Abstract

Objectives:

Extra-criteria manifestations of antiphospholipid syndrome (APS) might impact on prognosis and morbidity of the disease. In this study, we aimed to evaluate a population of patients with primary APS (PAPS) whether the extra-criteria manifestations were more frequently found in subjects with higher adjusted Global APS Score (aGAPSS) values when compared to patients with thrombotic and/or obstetric APS (“criteria” manifestations) only.

Methods:

Clinical records were analyzed to retrieve extra-criteria manifestation of APS, cardiovascular risk factors and antiphospholipid antibodies profile. The aGAPSS was calculated by adding the points, as follows: 3 for hyperlipidaemia, 1 for arterial hypertension, 5 for anticardiolipin antibodies IgG/IgM, 4 for anti-b2 glycoprotein I IgG/IgM and 4 for lupus anticoagulant.

Results:

This retrospective multicenter study included 89 consecutive PAPS [mean age 43.1(S.D.±12.9), female 67%, 52% arterial and 65% venous]. Twenty-seven patients (30.3%) had a history of livedo,
19(21.3%) had a history of confirmed thrombocytopenia, 3(3.4%) had biopsy-proven antiphospholipid antibodies (aPL)-related nephropathy and 3(3.4%) had a history of valvulopathy. Patients with extra-criteria manifestations presented a mean aGAPSS significantly higher [mean 10.30(S.D.±3.57, range 4-17) vs mean 8.16(S.D.±3.52, range 4-16, p=0.005). When comparing patients with and without extra-criteria manifestations, the first group had significantly higher incidence of anti-ß2GPI antibodies positivity (59% and 33%, respectively, p=0.015), double aPL positivities (53% and 31%, respectively, p=0.034), cerebrovascular events history (52% and 24%, respectively, p=0.007) and arterial hypertension (52% and 24%, respectively, p=0.007).

**Conclusions:**

Our results suggest that patients with higher aGAPSS, might be at higher risk for developing extra-criteria manifestations of APS and should therefore undergo a thorough laboratory and instrumental evaluation.
1.1 Introduction

The antiphospholipid syndrome (APS) is characterized by antiphospholipid antibodies (aPL) associated with thrombosis (arterial and/or venous) and/or pregnancy morbidity. The current Sydney classification criteria [1] do not consider a range of non-thrombotic clinical manifestations that are frequently observed in association with the presence of aPL, the so-called extra-criteria manifestations [2]. Although extra-criteria manifestations, such as thrombocytopenia, *livedo reticularis*, aPL related-nephropathy, cardiac valve disease, cognitive dysfunction and skin ulcers are relatively common, their accurate prevalence and associated thrombotic risk are unknown [3]. Furthermore, despite the diagnostic value of these extra-criteria manifestations has yet to be determined, they might be highly relevant and reveal correlations with prognosis or morbidity [4].

In fact, patients with APS still suffer for a significant burden of morbidity and mortality regardless a proper management with the current therapeutic tools; thus, it is imperative to increase the efforts in determining optimal prognostic markers, risk assessments measures and therapies to prevent complications.

Recently, the Global APS Score (GAPSS) and the adjusted GAPSS (aGAPSS), a simplified version of the same score, were designed to
evaluate the risk of patients to develop any clinical manifestation of APS [5–8]. These scores are important to predict which patients are at higher risk and that consequently will need closer follow-up and eventually specific treatment. It is debated whether patients with non-criteria manifestations are at a higher recurrence risk [4].

The purpose of this study was to evaluate in a population of patients with primary APS (PAPS) whether the extra-criteria manifestations were more frequently found in subjects with higher aGAPSS values when compared to patients with thrombotic and/or obstetric APS (“criteria” manifestations) only.

2.1 Patients and methods:

2.2 Patients

This retrospective multicenter study included 89 consecutive primary APS patients who attended the Hospital das Clinicas, Sao Paulo, Brazil and S. Giovanni Bosco Hospital, Turin, Italy. Inclusion criteria included the persistent aPL positivity and the fulfillment of the Sydney criteria for APS [1].

Both centers are tertiary referral hospitals and are responsible for the management of severe APS patients.
2.3 Extra-criteria manifestations of APS

Medical records were retrospectively checked for extra-manifestations of APS. *Livedo reticularis* and *racemosa* were assessed by physical examination as per standard of care of centers. Thrombocytopenia was defined as platelets level <100,000 mm$^3$ and confirmed with at least two examinations with a complete blood count and evaluation of the peripheral blood smear. aPL-related nephropathy was assessed with kidney biopsy [9] and valvulopathy was confirmed with echocardiography [10].

