is several tens of meters thick (Deiana et al., 2009).

108
 109 *Fig. 2. Geological map of the study area (modified after Carta Geologica Regionale 1:10000 – Regione Marche,*
 110 *2014): a) Scaglia Rossa Fm – several members; b) Scaglia Bianca Fm; c) Marne a Fucoidi Fm; d) Maiolica Fm; J)*
 111 *Jurassic formations. I-II and III-IV represent the traces of the geological sections. Red line indicates the area*
 112 *involved in the slope deformation.*

113
 114 The Umbro-Marchigiana succession underwent a compressive deformation during the Tortonian-Messinian,
 115 which generated the Apennine chain (Calamita, 1994). At that time, a sequence of thrust faults formed,
 116 producing shortening and tectonic overlaps. A shallow thrust plane that dips approximately 10° northwestward
 117 (Figs. 2 and 3) is present in the study area and the outcropping rocks are folded along an axial plane that strikes
 118 about N170°.

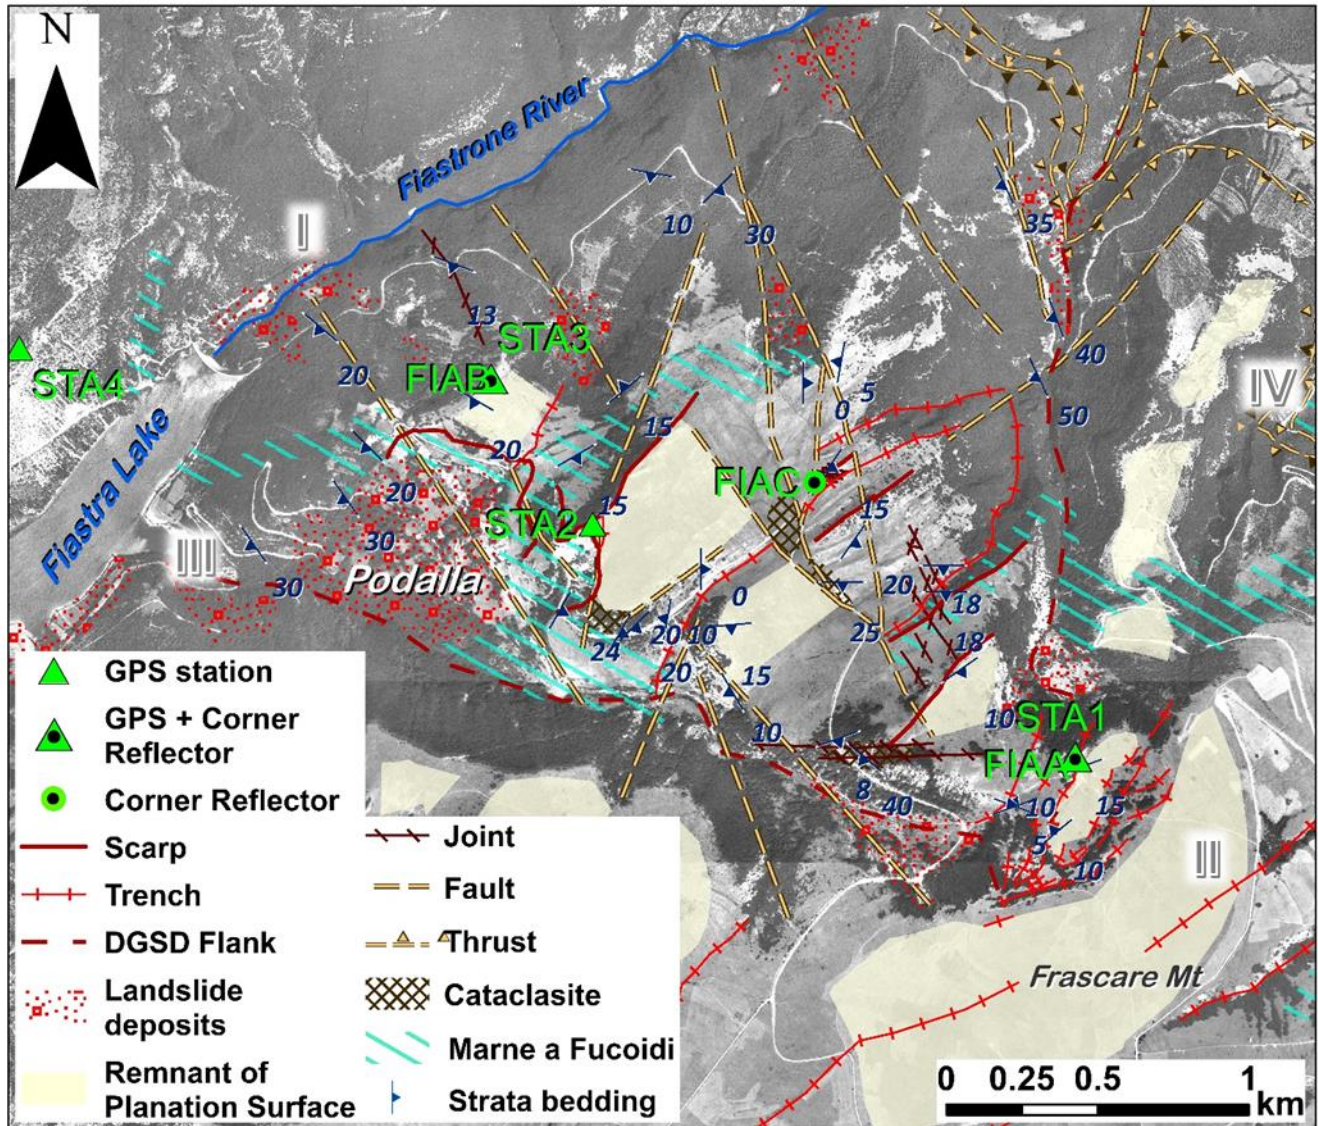

Fig. 3. Geomorphological map of the study area (modified after Tolomei et al., 2013). I-II and III-IV represent the traces of the geological sections.

Along almost the entire Apennine chain, the relief frequently results shaped by a gentle, rounded, high-elevation planation surface – the *Paleosuperficie* (Demangeot, 1965; Raffy, 1979). “Planation surface” is a descriptive term for a geographically plain surface resulting from erosion (Brown, 1969) and has not a genetic implication (Small, 1978). Coltorti & Pieruccini (2000) suggests that this surface was modelled very fast during the Lower Pliocene transgression.

Since the Late Pliocene/Lower Pleistocene, Central Apennines was the site of extensional tectonics related to a regional uplift that led to the opening of several intermontane basins and still goes on (Cavinato et al., 1994; Centamore et al., 2003). Related to this, the following systems of faults, with normal or transpressive kinematics, have been recognized in the study area (Figs. 2 and 3): Apenninic system (N150°–170°), anti-Apenninic system (N30°–50°) and N–S system (Aringoli et al., 2010; Tolomei et al., 2013).

133 The strong Pleistocene uplift induced the erosion of the planation surface that was incised by rivers and
 134 dissected by extensional tectonic structures. Minor erosional surfaces were modelled within the evolving
 135 drainage network and the remnants of the former *Paleosuperficie* were only locally preserved (Coltorti and
 136 Dramis, 1995).

