Abstract

Brown and black spots, caused by *Stemphylium* and *Alternaria* species, are important fungal diseases affecting European pear (*Pyrus communis* L.) in orchards. Both fungal genera cause similar symptoms, which could favour misidentification, but *Alternaria* spp. are increasingly reported due to the changing climatic conditions. In this study, *Alternaria* spp. were isolated from symptomatic leaves and fruits of European pear, and their pathogenicity was evaluated on pear fruits from cultivar 'Abate Fétel' and molecular and chemical characterization were performed. Based on Maximum likelihood phylogenetic analysis, 15 out of 46 isolates were identified as *A. arborescens* species complex (AASC), 27 as *A. alternata* and four were named *Alternaria* sp. Both species were isolated from mature fruits and leaves. In pathogenicity assays on pear fruits all isolates reproduced the symptoms observed in the field, both by wound inoculation and direct penetration. All but one isolates were produced Alternaria-toxins on European pears, including tenuazonic acid and alternariol (89.1% of the isolates), alternariol monomethyl ether (89.1%), altertoxin I (80.4%), altenuene (50.0%) and tentoxin (2.2%). These isolates also produced at least two mycotoxins and 43.5% produced four mycotoxins, with an average total concentration of the Alternaria-toxins exceeding 7.58×10^6 ng/kg. Our data underline the potential risks for human health related to the high mycotoxin content found on fruits affected by black spot. This study represents also the first report of AASC as agent of black spot on European pear in Italy.

Keywords: European pear, black spot, *Alternaria alternata*, *Alternaria arborescens* species complex, mycotoxin, alternariol.

1. Introduction

The estimated global production of pears is around 40 million tonnes/year, and the main producing country is China with over 16 million tonnes/year. Italy is the third world and first European producer country with 29,616 ha of cultivated area and a production of 716,821 tonnes/year in 2018 (FAOSTAT, 2020). In terms of production, the most important cultivar worldwide is Williams, whereas in Europe it is Conference, and in Italy it is Abate Fétel (FreshPlaza, 2020). Pear is highly appreciated due to its sweet and sour taste, but also for its beneficial role in human nutrition linked to the richness in polyphenols, flavonoids, vitamins, carotenoids, sugars, organic acids, fibres and minerals (Savić et al., 2019).

Among the most important fungal diseases affecting pear production in orchard, there are brown spot and black spot, caused by *Stemphylium* and *Alternaria* species, respectively. *Stemphylium vesicarium* (Cooke) Wint. is an economically relevant species affecting different crops, including pear. Fruits and leaves can be infected in the orchard causing huge economic losses (Köhl et al., 2013) with a global incidence between 1 to 10% (Montesinos and Vilardell 1992). *Stemphylium vesicarium* was reported on European pear (*Pyrus communis* L.) in Italy since the late '70 (Alberoni et al., 2008), whereas *Alternaria* spp. has been rarely reported. Both fungal genera cause similar symptoms, which could favour misidentification, but *Alternaria* spp. is increasingly reported due to the changing climatic conditions, that influence biological, environmental factors and a shift in microbial ecology (Van de Perre et al., 2015).

The genus *Alternaria* comprises ubiquitous species including saprobes and plant pathogens (Simmons, 2007). Two main species are associated with diseases on pears: *Alternaria gaisen* Nagano and *A. alternata* (Fr.) Keissl.. Alternaria black spot caused by *A. gaisen* on Japanese pear (*Pyrus pyrifolia* (Burm.f.) Nakai) is mainly distributed in Japan and Korea and was first reported in Italy in 1991 with a restricted distribution (EPPO, 2020). Black spots caused by *A. alternata* were reported in Japan in 1933 and later in Korea, Italy, France, Greece and India on Japanese pear cv. Nijisseiki (Cavanni and Ponti, 1991; Baudry et al., 1993; Sandeep 2005). *Alternaria alternata* on European pear was reported in Greece on several cultivars, including cv. Abate Fètel (Thanassolopolos, 1990). The pathogen was also reported in Japan on cultivar Le Lectier in 1993 (Tanahashi et al., 2016). During 2012, severe symptoms of Alternaria black spot were also reported on leaves and fruits of *Pyrus communis* cv. Abate Fétel in Italy (Gianetti et al., 2013). *Alternaria alternata* is also associated with

dead flower buds disease of both European and Japanese pear in different countries (Wenneker et al., 2019). *Alternaria alternata* is reported to be pathogenic on pears in Asian and American countries, where it causes Alternaria blotch of apple, and the pathotype causing this symptom is considered a quarantine pathogen in Europe (Maeno et al., 1984; Tanahashi et al., 2016).

