Unacylated ghrelin (UAG), the most abundant form of ghrelin in circulation, has been shown to exert cardioprotective effect in experimental cardiopathies. The present study aimed to investigate the cardioprotective effect of a linear bioactive fragment of UAG against myocardial ischemia-induced injury and dysfunction in C57BL/6 wild type mice and the mechanisms involved. Treatments were administered at doses of 100 (UAG), 1,000 and 3,000 (UAG\textsubscript{6–13}) nmol/kg at 12 h interval during 14 days prior to 30 min left coronary artery ligation and reperfusion for a period of 6 or 48 h. The infarct area was decreased in a dose-dependent manner at 48 h of reperfusion, with a reduction of 54% at the highest dose of UAG\textsubscript{6–13} tested. Myocardial hemodynamics were improved as demonstrated by an increase in cardiac output, maximum first derivative of left ventricular pressure, and preload recruitable stroke work, a load-independent contractility index. Six hours after reperfusion, circulating levels of IL-6 and TNF-α pro-inflammatory cytokines were reduced, and the effect was maintained at 48 h for TNF-α. 5′ AMP-activated protein kinase (AMPK) was activated, while acetyl-CoA carboxylase (ACC) activity was inhibited, along with a decrease in apoptotic protein levels. In isolated hearts, the effect of UAG\textsubscript{6–13} was unaffected by the presence of D-Lys\textsuperscript{3}-GHRP-6, a ghrelin receptor (GHSR1a) antagonist, suggesting that the peptide acted through a GHSR1a-independent pathway. The results support the therapeutic application of UAG bioactive peptide fragments against myocardial ischemia/reperfusion injury.

INTRODUCTION

Ghrelin, an endogenous selective ligand of growth hormone secretagogue receptor (GHSR), was discovered by Kojima et al. as the first known circulating octanoylated peptide (1). The predominant circulating form of ghrelin in circulation is unacylated in position 3 (unacylated ghrelin–UAG) (2). In contrast to acylated ghrelin (AG), UAG is devoid of growth hormone (GH)-releasing activity, orexigenic, adipogenic and diabetogenic activities; however it shares cardioprotective effects mediated through a still elusive receptor independent of GHSR1a (3). Although the mechanism through which UAG exerts cardioprotection has not been fully elucidated, activation of pro-survival pathways, in addition to anti-inflammatory and antifibrotic activities [reviewed in (4)], supports its therapeutic potential in myocardial ischemia/reperfusion (MI/R) injury. Indeed, MI/R is associated with intense inflammation, apoptosis, and ensuing morbidity associated with pathological remodeling (5, 6).

Structure-activity relationship studies of UAG uncovered the bioactivity of shorter fragments devoid of serine in the third position (7). In particular, linear UAG$_{6-13}$ (Ser-Pro-Glu-His-Gln-Arg-Val-Gln-NH$_2$) and its head-to-tail cyclic derivative (cUAG$_{6-13}$), retain UAG bioactivity in enhancing survival of pancreatic islets and beta cells and diminishing oxidative stress and senescence of human circulating endothelial progenitor cells (7). UAG$_{6-13}$ blocked streptozotocin-induced diabetes in rats (7), whereas cUAG$_{6-13}$ (AZP-531) reduced high fat diet-associated inflammation and prediabetes in mice (8). Administration of AZP-531 in mice subjected to transient left coronary artery ligation (LCAL) at 5 min (pre-) and 30 min (post-) reperfusion reduced myocardial infarction through attenuating reperfusion-elicited oxidative stress and activating pro-survival pathways (9).

The present study aims to investigate the cardioprotective effect of linear UAG$_{6-13}$ in reducing MI/R-induced injury and improving hemodynamic performance and to examine underlying mechanisms.

MATERIALS AND METHODS

Mice Treatments and Surgery

All experimental procedures were approved by the Institutional Animal Ethics Committee, in accordance with the Canadian Council on Animal Care guidelines for use of experimental animals and to the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (A5213-01).