137 In the study area, the Fiastrone River follows an important N30°–50° fault and formed a deep gorge at the toe
 138 of the investigated slope. Remnants of the Pleistocene planation surface are preserved in the study area,
 139 although they are displaced by numerous steps, counterslopes and meter-scale scarps related to the DGSD
 140 activity (Fig. 3). In detail, a system of trenches located over an area about 1 km long and 400 m wide, are
 141 present on the upper part of the slope. The trenches have a slightly curved shape, are roughly NE-SW oriented,
 142 up to 10 m deep, 20-30 m wide, and 800 m long (Figs. 3 and 4a, b). The largest ones are mostly vegetated and
 143 filled with debris (Fig. 4a, b), while the youngest ones are smaller, narrower and contain no debris or
 144 vegetation (Aringoli et al., 2010).

145
 146 Fig. 4. a) and b) Upper trench of the Fiastra DGSD, close to STA1; c) Photo of Podalla landslide taken from STA4;
 147 d) New scarp formed in the upper trench, close to STA1, as consequence of the October 30, 2016 earthquake.

148 The presence of these features led to Tolomei et al. (2013) to state that the Fiastra DGSD (hereinafter FD) is a
 149 *sackung*, which is slowly moving towards the NNW along a gently dipping sliding plane and is upward bounded
 150 by curved trenches (Fig. 3). Previous studies (Aringoli et al., 2010; Tolomei et al., 2013) consider that the
 151 shallow thrust to the east (Figs. 2 and 3) is favourably oriented with respect to FD block movement and is a
 152 potential detachment surface. Moreover, Tolomei et al. (2013) observed an acceleration period in the FD InSAR
 153 time series that started at the end of September 1997. Therefore, they do not exclude that, as observed for
 154 other DSGSD in the area by Moro et al. (2007), FD was reactivated, at least locally and for a short period, by the
 155 M_w 5.7 and M_w 6.0 Colfiorito earthquakes, which occurred on September 26, 1997, 20km far away.

156

157 **1.3. Material and methods**

158 A multidisciplinary approach that combines field geomorphological survey, installation of permanent GPS
159 stations, and InSAR elaborations was adopted for this study. The geomorphological survey was carried out to
160 locate the best places to install four GPS stations and to update the existing cartography by mapping trenches
161 and the remnants of the planation surface. Four corner reflectors were placed next to the GPS stations for
162 satellite SAR acquisitions (Figs. 2 and 3).