The taxonomy of the genus *Alternaria* has undergone different revisions and the current classification, based on morphological and molecular approaches, divides the genus into 27 sections (Lawrence et al., 2016). Most of the small-spored *Alternaria* species with concatenated conidia are grouped in *Alternaria* section *Alternaria,* with almost 60 morphological or host-specific species (Woudenberg et al. 2013), and *A. gaisen*, *A. alternata* and *A. arborescens* are the most important plant pathogens within this section. Different molecular approaches have been proposed to identify species within section *Alternaria*, including random amplified polymorphic DNA, amplified fragment length polymorphism, selective subtractive hybridisation and sequence characterised amplified genomic regions (Roberts et al. 2000; Somma et al. 2011; Roberts et al. 2012; Stewart et al. 2013). None of these approaches resulted in a clear distinction of species inside this section. Later, a multi-gene phylogeny based on nine gene regions was used in the study of Woudenberg et al. (2015), and 35 morpho-species of *Alternaria* section *Alternaria* were synonymised as *A. alternata*.

The genus *Alternaria* is known to produce several secondary metabolites, including mycotoxins, and the most studied are alternariol (AOH), alternariol monomethyl ether (AME), tentoxin (TEN), tenuazonic acid (TeA), altenuene (ALT), and altertoxins (ATXI, ATXII, and ATXIII) (Escrivá et al., 2017). The presence of mycotoxins creates issues to food safety and the consumer health (Pose et al., 2010; Prelle et al., 2013). Mycotoxins are classified as non-host specific toxins and recently some studies reported their role in the pathogenicity of *Alternaria* spp. (Graf et al., 2012; Meena et al., 2017; Wenderoth et al., 2019). Andersen and Thrane (1996) used a high-performance liquid chromatography (HPLC) to distinguish small-spored *Alternaria* species from cereals, combined to morphological and cultural characteristics, whereas Siciliano et al. (2018) used HPLC with tandem Mass Spectrometry (HPLC-MS/MS) combined with molecular and morphological analyses to characterize *Alternaria* isolates isolated from basil.

The aim of the present work was to identify and characterize *Alternaria* spp. isolated from European pear in Italy, by evaluating their pathogenicity on fruits of pear cv. Abate Fétel. Molecular and chemical approaches were used to establish the species occurrence in orchard and to evaluate the potential risks for human health.

2. Materials and methods

Fungal isolates

Alternaria spp. samples were collected from pear fruit and leaves showing black spots in seven orchards of *Pyrus communis* cv. Abate Fétel located in north-western Italy, during August-October 2018 (Table 1). Symptoms on leaves were small and circular, or with irregular margins, brown to black spots of 2 to 5 mm diameter, often converging to determine a widespread desiccation (Fig 1). On fruits, circular spots of 1 to 3 mm diameter sometimes surrounded by a reddish halo and centred on the lenticels were observed (Fig 1). The samples were surface-disinfected with 1% sodium hypochlorite, washed in sterile deionized water and air dried. Four to five fragments from each fruit/leaf lesion (black spots) were cut and plated onto Potato Dextrose Agar (PDA, Merck, Germany) Petri dishes. After 4 days of incubation at 25°C, 46 out of 70 samples (Table 2), selected on the basis of colony morphology and source of isolation, were maintained as monoconidial cultures in tubes of PDA and used for the molecular, biological and chemical characterization studies.