Four-month-old male C57BL/6 mice, bred and maintained in-house, were used to determine the effect of UAG$_{6-13}$ pretreatment on myocardial infarct size and myocardial functional recovery after 30 min of ischemia and 48 h of reperfusion. UAG-treated mice were used as a positive control group with known cardioprotective effects. Additional groups of mice were used to investigate the effect of UAG$_{6-13}$ pretreatment on inflammatory and/or metabolic critical processes in the early (6 h) post-reperfusion stage. The isolated perfused heart model was used to determine whether myocardial GHSR1a was involved in the cardioprotective effect of UAG$_{6-13}$ fragment through pharmacological means, e.g., use of AG receptor antagonist (D-Lys$^3$-GHRP-6).

MI/R was performed as described previously (10, 11), as shown in Figure 1A. Briefly, C57BL/6 mice were pretreated during 14 days by twice daily subcutaneous (s.c.) injections of UAG (100 nmol/kg), UAG$_{6-13}$ (1 or 3 µmol/kg), or vehicle (0.9% NaCl). The last dose of these drugs was administered 30 min prior to ligation of the left anterior descending (LAD) coronary artery and on the following day, where applicable. Mice were injected intraperitoneally (i.p.) with buprenorphine (0.05 mg/kg) prior to endotracheal intubation and ventilated using Minivent mouse ventilator (Harvard Apparatus, Holliston, MA, USA) during surgery under isoflurane anesthesia. Transient myocardial ischemia was induced by the insertion of an 8–0 nylon suture tied over a piece of tubing at 1 mm below the edge of atrial appendage. Lidocaine (6 mg/kg) i.p. was injected just after occlusion and 10 min prior to reperfusion to prevent fatal arrhythmias. The chest cavity was closed using a 6–0 silk suture and the animals were allowed to recover for 6 or 48 h. Mice subjected to 6 h of reperfusion were anesthetized with isoflurane and euthanized by exsanguination. Assessment of the impact of treatments on myocardial infarction area was performed following re-occlusion of the original ligation site after 48 h of reperfusion, followed by injecting 300 µL of KCl (1 M) in the subclavian vein and Evans blue (2%) through the aorta. Analysis was performed on triphenyltetrazolium chloride (TTC) (1%)-stained slices by computerized planimetry by an observer blinded to the treatment protocol (10).

Myocardial Hemodynamics as Assessed by Conductance Catheter

Left ventricle (LV) function parameters were derived from pressure-volume (PV) analysis using a miniaturized PV conductance catheter, as described previously (10). Briefly, a left thoracotomy was performed at 48 h post-surgery, and a microtip 1.4 Fr PV catheter (SPR 839, Millar Instruments) was inserted through the LV apex, connected to a transducer system (Millar). PV signals were recorded at steady-state and during vena cava occlusion to reduce pre-load transiently. Absolute volume data were adjusted by inserting the catheter in a cuvette with pre-defined volume containing heparinized blood at 37°C at the end of each experiment and corrected for the parallel conductance through the hypertonic saline bolus injection method. Data were analyzed using IOX2 software (EMKA technologies, Paris, France).

Isolated Perfused Heart Assay

Hearts from anesthetized (3% isoflurane mixed with 100% oxygen) and heparinized (5,000 U/kg, i.p.) male C57BL/6 mice were isolated and immersed in ice-cold Krebs-Henseleit bicarbonate buffer containing 118 mM NaCl, 25 mM NaHCO$_3$, 4.7 mM KCl, 1.2 mM KH$_2$PO$_4$, 2.5 mM CaCl$_2$, 1.2 mM MgSO$_4$, 11 mM glucose, 8 nM insulin, 1.5 mM lactate, 0.2 mM pyruvate, and 0.5 mM EDTA, as described previously (11). After pericardial fat removal, the aorta was cannulated with an 18-gauge cannula, and the heart was perfused retrogradely in a non-recirculating...
mode at a constant perfusion pressure of 80 mmHg with Krebs-Henseleit bicarbonate buffer supplemented with 1.2 mM palmitate in 2% fatty acid-free bovine serum albumin and gassed with 95% O₂-5% CO₂. Hearts were subjected to 30 min of aerobic perfusion, followed by 40 min of low-flow ischemia (10% of preischemic flow) and 10 min of reperfusion. Hearts with rate of perfusion pressure (RPP) <10,000 mmHg/min during baseline were excluded from the study. AG, D-Lys³-GHRP-6 and UAG₆₋₁₃ were administered in a non-recirculating mode via retrograde perfusion throughout the 10 min of reperfusion post-ischemia via a side port directly above the aortic cannula at final concentrations of 1, 10, and 30 µM, respectively. Contractile function was monitored continuously by means of a fluid-filled balloon inserted in the LV connected to a pressure transducer. Ventricular pressures and heart rates were recorded with a PowerLab/8sp instrument and analyzed with Chart v5.0.1 software (AD Instruments, Bella Vista, NSW, Australia). Coronary effluent was collected at various time intervals for measurements of coronary flow.