163 The GPS network consists of four single-frequency stations (L1), using U-BLOX M8T chipsets, that transfer data
164 in real time to the analysis centre at the Istituto Nazionale di Geofisica e Vulcanologia (INGV) in Rome (Italy)
165 since October 2015. Three stations (STA1, STA2, and STA3) are distributed along the FD slope, close to the most
166 significant geomorphological features of the DGSD; the fourth station (STA4) was placed on the opposite side
167 of the valley and represents the reference point to which the measurements at the other three stations are
168 referred (Fig. 3). STA1 and STA3 were previously equipped with double frequency receivers (Leica GX1230),
169 named respectively FIAA and FIAB (Fig. 3) that operated from December 2014 until December 2016, thus
170 acquiring one year of simultaneous observations. The single and double frequency stations were operated
171 jointly to facilitate comparison of the results and for calibration purposes.

172 During the seismic sequence, the reference station (STA4) moved as consequence of ground shaking thus, we
173 calculated the variation in length of the baseline between the uppermost (STA1) and the lowermost (STA3)
174 stations and we used it as proxy to estimate the FD co-seismic deformation.

175 During the earthquakes on January 18, 2017, the GPS stations were buried by snow and stopped transmitting
176 for one week. Moreover, STA2 suffered a transmission problem and only resumed operation following a site
177 visit on March 24, 2017. Thus, we do not have the co-seismic displacements of the GPS points during the
178 January 2017 earthquakes, and could only compare their positions before and after the seismic events.

179 The single frequency GPS data were processed using NDA-Lite software (Chersich and Curone, 2011). We show
180 the time series and the map view of the three stations in the FD area in Figs. 9 and 10 respectively, as well as
181 the variation in length of FIAA-FIAB/STA1-STA3 baseline (Figs. 11 and 13). The double frequency GPS data were
182 processed with BERNES software (Beutler et al., 2007) using a standard analysis procedure (Devoti et al.,
183 2011). We plotted the resulting FIAA-FIAB/STA1-STA3 baseline time series with those of potential triggering
184 factors (i.e. temperature, rainfall, and earthquakes) to determine which of the triggering factors is more
185 important (Figs. 11 and 13). Meteorological data have been taken from the station at Pintura, about 10 km
186 south of the study area.

187 The InSAR analysis have been performed with X-band Cosmo-SkyMed (CSK) and C-band Sentinel-1 data, which
188 cover both valley walls of Fiastrone River and Fiastra Lake. In particular, CSK dataset used in this work consists
189 of 29 SAR images acquired from February 2011 to October 2015. They were acquired along descending orbit
190 with an incidence angle of $\sim 34^\circ$ and an azimuth angle of $\sim 169^\circ$. The data were multi-looked by factors 5x5 to
191 reduce the speckle noise thus obtaining a pixel size of about 10m along both range and azimuth directions. We
192 applied the InSAR technique estimating 195 interferograms by setting the thresholds for the maximum
193 perpendicular and temporal baselines to 800m and 500days, respectively. The topographic phase component
194 was removed by the 10 m TINITALY Digital Elevation Model (DEM). Then, we exploited the multi-
195 baseline/multi-temporal Interferometric Point Target Analysis approach in the framework of the GAMMA
196 software packages (Werner et al., 2003) for retrieving the point time series of the observed scene.

Concerning the Sentinel-1 SAR data, the results have been already presented in Polcarì et al. (2017). The InSAR analysis was performed by means of two pairs of descending data acquired on August 21st and 27th 2016, and on October 25th and 31st 2016. The two retrieved interferograms were filtered by Goldstein filtering (Goldstein and Werner, 1998) and unwrapped by using the Minimum Cost Flow phase unwrapping algorithm (Costantini, 1998). The 30 m SRTM DEM was exploited to remove the topographic component.

1.4. Results

Based on field survey, we mapped the remnants of the planation surface throughout the study area. It is generally linear and has a low gradient. Its shape has been probably influenced by the gently dip of the strata ($<20^\circ$) although the latter changes according to the presence of tectonic features as the main normal faults and the thrust plane (Fig. 3). Scarps and trenches related to slope instabilities abruptly interrupt the spatial continuity of the planation surface even outside the FD area, indicating that several portions of the southern flank of Fiastrone valley are affected by gravitational slope deformation (Fig. 3).

In detail, the presence of trenches at the summit, as well as counterslopes, many other trenches and scarps in the middle part of the slope (Figs. 3 and 5) led to concur with Tolomei et al. (2013) that FD is a *sackung* type deformation.