Micro and macro-morphological observations

For the macro-morphological analysis, all the isolates were plated onto PDA medium and incubated at 25 ± 1 °C in the dark. Radial growth was measured after 6 days, along two perpendicular lines intersecting the centre of the plate, where the inoculum plug (3 mm) was positioned. For the micro-morphology, the isolates were grown onto Potato Carrot Agar (PCA, HiMedia Laboratories, India) for 20 days and conidia were observed using a Nikon Eclipse 55i microscope at 40× magnification. The radial growth of cultures derived from twenty conidia per isolate was measured.

DNA extraction and molecular analysis

DNA was extracted from mycelium collected on PDA plates incubated at 25 °C in the dark for 8 days using Omega E.Z.N.A. Fungal DNA Mini Kit (VWR International, USA) according to manufacturer's instructions. Partial amplification of the RNA polymerase second largest subunit (RPB2), Alternaria major allergen gene (Alt-a1), endopolygalacturonase gene (endoPG) and an anonymous gene region (OPA10-2) were obtained using the primers and conditions listed in Supplementary Table 1. PCR was carried out using Taq DNA polymerase kit (Qiagen, Germany) in a total volume of 25 µL containing 2.5 µL of Qiagen PCR Buffer 10 X, 0.5 µL of $MgCl_2$, 0.75 µL of dNTPs (10 mM), 1 µL of each primer (10 µM), 0.2 µL of Taq DNA polymerase and 20 ng of template DNA. The PCR products were checked by gel electrophoresis in 1% agarose with 1 µL of GelRed™ (VWR International) at 100 V/cm for 45 min and purified using QIAquick© PCR purification Kit (Qiagen). Macrogen, Inc. (The Netherlands) sequenced the amplicons in both directions. The consensus sequences were created using a DNA Baser program (Heracle BiosoftS.R.L., Romania) and

alignment was performed using CLUSTALW through Molecular Evolutionary Genetics Analysis (MEGA6) software, version 6.0. After cutting the trimmed regions and manual correction, a dataset of 749 bp for RPB2, 354 bp for Alt-a1, 328 bp for endoPG, and 597 bp for OPA10-2, was obtained. MEGA version 6 was used to determine the best-fit nucleotide model for each dataset, for the concatenated dataset and to perform phylogenetic analysis under the Maximum Likelihood (ML) optimality criterion. All the reference sequences used for phylogeny are reported in Supplementary Table 2. All sequences were deposited in GenBank with accession numbers reported in Table 2.

Pathogenicity assays on pear fruits

Two *in vivo* assays were performed to test the pathogenicity of *Alternaria* spp. isolates. Healthy pear fruit cv. Abate Fétel at commercial maturity were surface sterilized with 1% sodium hypochlorite and rinsed in sterile deionized water. The first assay was performed to evaluate the pathogenicity on wounded fruits, where three wounds (2 mm diameter) were made per fruit, and each fruit was inoculated with a monoconidial suspension of $1x10^5$ conidia/mL prepared by growing isolates on Potato Carrot Agar (PCA; PCA, HiMedia Laboratories, India) for 20 days with a photoperiod of 12 h light: 12 h dark. The fruits were maintained at 24 ± 1 °C and exposed to natural daylight. The control pears were prepared as described above but they were treated with sterile deionized water. After 14 days, rot diameters were measured. The experiment was performed twice, with three biological replicates and nine technical replicates per isolate (n=18).

A second assay was performed at room temperature to evaluate the pathogenicity by direct penetration on healthy, non-wounded, fruits, inoculated with three mycelial plugs (5 mm each) per fruit. Mycelial plugs were obtained by culturing a selection of 17 isolates representative of fungal species, plant tissue, and orchard, onto Malt Extract Agar (MEA; Sigma-Aldrich, USA) plates incubated at 25 ± 1 °C in the dark for eight days. The plugs were fixed to the fruits using Parafilm. The fruits were maintained at 24 ± 1 °C. The control pears were prepared as described above but using medium plugs of MEA. After 14 days, rot diameters were measured. The experiment was performed twice, with three biological replicates and nine technical replicates per isolate (n=18).