**Western Blots**

LV were homogenized using a dounce homogenizer (TRI-R S63C, ON, Canada) in PBS containing a protease and phosphatase inhibitors cocktail (Thermo Scientific Pierce). Homogenates were separated into two tubes. Total homogenates were obtained by sonication for 60 min on ice with an equal volume of lysis buffer (150 mM NaCl, 100 mM Tris-HCl, 2% Triton X-100, 0.2% SDS, pH = 7.4), centrifuged at 12,000 g for 20 min at 4°C, and the supernatant was kept at −80°C. To collect the cytosolic fraction, the other tube was centrifuged at 1,000 g for 10 min at 4°C, the supernatant was centrifuged at 9,000 g for 10 min at 4°C, and the supernatant was kept at −80°C. The protein concentration was determined by the BCA assay (Pierce Biotechnology). Equal amounts (25 µg) of protein extracts were loaded on SDS-polyacrylamide gels and transferred to PVDF membranes (Bio-Rad Laboratories). After blocking, membranes were incubated overnight at 4°C with the following primary antibodies; polyclonal rabbit anti-Akt and anti-phosphoSer473-Akt were used for the total homogenates, while polyclonal rabbit anti-acetyl-coenzyme A carboxylase (ACC), anti-phosphoSer79-ACC (ACC1 and ACC2), anti-5′ AMP-activated protein kinase (AMPK)α₁/α₂, anti-phosphoThr172-AMPK (1:1,000 Cell Signaling Technology, Danvers, MA, USA), monoclonal mouse anti-cytochrome c (BD Biosciences, Franklin Lakes, NJ, USA), polyclonal goat anti-AIF (Santa Cruz, Dallas, TX, USA) were used for the cytosolic fractions. Monoclonal mouse anti-α-tubulin (1:5,000, Abcam) was used as an internal control and detected on the same membrane (Supplemental Figures 2–10). Membranes were incubated with HRP-conjugated secondary goat anti-rabbit IgG (1:10,000, Jackson ImmunoResearch), goat anti-mouse IgG (1:10,000, KPL) or donkey anti-goat IgG (1:10,000, Abcam). Bands from the same blot were detected by enhanced chemiluminescence and analyzed using ChemiDoc XRS+ (Bio-Rad, ON, Canada).
Plasma Cytokines
Blood from non-fasted mice was collected on 4 mM EDTA to determine interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) plasma levels using commercial kits (eBioscience, Waltham, MA, USA; catalog numbers 88-7064 and 88-7324, respectively) by following manufacturer’s instructions.

Statistical Analysis
Data are represented as mean ± SEM. Comparisons between groups were performed using unpaired one- or two-way ANOVA followed by Student-Newman-Keuls (SNK) method for multiple post hoc comparisons (GraphPad Prism Version 7.02, San Diego, CA). Probability values <0.05 were considered statistically significant.