2.4 Autoantibody detection

The aPL profile included anticardiolpin antibodies (aCL), lupus anticoagulant (LA) and anti-ß2 glycoprotein I (anti-ß2GPI) antibodies. Plasma samples were tested for the presence of LA according to the recommended criteria from the International Society on Thrombosis and Haemostasis (ISTH) Subcommittee on Lupus Anticoagulant/Phospholipid-Dependent Antibodies [11,12]. The aCL and anti-ß2GPI were detected by ELISA as described previously [13].

2.5 Cardiovascular risk factors assessment
Cardiovascular risk factors (including hypertension, dyslipidemia, diabetes, hormone replacement therapy and smoking) were assessed following the National Institute for Health and Care Excellence (NICE) guidelines [16]. In detail, enrolled patients underwent a physical examination, blood pressure determination and phlebotomy for vascular risk factors. Arterial hypertension was defined as an appropriately sized cut-off (140/90 mmHg or higher)[15], high blood pressure on at least two occasions or use of oral antihypertensive medications. Serum total and high-density lipoprotein (HDL) cholesterol levels were determined with standardized enzymic methods and interpreted according to current cut-off values [15].

2.6 Adjusted GAPSS calculation

The cumulative aGAPSS was calculated for each patient as previously reported by adding together all points corresponding to the risk factors [5]. After its first description, GAPSS was prospectively validated [7] and applied in a cohort of patients with PAPS [8]. To increase the generalizability of the findings, in this study we applied an adjusted version of GAPSS (aGAPSS). This comprises only aPL testing included in the current classification criteria for APS (excluding aPS-PT, not routinely available in all the laboratories). Data are presented as aGAPSS. The aGAPSS was calculated by adding the points
corresponding to the risk factors, based on a linear transformation derived from the β regression coefficient as follows: 3 for hyperlipidaemia, 1 for arterial hypertension, 5 for aCL IgG/IgM, 4 for anti-b2 glycoprotein I IgG/IgM and 4 for LA.

2.8 Statistical analysis

Categorical variables are presented as number (%) and continuous variables are presented as mean (S.D.). The significance of baseline differences was determined by the chi-squared test, Fisher’s exact test or the unpaired t-test, as appropriate. A two-sided P-value <0.05 was statistically significant. All statistical analyses were performed using SPSS version 19.0 (IBM, Armonk, NY, USA).

3.1 Results:

A total of 89 consecutive PAPS patients [mean age 43.1 (S.D.±12.9), female 67%] were included in the analysis. Forty-six patients had at least one episode of arterial thrombosis (51.7%) and 58 (65.2%) had at least one episode of venous thrombosis. Demographic, clinical and laboratory characteristics are summarized in Table 1.

Table 1. Demographic, clinical and laboratory characteristics of the cohort

When considering the extra-manifestation of APS, 27 patients (30.3%) had a history of livedo, of those 21 patients had *livedoreticularis* and six *livedoracemosa*. Nineteen patients (21.3%) had a history of confirmed thrombocytopenia (range 30,000/µl-100,000/µl), three patients (3.4%) had biopsy-proven aPL-related nephropathy and three patients (3.4%) had a history of valvulopathy. Table 2. Patients cardiovascular risk factors and aPL positivity between groups

aPL= Antiphospholipid antibodies; S.D. = standard deviation; aGAPSS = adjusted global antiphospholipid score

*statistically significantly different when compared with the group of “No extra-criteria manifestation”

Patients with extra-criteria manifestations presented a mean aGAPSS of 10.30 (S.D. ±3.57, range 4-17), significantly higher when compared with patients without extra-criteria manifestations of APS (8.16; S.D. ±3.52; range 4-16; p = 0.005). When comparing patients with and without extra-criteria manifestations, the first group had significantly higher incidence of anti-ß2GPI antibodies positivity (59% and 33%, respectively, p=0.015), double aPL positivities (53% and 31%, respectively, p=0.034), cerebrovascular events history (52% and 24%, respectively, p=0.007) and arterial hypertension (52% and 24%, respectively, p=0.007).

Similarly, when considering patients with livedo (both reticularis and racemosa), significantly higher aGAPSS values were seen when compared to patients with no extra-criteria manifestations [mean
aGAPSS 10.4 (S.D. ±3.9, range 4-17) Vs. mean aGAPSS 8.16 (S.D. ±3.52; range 4-16); p=0.014]. Further statistically significant differences were seen in the livedo group when compared to the extra-criteria group when analyzing the rate of arterial events (74% and 47%, respectively, p=0.02), cerebrovascular events (70% and 24%, respectively, p<0.001) and arterial hypertension (44% and 71%, respectively, p=0.004). Interestingly, the livedo group had significantly lower rate of venous events (44% and 71%, respectively, p=0.025). When considering only patients with livedoreticularis, the same statistically significant differences were seen. However, due to the small number of patients with livedoracemosa, a similar analysis could not be performed considering only the subgroup of patients with livedoracemosa.