***In vivo* mycotoxin production**

Chemicals

Standards of tenuazonic acid (TeA) copper salt from *A. alternata* (purity ≥98%), alternariol (AOH) from *Alternaria* spp. (purity ≥94%), alternariol monomethyl ether (AME) from *A. alternata* (purity ≥98%) and tentoxin (TEN) from *Alternaria tenuis* (purity ≥99%) were purchased from Sigma-Aldrich, whereas altenuene (ALT) from *Alternaria* spp. (purity ≥98%) and altertoxin I (ATX-I)

(purity ≥ 97%) from *Alternaria* spp. were purchased from Fermentek (Jerusalem, Israel), all in crystallized form. A stock solution of 1000 µg/mL was prepared in methanol for each mycotoxin and the working solution of 10 µg/mL was prepared by dilution and mixing the stock solution of each analyte and kept at −20 °C. Standard solutions for HPLC calibration and for additional experiments were prepared daily by diluting the working solution in solvent (CH_3CN:H_2O, 50:50, v/v) or blank matrix. Methanol, acetonitrile (VWR International,) and toluene (Sigma-Aldrich) were HPLC-grade. Ammonium acetate and hydrochloric acid (Sigma-Aldrich) were analytical reagent-grade. Water was obtained from a Milli-Q system (G. Maina, Italy).

Alternaria-toxins extraction from pear fruit

From each pathogenicity assay with wounded and inoculated fruits, two pears (biological replicates) were used to analyse the mycotoxins production *in vivo*. From each fruit, 3 cm-diameter rotten tissues were sampled and homogenized. Two technical replicates (4 g) from each fruit were placed in a centrifuge tube with 20 mL of extraction solution (CH_3OH:CH_3CN:H_2O, 10:45:45, v/v/v) and 500 µL of HCl 2 N. The mixture was shaken for 30 min in an ultrasonic bath and then centrifuged at 4691 g for 15 min. Sample extract was filtered through a Clarify-PP 0.22 µm polypropylene filter (Agela Technologies, China) and transferred to a new centrifuge tube with 10 mL of toluene (twice), vortexed for 1 min and centrifuged at 4691 g for 10 min. The organic phase was evaporated to dryness in a rotary evaporator at 50 °C and the residue dissolved in 500 mL of H_2O:CH_3CN 1:1 for the HPLC-MS/MS analysis. The assay was performed twice, with two biological replicates and four technical replicates (n=8).

HPLC-MS/MS analysis of Alternaria-toxins

The analysis of Alternaria-toxins was carried out using a 1260 Agilent Technologies system (Agilent, USA) consisting of a binary pump and a vacuum degasser, connected to a Varian autosampler, Model 410 Prostar (Hansen Way, USA), equipped with a 20 µl loop coupled to a Varian 310-MS TQ Mass Spectrometer. The chromatographic column used for LC separation was a Gemini-NX C18 (150 x 3.0 mm, 3.0 µm, Phenomenex, Torrance, CA, USA). Water (solvent A) and acetonitrile (solvent B), both with ammonium acetate 5 mM, were used as mobile phase at a flow rate of 300 µL/min. The initial mobile phase contained 40% B and was held for 2 min, and then the proportion of B was linearly increased to 100% over 6 min and then held for 4 min; finally, the column was returned to initial conditions and equilibrated for 10 min before the next injection. Sample ionization was performed by an electrospray (ESI) ion source operating in negative ion mode and the quantification was carried out performed using multiple reaction monitoring (MRM) using the following transition reactions: m/z 196>139 CE 20 eV and m/z 196>112 CE 24 eV for TeA; m/z 257>213 CE 22 eV and

m/z 257>147 CE 34 eV for AOH; m/z 271>256 CE 22 eV and m/z 271>228 CE 28 eV for AME, m/z 413>271 CE 16 eV and m/z 413>141 CE 18 eV for TEN, m/z 291>229 CE 12 eV and m/z 291>247 CE 20 eV for ALT, m/z 351>297 CE 25 eV and m/z 351>263 CE 35 eV for ATX-I. The collision gas (Ar) pressure was set at 2 mbar for all experiments.