216 Fig. 5. Google Earth image including the main features of FD.

217

218 Moreover, by analysing the stereonet of the main tectonic and geomorphological features mapped during the
 219 field survey, it resulted that many scarps are parallel to fault directions, as like the right flank of FD, testifying a
 220 structural influence on the FD shape. On the other hand, the left flank of FD appears to be almost
 221 perpendicular to many fault directions, as like to some scarps and trenches, indicating that its formation may
 222 be the direct consequence of the FD movement and has not to be necessarily related to pre-existing planes
 223 (Fig.6). The orientation of all the geomorphic features, and their distribution (Fig. 5), allows to confirm that the
 224 expected direction of movement of FD is NNW.

225

226

227 Fig. 6. Stereonet has been computed trough Daisy 3 software.

228

229 If we consider the intersections between the FD flanks and both the bedding and the thrust plane, we observe
 230 that the intersections occur at lower angles than the slope angle, indicating the presence of potential sliding
 231 surfaces favourably oriented with respect to the slope. In particular, the intersection with the thrust plane is
 232 closer than the bedding to the slope projection (Fig. 6). This means that the bedding planes would require
 233 lower friction angle than the thrust plane in order to be kinetically free. This allows to state that strata bedding
 234 is not likely to be a preferential predisposing factor for the FD sliding and this can be seen as the consequence
 235 of the general low dipping of the strata and their highly variable direction.

236

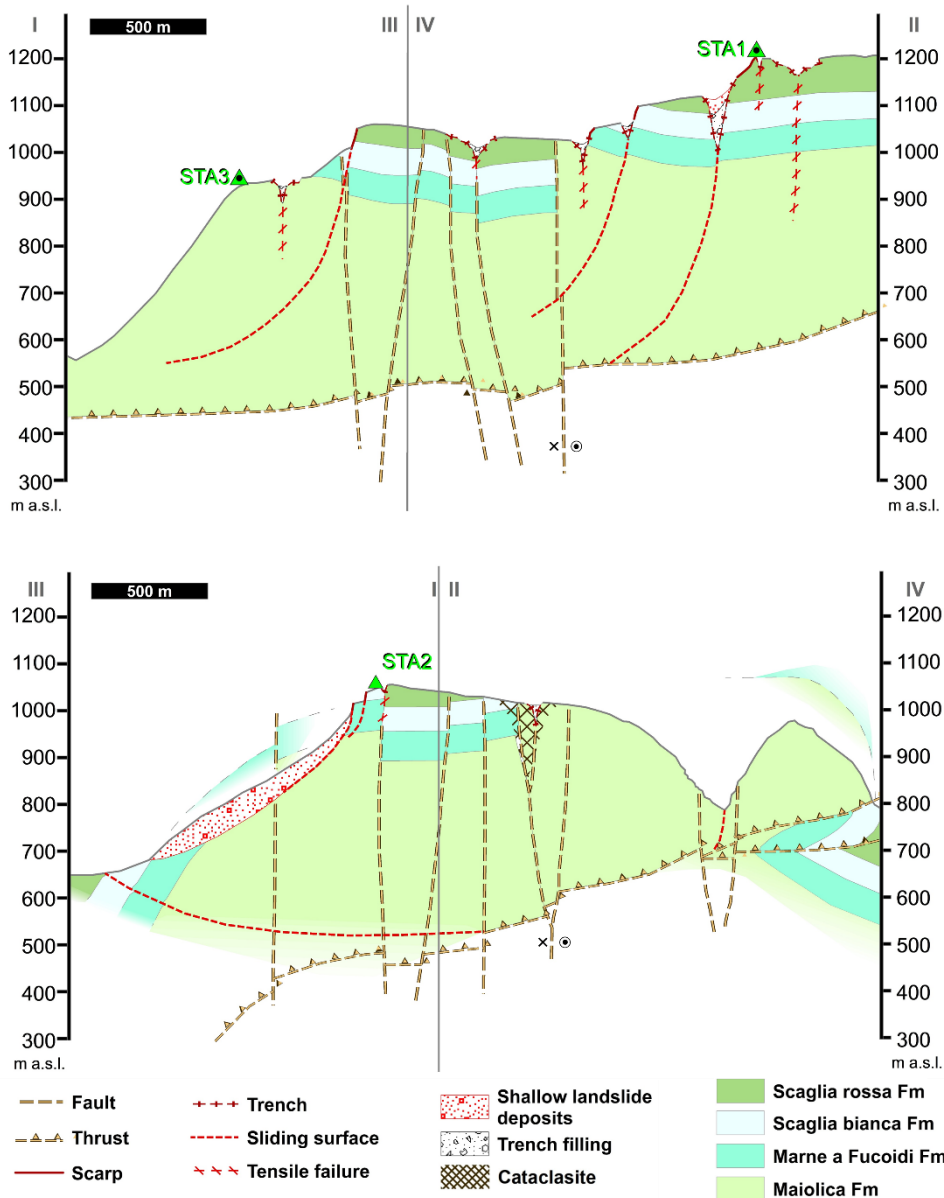

Fig. 7. I-II and III-IV geological sections. Vertical exaggeration is 2:1.