Likewise, when considering patients with thrombocytopenia, significantly higher aGAPSS values were seen when compared to patients with no extra-criteria manifestations [mean aGAPSS 10.6 (S.D. ±3.8, range 4-17) p=0.018]. In patients with thrombocytopenia was also observed higher rate of aCL positivity (84% and 53%, respectively, p=0.02).

Due to the small number of patients with biopsy proven APS nephropathy (aGAPSS range 8-14) and valvulopathy (aGAPSS range 9-14), statistical differences could not be calculated separately for these
manifestations. No statistical significant differences were observed when comparing separately each cardiovascular risk factor (smoking, diabetes, dyslipidemia) nor other thrombotic risk factor (hormonal therapy, immobilization, surgery, malignancy).

4.1 Discussion:

The GAPSS score was conceived and validated in a comprehensive series of studies evaluating different patients populations [5,16–18]. The GAPSS model evaluates the risk profile of patients to develop thrombosis or pregnancy morbidity in the context of aPL positivity, based on traditional cardiovascular risk factors and aPL profile, considered as independent risk factors for developing any clinical APS manifestation. Very recently, in a systematic review that included 2273 patients, GAPSS was found to be a valid tool to stratify patients with aPL according to their thrombotic risk, being the highest levels of GAPSS found in patients who experienced thrombosis, especially arterial. Furthermore, the GAPSS was also proven to identify patients at higher risk of developing recurrences of any clinical manifestations of APS[19].

In the original GAPSS, anti-phosphatidylserine/prothrombin antibodies (aPS-PT) were included in the score. However, these are not currently part of the international consensus classification criteria [1]
and aPS-PT antibodies are not routinely tested in most clinical laboratories. For the above reasons, in our current study we applied the aGAPSS (excluding aPS-PT), already tested and validated in previous studies [20–22].

In this study, we highlight the clinical relevance of extra-criteria manifestations in risk assessment of APS using the aGAPSS.

Our cohort included 89 thrombotic PAPS patients and 49% of those patients experienced at least one extra-criteria clinical manifestation of APS. Higher levels of aGAPSS were seen in patients with extra-criteria clinical manifestations of APS, both when analyzing the extra-criteria manifestations as a group or as single manifestations.

Our results support the idea that patients with higher risk profile should undergo careful routine evaluation and risk assessment (Figure 1).
This is particularly important for the risk of developing arterial events, that include the potentially most life-threatening manifestations of the syndrome, being the central nervous system the most common affected site [23] and that was found in this analysis highly associated with extra-criteria manifestations of APS.

A throughout analysis of laboratory and instrumental investigation should be warranted in higher risk APS patients. aGAPSS might represents a substantial tool in identifying this particular subgroup and in quantifying the risk of developing any other clinical manifestation of APS, highly impacting on the clinical follow-up of patients and potentially in therapeutic long-term choices. Such patients
may require intensified diagnostic workout during the follow-up (e.g., routine echocardiography and routine microscopic examination of the urine sediment).

**Limitations of the study**

We acknowledge few limitations for our study. The use of a cross-sectional approach might influence the reproducibility of the results, as individual aGAPSS scores could variate at different time points. Further prospective analysis to confirm our findings is highly needed. However, one should consider the fact that APS is a rare condition and extra-criteria manifestations are present just in a subset of APS patients [4]. While a longitudinal study would be highly informative, a prospective data collection may require international joint efforts. From that perspective, it is worth mentioning the AntiPhospholipid syndrome alliance for clinical trials and International networking (APS ACTION) is the first-ever international research network that has been created specifically to design and conduct well-designed, large-scale, multicenter clinical studies in persistently aPL-positive patients [24–27]. Secondly, due to the retrospective nature of the data collection, the diagnosis of aPL-related nephropathy could only be assessed if the patient underwent a renal biopsy. Furthermore, extra-criteria
neurological manifestations of APS are an heterogeneous group of clinical entities, sometimes very common in the general population (e.g. migraine, mood disorders), making their attribution to aPL might challenging.

Finally, the effect of therapy and therapy compliance could not be properly assessed, as treatment was heterogeneously controlled in this cohort and varied according to the clinical manifestations and the clinician’s judgment.

**Conclusion**

To date, identifying APS patients who are at high risk for developing any thrombotic event is still an unmet clinical need and remains a major challenge for the treating physicians. Following the findings of our study, we suggest that PAPS patients with a higher risk profile according to aGAPSS might be at higher risk for developing extra-criteria manifestations (such as thrombocytopenia, livedo and/or nephropathy) and should therefore undergo a throughout laboratory and instrumental evaluation.

With the help of joint efforts and multicenter prospective studies confirming our findings, aGAPSS might aid the treating clinician for risk stratification of APS patients.