HPLC-MS/MS method validation for Alternaria-toxins

The developed analytical method was evaluated for linearity, limit of detection (LOD), limit of quantification (LOQ), recovery and matrix effect (ME) for TeA, AOH, AME, TEN, ALT and ATX-I. These parameters were validated by following the guidelines of EN ISO/IEC 17025:2017 and performance criteria reported in Commission Regulation (EC) 401/2006. Different concentrations of mycotoxin standards were analysed to evaluate the linearity of measurements. Calibration standards were prepared by diluting the working solution in blank matrix. LOD and LOQ were estimated by the linearity of the calibration curves using spiked matrix samples. The recovery of Alternaria-toxins was determined at three concentrations in the pear matrix. Blank samples were spiked with standards of TeA, AOH, AME, TEN and ATX-I at low (50 µg/kg), middle (250 µg/kg) and high concentration (500 µg/kg) in three replicates, prior to extraction, and after extraction for the ME. The precision of the method was studied by investigating repeatability and reproducibility of peak area of all mycotoxins. Repeatability (intra-day precision) was evaluated by measuring 5 parallel injections of 3 replicates within a day. Reproducibility (inter-day precision) was calculated from the data of the experiment carried out in three consecutive days. Mixed standard solutions of TeA, AOH, AME, TEN and ATX-I were used at the concentration of 200 µg/L. Evaluation of repeatability and reproducibility was based on calculating the relative standard deviation (RSD %).

Statistical Analysis

The analysis of the differences between the mycotoxins produced by the isolates correlated to the species was performed using Mann-Whitney two-tailed test using the software IBM SPSS statistics software Inc. version 24 (Chicago, IL, USA). Mean mycotoxins concentrations were calculated by using 0 for negative samples. Experimental results are reported as mean ± standard deviation (SD).

3. Results

Taxonomic assignment

Forty-six isolates of *Alternaria* spp. were collected from pear leaves (23) and fruits (23). Isolates showed an initially light grey colour that turned into olive to dark green. Colonies were mostly with

white margins onto PDA plates (Supplementary Fig. 1), with a mean radial growth of 3.75 ± 0.87 cm after 7 days growth at 25 ± 1 °C. Hyphae were brown, while conidiophores were light brown. Conidia were ovoid or ellipsoidal with 1-4 transverse septa and 0-5 longitudinal septa, mean 20.07 ± 0.64 µm in length and 11.41 ± 0.06 µm in wide (Supplementary Fig. 1). Based on these morphological observations, the isolates were tentatively identified as *Alternaria* spp. (Simmons, 2007; Woudenberg et al., 2013).

According to the classification reported by Woudenberg et al. (2015) and Lawrence et al. (2016), the isolates could not be attributed to *Alternaria* section *Alternaria* by morphological observations (Table 2) and a specific expertise is needed to correctly identify based only on morphological characters. An alternative identification tool in species assignation is represented by molecular analysis.

The dendrogram (Fig. 2) and bootstrap consensus tree (Supplementary Fig. 2), obtained with phylogenetic ML analysis based on 4 concatenated genes, showed that the isolates clustered in two groups, each one including the reference species of *Alternaria* section *Alternaria*, with a statistical support lower than 70%. Fifteen out of 46 isolates grouped together with the CBS references isolates of *A. arborescens* species complex (AASC), whereas three isolates (GB3, GB4, 2AFA) did not cluster with any CBS references isolates. The remaining 28 isolates grouped together with the CBS references isolates of *A. alternata* (Fig. 2). The two species were isolated from both fruits and leaves and were present in all the sampled orchards except for orchard n° 7, where only *A. alternata* was found.