RESULTS
UAG and UAG<sub>6−13</sub> Pretreatments Protect From Myocardial Ischemia/Reperfusion Injury and Preserve LV Hemodynamics
C57BL/6 mice were pretreated with UAG, UAG<sub>6−13</sub> or 0.9% NaCl (vehicle) at 12 h interval for 14 days and 30 min prior to LCAL induced by the proximal occlusion of the LAD coronary artery, followed by 6 or 48 h of reperfusion (Figure 1A). Our results display a consistently large myocardial area-at-risk (AAR) (slightly more than 50% of the LV area) in all groups as shown by representative photomicrographs of TTC-stained midventricular, transverse slices (Figure 1B). The AAR/LV ratio did not differ significantly between groups (Figure 1C), suggesting that the ligation was reproducibly performed at the same LAD level. We first investigated the cardioprotective effect of UAG at a dose equimolar to that previously published for AG shown to exert a cardioprotective effect in experimental cardiopathies (12, 13). Our results show that prophylactic administration of UAG (100 nmol/kg twice daily), used as a positive control, significantly reduced infarct area (IA) to LCAL induced by the proximal occlusion of the LAD coronary artery, followed by 6 or 48 h of reperfusion (Figure 1A). Compared to vehicle-treated mice, UAG<sub>6−13</sub> reduced myocardial infarction to a similar extent (34–54%) (Figure 1D).

In parallel studies, the effect of a preventive administration of UAG and UAG<sub>6−13</sub> on systemic hemodynamics and indices of systolic and diastolic function was determined using conductance catheter-derived PV relationship at 48 h of reperfusion as carried out previously (10, 11). Vehicle-treated mice exhibited similar LV dysfunction as those subjected to the same MI/R protocol (10, 11). Compared to vehicle-treated mice, UAG<sub>6−13</sub> improved systemic hemodynamics by increasing stroke volume and cardiac output by 40 and 58%, respectively (Table 1). Although systolic LV indices, including ejection fraction (EF), end systolic pressure (ESP), and end systolic volume (ESV), were modestly improved by the peptides at their respective administered doses, stroke work was increased by 55 and 81% by UAG and UAG<sub>6−13</sub>, respectively. The peak rate of rise in the first derivative of left ventricular pressure (dP/dt<sub>max</sub>) was increased by ~40% by both treatments as well as that of preload recruitable stroke work (PRSW), a load-independent indice of contractility, by 49% (UAG) and 39% (UAG<sub>6−13</sub>). Reduced tau and increased dP/dt<sub>min</sub> suggested improved diastolic relaxation.

UAG and UAG<sub>6−13</sub> Pretreatments Exert Anti-Inflammatory Effects
We investigated the potential anti-inflammatory effect of UAG and UAG<sub>6−13</sub> peptides in early (6 h) and late (48 h) reperfusion following myocardial ligation. Our results show that after 14 d pretreatment twice daily, UAG (100 nmol/kg) and UAG<sub>6−13</sub> (3,000 nmol/kg) transiently reduced plasma IL-6 levels by 76 and 70% at 6 h, respectively, whereas this effect vanished by 48 h (Figures 2A,B). In a similar manner, substantial inhibitory effect of treatments was observed on plasma TNF-α levels at 6 h following MI/R, by 43% (UAG) and 62% (UAG<sub>6−13</sub>). The inhibitory effect was maintained at 48 h, as shown by a 78% in UAG-treated, and 46 and 80% reductions in UAG<sub>6−13</sub> (1,000 and 3,000 nmol/kg)-treated mice (Figures 2C,D).
Neither UAG nor UAG<sub>6−13</sub> pretreatment modulated body weight, food or water intake, glycemia, insulin and non-esterified fatty acid (NEFA) plasma levels (Supplemental Figure 1).