However, the proposed schemes should be validated with underground data to be completely reliable. At this stage, they only represent a hypothesis to describe the internal structure of FD.

To conclude, on the left flank of FD, we mapped the main scarp of the Podalla landslide, a minor and shallower failure (Figs. 3, 4c, 7 and 8) that shows signs of possible reactivation and was already studied by Aringoli et al. (2010). In this site, strata bedding is parallel to the slope, Marne a Fucoidi Fm widely outcrops and the lower part of the slope is covered by landslide deposits consisting of decimetric to metric calcareous blocks (Figs. 2, 3 and 7). Moreover, a rockfall source area is present upslope of the main scarp of Podalla landslide and shows features of an incipient enlargement, such as fractures. Here STA2 was placed (Fig. 8). Based on the field survey and the geological section (Fig. 7), we conclude that the Podalla landslide may be considered as a rockslide probably induced by the dipping of the strata and the presence of Marne a Fucoidi Fm, as previously stated by Aringoli et al. (2010). This instability may also induce the uppermost rockfall causing a general retreat of the slope parallel to the left flank of FD.

Fig. 8. Google Earth image including the main features of Podalla landslide.

The three GPS stations recorded significant movements, both horizontal and vertical, during the largest seismic events ($M_w > 5.0$) of the 2016-2017 seismic sequence in Central Italy (Fig. 9). However, at the time of the first

267 two earthquakes, only STA1 experienced significant changes in its position, above the slow background rate,
268 with about 20-30 mm of movement toward the NNW and about 30 mm downward (Figs. 9 and 10).

269

270 Fig. 9. Movement of each GPS station along vertical, east-west, and north-south directions from October 2015
 271 to March 2017; vertical green lines indicate the occurrence of the largest earthquakes (M_w 5.0-to-6.5).

272
 273 Fig. 10. Horizontal displacement of each GPS station during the main earthquakes: blue points indicate the
 274 hourly estimates of the position of the station, red arrows indicate the movement vector of the GPS station
 275 along the horizontal plane at the time of the earthquakes, the occurrence of the seismic event and the
 276 correspondent displacement is written close to the arrows. When technical problems occurred during the
 277 earthquake, the correspondent displacement refers to longer periods.

278
 279 Later, during the October 30, 2016 earthquake, which was the strongest of the whole sequence (M_w 6.5), all
 280 three GPS stations recorded appreciable movements (Figs. 9 and 10). STA1 moved about 85 mm toward the
 281 NNW (Fig. 10) and 40 mm downward (Fig. 9), STA2 moved 9 mm westward (Fig. 10) and about 20 mm
 282 downward (Fig. 9), and STA3 moved 6 mm toward the NE (Fig. 10). The ground shaking also produced some
 283 field evidences generating a new, centimetric, scarp in the calcareous bedrock cropping out near to STA1 (Fig.
 284 4d).

285 Finally, although we could not directly measure the co-seismic displacement stemming from the $M_w > 5.0$
 286 earthquakes on January 18, 2017, STA1 and STA3 showed about 15 mm movement toward NNW (Figs. 9 and
 287 10) and STA2 recorded a westward displacement of 90 mm after we restored the antenna some weeks later
 288 (Fig. 10). This rather high displacement may be affected by an unknown deformation caused by the snow cover
 289 or bad weather conditions. Nevertheless, as mentioned above, STA2 is upslope of the main scarp of the Podalla
 290 landslide (Fig. 8) and the westward movements experienced during the earthquakes are consistent with
 291 potential direction of movement of the instability.

Fig. 11. Variation in the length of STA1-STA3/FIAA-FIAB from December 2015 to August 2016, measured with double frequency antennae and plotted with daily mean temperature (green line) and daily rainfall (blue histogram).

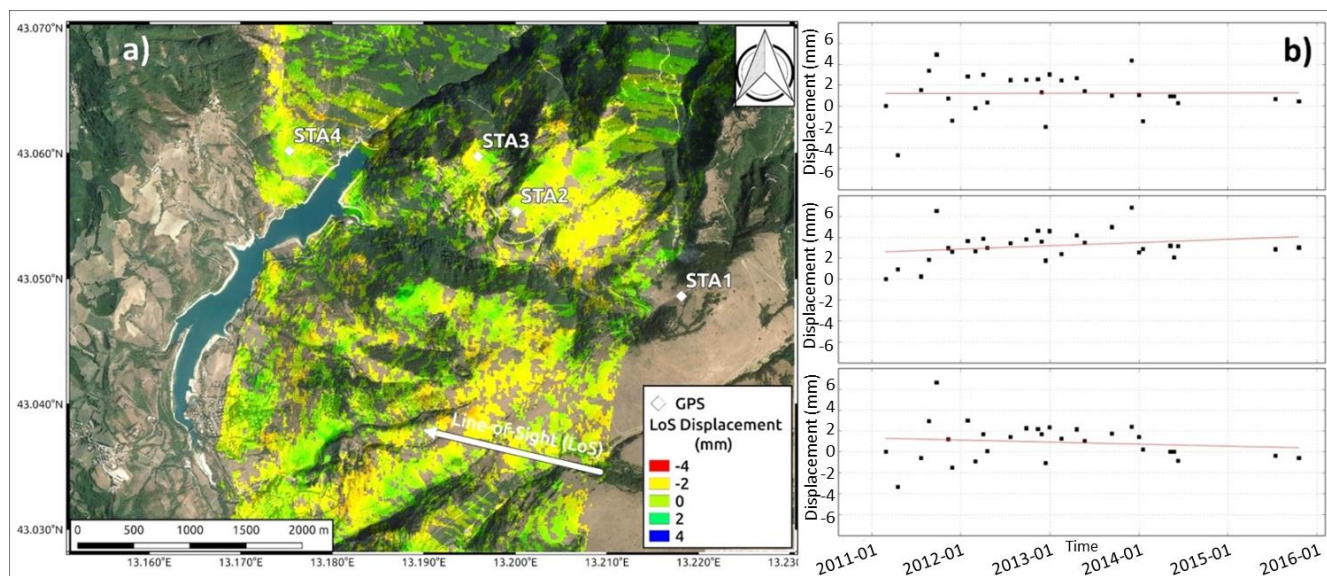

Figures 11 and 13 show the daily estimates of the length of the FIAA-FIAB baseline (Cartesian distance) before and during the earthquakes. Before the seismic sequence, from December 2014 to August 2016, the average baseline shortening rate was about 5mm/y, as detected by both single and double frequency GPS (green and blue dotted lines in Fig. 13). We detected increasing rates during cold periods (light blue in Fig. 11) and reduced rates in summer (red line in Fig. 11). In particular, we observed shortenings of 17 and 7.4 mm/y in winter and 3.5 and 4 mm/y during warmer periods (Fig. 11). This shortening does not seem to be related to rainfall (blue histogram in the upper part of the Fig. 11). In general, the shortening of the baseline can be attributed to different movement rates between STA1 and STA3. In detail, the uppermost station (STA1) is most likely the moving site that causes the progressive decreasing of the distance between the two stations observed in Fig. 11.

In winter, temperatures are frequently below 0°C, thus we might interpret the higher shortening rates as due to ground volume changes that are probably related to shallow processes due to freeze-thaw cycles. The lower rates (<5mm/y) movement in warm periods can be considered representative of the DGSD activity, because no external processes appear to be involved.

Therefore, in absence of other factors, the incision of Fiastrone River, whose valley is very narrow and deep, can be considered an important underlying cause of the low, apparently constant, deformation rate of FD. Although this has been as observed in numerous similar cases in Central Apennines (Galadini, 2006; Aringoli et al., 2010), to calculate the incision rate of Fiastrone river would be required to confirm this consideration.

The notable fluctuations in baseline length during cold periods, which occasionally shortens or lengthens the baseline length by several millimetres but does not induce permanent displacements, seem to coincide with freezing temperatures <0°C (see green line in Fig. 11). At this stage of our research, we could argue that ice or snow cover on the GPS antenna may have caused an apparent shift of the antenna phase centre (the ideal point where the GPS signal is detected), producing the observed shifts in position.

320 The InSAR elaborations of COSMO-SKYMED images from 2011 to 2015, confirm that, in the study area, the
 321 ground deformation, as measured along the line of sight, is very small (Fig. 12a) and that it did not experience
 322 significant oscillations thought time (Fig. 12b).

323
 324 *Fig. 12. a) Ground deformation in the study area detected by InSAR of COSMO-SKYMED satellite images during*
 325 *the period February 2011 - October 2015; b) Time series of ground deformation in the proximity of STA3.*

326
 327 After the seismic sequence started in Central Italy, the STA3-STA1 baseline experienced one-order-of-
 328 magnitude higher instantaneous episodes of shortening during the strongest earthquakes (coloured stars in
 329 Fig. 13 – number inside indicates the magnitude). The baseline shortened in a NNW direction, almost
 330 perpendicular to the main trenches of FD and in line with the direction of movement previously inferred. The
 331 shortening is mainly due to valleyward movement of STA1, since STA3 experienced small displacements (Fig. 9).
 332 The baseline shortened by about 10, 25, and 55 mm during, respectively, the August 24, October 26, and
 333 October 30, 2016, seismic events (Fig. 13). STA 1 and STA 3 experienced the same amount of displacement only
 334 during the earthquakes of January 2017 (Fig. 9) thus they did not vary their distance at this time (Fig. 13).