**Phosphorylation of Myocardial AMPK, ACC and Apoptosis-Related Markers After MI/R in UAG and UAG<sub>6−13</sub>-Treated Mice**

Western blots analysis of LV protein homogenates showed that the mean relative ratio of pThr172-AMPK to total AMPK band density was increased by 83% after 6 h reperfusion in ischemic hearts of mice treated twice daily with UAG<sub>6−13</sub> (3,000 nmol/kg), compared with vehicle-treated mice (Figure 3A). In contrast, pSer473-Akt to total mean Akt ratio was unchanged compared to that of vehicle-treated mice at this time-point (Figure 3B). However, the mean ratio of pSer79-ACC to total ACC was increased by 91% in both UAG (100 nmol/kg) and UAG<sub>6−13</sub> (3,000 nmol/kg)-twice daily treated mice (Figure 3C). Expression of mitochondrial signaling proteins of apoptosis, cytochrome c, and apoptosis inducing factor (AIF), was significantly reduced in LV cytosolic fraction by UAG<sub>6−13</sub> treatment but not in UAG-treated mice (Figures 3D,E). Complete scanned gels for western blots are shown in Supplemental Figures 2–10.

**UAG<sub>6−13</sub> Improves Myocardial Hemodynamics in Isolated Hearts in a GHSR1a-Independent Manner**

To investigate whether UAG<sub>6−13</sub> exerts cardioprotective effect through a GHSR1α-independent pathway in the heart, we used an isolated heart model of low-flow ischemia and reperfusion in Langendorff mode to assess the rate of perfusion pressure (RPP) and additional hemodynamic parameters. Hearts from 20 mice were sorted according to the following pharmacological treatments: AG and AG + D-Lys<sub>3</sub>-GHRP-6, as positive and negative control groups; UAG<sub>6−13</sub> and UAG<sub>6−13</sub> + D-Lys<sub>3</sub>-GHRP-6, as tested groups. Our results show that the RPP was largely preserved in the presence of both AG and UAG<sub>6−13</sub> at reperfusion (Figure 4A). Treatment with D-Lys<sub>3</sub>-GHRP-6 completely abolished RPP rescue by AG at reperfusion; in contrast, D-Lys<sub>3</sub>-GHRP-6 did not have any effect on UAG<sub>6−13</sub>-elicited cardioprotection. Consistent with improved RPP in the presence of UAG<sub>6−13</sub>, myocardial hemodynamics tended to be improved by UAG<sub>6−13</sub> treatment with or without D-Lys<sub>3</sub>-GHRP-6, although no change was observed in heart rate and coronary flow (Figures 4B–G).

**DISCUSSION**

The main finding of this study is that a preventive treatment with a linear UAG fragment, UAG<sub>6−13</sub>, reduced MI/R-induced injury and rescued hemodynamic dysfunction in mice, in a GHSR1α-independent manner. The cardioprotective effects were associated with potent, time-dependent, and systemic anti-inflammatory effects of the treatment. These observations are consistent with those of Harisseh et al. who showed that an acute administration of cyclic UAG<sub>6−13</sub> (cUAG<sub>6−13</sub> or AZP-531), in a similar dose range, reduced infarct size following MI/R in...
mice, as a consequence of an early activation of pro-survival and anti-oxidative pathways (9).

AG/GHSR1a axis has been proposed as a promising therapeutic target in a variety of metabolic disorders due to its pleiotropic effects on appetite, energy metabolism, glucose homeostasis, and GH release. While the two circulating forms of ghrelin present distinct endocrine activities (14), they also share many peripheral biological activities, through the binding of an as of yet elusive receptor (15–18). Both forms may be beneficial to rescue myocardial dysfunction elicited by drugs such as isoproterenol or doxorubicin or ischemia in isolated hearts, cardiomyocytes and in preclinical models (12, 13, 19–23). While AG is cardioprotective, its pleiotropic effects and GH secretagogue activity may jeopardize its favorable effects in protecting the heart following long-term exposure with the potential of eliciting serious adverse events such as cancer growth and metastasis (24). In contrast, UAG, the most abundant circulating form of ghrelin, shows GH- and GHSR1a-independent effects in promoting anti-apoptotic pathways in cardiomyocytes and protecting against drug-induced cardiac dysfunction and fibrosis (13).

UAG fragments were studied for their bioactivity and ability to mimic UAG pro-survival effect on beta cells and human pancreatic islets (7). UAG fragment 6-13 showed cardioprotective effect (9), and full cyclization of the peptide did not affect its bioactivity and improved its pharmacokinetics (25). Cyclic UAG6–13 improved mitochondrial function, reduced apoptosis and myocardial damage at 15 min and 24 h following reperfusion, respectively. In agreement, our results show reduced myocardial damage at 48 h following reperfusion and further show that these beneficial effects were associated with improved hemodynamics and reduced plasma TNF-α levels at this time point. In addition, the anti-apoptotic effect observed by Harisseh et al. (9) after 15 min of reperfusion appeared to be maintained at 6 h, a time point at which changes in myocardial metabolism is apparent (10). Although the present work does not allow direct comparison of the cardioprotective efficacy of cyclic and linear forms of UAG6–13 as experimental designs, doses and endpoints differed between studies, the present work confirms that the UAG6–13 fragment is cardioprotective and furthermore, that it also improves cardiac hemodynamics and contractility, as shown by a significant increase in cardiac output, dP/dt max and PRSW.

Both oxidative stress and pro-inflammatory cytokines play a role in promoting an inflammatory response to MI/R (26). In the present study, we further investigated the effect of UAG and UAG6–13 on plasma levels of IL-6 and TNF-α at 6 h of reperfusion, a time point at which myocardial levels of these cytokines are elevated in humans (27). Our results show that treatment with UAG and UAG6–13 elicited a striking, but transient, reduction of IL-6 plasma levels, whereas TNF-α levels were diminished at both 6 and 48 h after reperfusion. Of interest, UAG and UAG6–13 shared a similar transient
As reported previously for HL-1 cardiomyocytes (22), the ratio of p-AMPK/AMPK was not significantly changed in UAG-treated mice, but was increased by UAG$_{6-13}$ at 6 h of reperfusion, which may contribute to protect the heart through the attenuation of TNF-$\alpha$-elicited apoptosis (32) and/or modulate myocardial energy metabolism. Along these lines, p-ACC/ACC was increased by the pretreatments, leading to enhanced $\beta$-oxidation and ATP production (33). Whether myocardial glucose metabolism was increased and fat metabolism decreased by the treatments remain to be investigated.

An enigmatic issue about the receptor or receptor subtypes involved in mediating the effects of UAG and UAG fragments still remains. In the heart, a number of different receptor subtypes have been proposed, including ghrelin receptor-like receptor (GRLR) that would bind ghrelin and UAG as well as UAG receptors and GHSR1a (34). To investigate whether UAG$_{6-13}$ exerted its cardioprotective effect via the ghrelin receptor GHSR1a, we perfused isolated mice hearts in the presence or absence of the ghrelin antagonist, D-Lys$_3$-GHRP-6, a selective antagonist of the AG receptor. Our results showed that while D-Lys$_3$-GHRP-6 inhibited AG-induced rescue of RPP, it did not interfere with the effect of UAG$_{6-13}$. These observations support that the cardioprotective
effect on myocardial hemodynamics afforded by UAG$_{6-13}$, even at a dose of 30 μM, is likely to be mediated by UAG receptors. In the present study, the effect of UAG$_{6-13}$ was investigated in pretreated mice. Although this experimental design may limit translation to acute clinical situation of MI/R, previous studies investigating the cardioprotective effect of hexarelin, a small synthetic growth hormone peptide, required a 7–14 days pretreatment in rats (35). Yet, hexarelin was later shown to improve cardiac performance by increasing left ventricular ejection fraction in humans following an acute administration (36, 37). The cardioprotective effect of a single dose of the linear octapeptide UAG fragment in mice after the onset of myocardial ischemia remains to be investigated.

In conclusion, the results of this study show that a pretreatment with a linear bioactive fragment of UAG reduced myocardial damage following MI/R and for the first time shows that these beneficial effects are associated with improved myocardial hemodynamics, along with potent and prolonged anti-inflammatory effects over 48 h. These observations add to the early (15 min) anti-oxidative and pro-survival activation pathways seen with the cyclic peptide (9). Furthermore, we show that UAG$_{6-13}$ exerted cardioprotective effects via mechanisms that are independent of GHSR1a. Taken together, these results support further studies to investigate the mechanisms and pharmacokinetics of the peptide for the translation of these observations.