335

Fig. 14. a) FIAA-FIAB baseline shortening plotted against the magnitude of the main earthquakes of the sequence. The stronger the earthquake, the larger the shortening, in accordance with a non-linear correlation. In detail, the exponential model best fits our data. b) FIAA-FIAB baseline shortening plotted against epicentral distance of the main earthquakes of the sequence. Size of circles represents the number of strong earthquakes ($M_w > 5$) on the same day.

InSAR analysis of Sentinel-1 images, presented in Polcari et al., 2017, allowed to compare with GPS measurements and to investigate the ground deformation in those areas where GPS stations are not present. InSAR data confirmed that, in proximity of STA1, the ground did not move the same that in STA3 at the time of Accumoli (Fig. 15A) and Norcia (Fig. 15B) earthquakes although values of deformation are not the same between InSAR and GPS (Tab.1). In general, with respect to GPS measurements, InSAR underestimates STA1 displacement (it is not detected during the first event, Fig. 15A) and overestimates the movements of STA3, whereas values of STA2 are in accordance (Tab. 1).

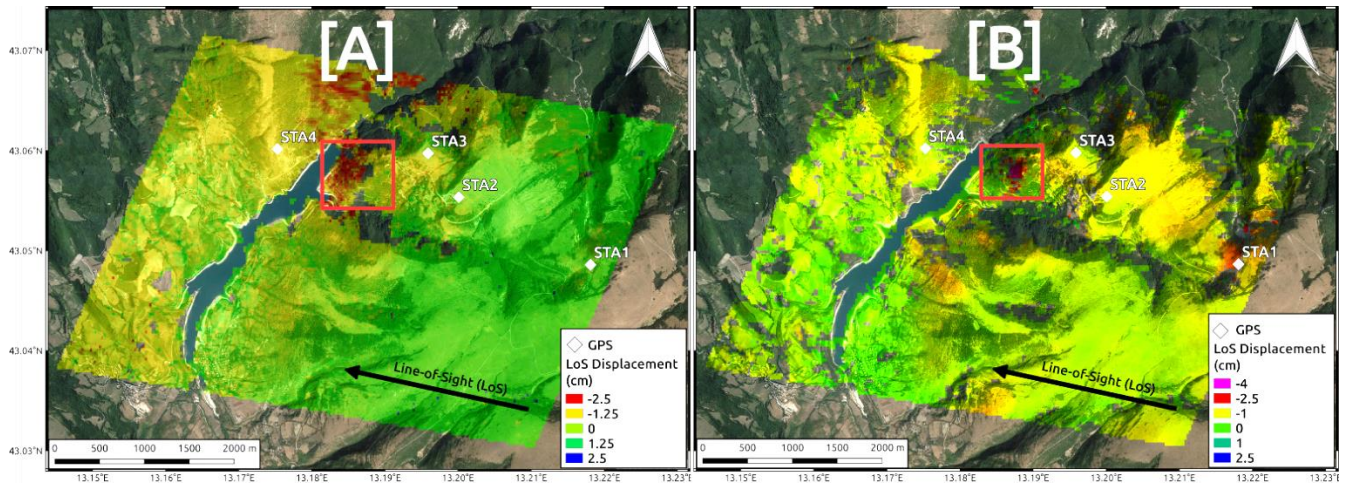

Fig. 15. Ground deformation in the study area detected by InSAR of Sentinel-1 images during the A) Accumoli (August 24, 2016) and B) Norcia (October 30, 2016) earthquakes (modified after Polcari et al., 2017).

Moreover, a cumulative displacement up to 60 mm along the radar line of sight was measured on the lower part of the slope, downslope of STA3 (red square in Fig. 15), as consequence of Accumoli (Fig. 15A) and Norcia (Fig. 15B) earthquakes. This can indicate the presence of a shallow process in this sector of the FD, as a rockslide, which moves with higher rate than the deep deformation affecting the whole slope. Furthermore, especially during the first event, a large area on the opposite side of the valley experienced a significant displacement of about 20 mm (Fig. 15A). This latter point implies a possible movement of the GPS reference station that has to be further investigated and, if the deformation will persist, it should become visible in the STA4 GPS time series as well.

381

	Accumoli (August 24th, 2016)		Norcia (October 30th, 2016)	
Point	GPS (cm)	InSAR (cm)	GPS (cm)	InSAR (cm)
STA1	-1.2 ± 0.7	0.2 ± 0.5	-7.6 ± 0.6	-3.1 ± 0.5
STA2	-0.02 ± 0.5	-0.04 ± 0.5	1.6 ± 0.4	-1.0 ± 0.5
STA3	0.01 ± 0.3	-0.15 ± 0.5	-0.02 ± 0.3	-0.9 ± 0.5

382 *Tab. 1. Comparison of Sentinel-1 InSAR and GPS measurements, projected along the satellite line of sight.*

383

384 The partial discordance between InSAR and GPS can be due to different reasons. First, the error associated to
385 the measures has to be considered (Tab. 1). This is of about 0.5 cm in the calculation of ground deformation
386 and 1-1.5 mm/y in the calculation of mean ground velocity for InSAR technique. Moreover, we cannot exclude
387 the potential influence of the possible movement of the reference station on the GPS measures. Finally, the
388 proximity of Fiastra Lake, which has a high level of water vapour especially in the summer season, could give
389 rise to an atmospheric effect that might influence InSAR data (Polcari et al., 2017).

390 Thus, considering all these aspects, the accordance between the two techniques is generally good.

391

392

393 **1.5. Conclusions**

394 By integrating the information provided by both InSAR and GPS acquisitions, we can conclude that the Fiastra
395 DGSD (FD) experienced significant step-like accelerations during the seismic sequence of Central Italy in 2016
396 and 2017. In detail, the normal average activity rate in absence of $M_w > 5.0$ earthquakes is very slow, linear and
397 probably associated with creep-type motion. This rate does not appear to be homogeneous in every sector of
398 the DSGD but is generally lower than 3 mm/y. In detail, the area of the uppermost trenches, i.e. in the vicinity
399 of STA1, likely moves faster than the lowest sector of the DSGD, where STA3 is placed.

400 Despite some winter acceleration that we attribute to shallow processes due to freeze-thaw cycles, no
401 correlation between rainfall and the normal creep activity rate of the DSGD was observed. Therefore, although
402 the influence of rainfall and snowmelt cannot be completely ruled out, we consider that the erosion of the toe
403 of the slope by Fiastrone River may represent an important causative factor for the normal movement rate of
404 the deformation. We conclude that the mass movement (a *sackung* type) exploits the high-angle pre-existing
405 tectonic discontinuities, and perhaps a basal low-gradient thrust fault. The presence of other DGSD-like
406 geomorphological features elsewhere on the slope confirms the predisposition of the whole valley to this type
407 of phenomenon.

408 On the other hand, the step-like accelerations triggered by earthquakes, are one to ten times higher than the
409 average normal activity rate of the Fiastra DGSD. In detail, the movement mainly depended on the magnitude
410 of the earthquake and the distance from the epicenter, and only secondarily on the number of big earthquakes
411 on a given day. We measured about 60 mm as the maximum instantaneous deformation, which occurred
412 during an M_w 6.5 earthquake about 25 km far from the study area. Earthquakes smaller than M_w 5.0 or farther
413 than 70 km from the study area did not produce significant movements of the Fiastra DGSD.

Moreover, InSAR detected significant movements of a large area in the lower part of the Fiastra DGSD during the August 24, 2016 and October 30, 2016 earthquakes. In addition, along the southern flank of the DGSD, the GPS station placed in the Podalla landslide area, which shows field evidences of recent past activity, experienced 1 to 10 cm westward displacement during the October 30, 2016 and January 18, 2017 earthquakes. Therefore, we conclude that these two sectors of the Fiastra DGSD currently represent the most hazardous sites in the study area because the slope at those sites resulted particularly unstable and moving faster.

Regarding the methods adopted in this work, we found a generally good accordance between single and double frequency GPS receivers, in spite a gap during the earthquakes sequence. Thus, we consider that the low-cost GPS system that we tested is reliable and can be used in similar studies although the sensitivity of the instrument to bad weather conditions suggests particular care in arranging reliable antenna supports and placing. A characteristic of GPS systems is that they furnish only point data, thus areal patterns cannot be directly measured, but rather must be inferred.

In conclusion, we consider that the combination of InSAR and GPS data is a useful monitoring system for earthquake-activated, slow-moving landslides. In particular, InSAR techniques provide areal data that can be useful to extend the GPS point data over large areas. Moreover, SAR measurements are not subject to the weather limitations of GPS. On the other hand, we have to consider that, at present, SAR can only make measurement along the satellite line of sight and thus is likely less accurate than GPS.

1.6. Acknowledgements

The authors want to thank the editors and reviewers for the constructive feedbacks during the revision process. Authors do also thank the European Space Agency (ESA) and the Italian Space Agency (ASI) for providing Sentinel-1 and CosmoSkyMed SAR data, respectively.