By considering each gene locus, phylogenetic tree topology and species assignment were different for some isolates (data not shown). However, the phylogeny based on OPA 10-2 (Fig. 3) was the only region showing strong bootstrap support for the AASC clade (74% bootstrap), where isolates clustered with AASC references. Only one isolate (2AFA) did not cluster with the references in the AASC clade. Furthermore, a second subgroup (bootstrap 84%) with two isolates (GB4 and MS5) did not cluster with the reference isolates of *A. alternata*. Based on these observations, we decided species assignment on the congruence between the results of the concatenated dataset and the single OPA 10-2 dataset. Fifteen isolates were identified as AASC, 27 isolates as *A. alternata* and the four isolates not clustering with the others (2AFA, GB3, GB4 and MS5) were named *Alternaria* sp..

Pathogenicity on pear fruits

All isolates were pathogenic when artificially inoculated on European pear (Table 2), with a mean rot diameter of 4.0 ± 0.59 cm. The isolate BR3, isolated from fruit, showed the highest rot diameter (4.92

± 0.90 cm), whereas the isolate F1A, isolated from leaf, showed the lowest rot diameter (3.01 ± 0.06 cm). All isolates inoculated on pears caused the development of black rot (Fig. 4).

A selection of isolates was used to perform the pathogenicity assay on healthy non-wounded fruits. All isolates confirmed to be pathogenic by directly penetrating the fruits (Fig. 5; Supplementary Table 3), with a mean rot diameter of 3.03 ± 0.52 cm. The isolates ALTCER2A and ROS15, isolated from fruit and leaf respectively, showed the highest rot diameter (3.83 ± 0.25 cm).

Alternaria-toxins production on pear

Six mycotoxins (TeA, AOH, AME, ALT, ATX-I and TEN) were investigated using the external calibration method and the range of calibration curve was defined for each analyte based on the amount detected in pear samples. In order to validate the method, some pear samples were analyzed for the absence of the target mycotoxins to evaluate their natural occurrence. Good linearity was obtained for every compound ($R^2 > 0.993$). All the calculated recoveries were between 70% and 100% (Supplementary Table 4), in accordance with the Commission Regulation (EC) No 401/2006 of February 2006. The matrix mostly influenced TeA and AOH with signal suppression and enhancement, respectively (Supplementary Table 4). To compensate for the matrix effects on quantitative results, the calibration curve in blank matrix was built. The LOD and LOQ values of the six analytes are shown in Supplementary Table 4. The precision of data obtained (intra-day and inter-day data) at 200 µg/L concentrations of all mycotoxins were within 10.0 RSD %. The retention times of the toxins were TeA 1.8 min, ALT 4.1 min, TEN 6.1 min, ATX-I 6.5 min, AOH 7.7 min, and AME 9.9 min.

All *Alternaria* isolates were analysed for production of the six mycotoxins on pears (Table 3) and confirmed to be mycotoxin producers, being able to produce at least one analyte. The only exception is represented by isolate DV2, which did not produce any mycotoxin (Fig. 6). TeA and AOH were the most frequently produced mycotoxins (both 95.6%), followed by AME, ATX-I, ALT and TEN (89.1%, 80.4%, 50.0% and 2.2% respectively). About 39% of isolates showed the ability to produce simultaneously five mycotoxins (TeA, AOH, AME, ALT and ATX-I), but not TEN, produced only by isolate MS3 (*A. alternata*). Twenty isolates (43.5%) were able to produce four mycotoxins (TeA, AOH, AME and ALT or ATX-I), whereas six isolates (13%) produced three secondary metabolites. One isolate (ROC) produced only TeA. We also note that AOH and AME were detected together in 89% of the samples.

The most mycotoxigenic isolates were 2AFA (*Alternaria* sp.), F1A (AASC), BR7 (*A. alternata*), ALTFRC (AASC), GB3 (*Alternaria* sp.), DV3 (AASC) and ROS3 (AASC), with a total concentration (all six analytes together) ranging from 20.60 µg/g to 40.57 µg/g, whereas the lowest mycotoxigenic

290 isolates were ROC (*A. alternata*), MS6 (*A. alternata*), ALCER2A (*A. alternata*), GB1 (AASC), GBF
291 (*A. alternata*) and AL1 (AASC), with a total concentration of less than 1 µg/g. In particular, TeA and
292 AME were the most abundant mycotoxins, with concentrations ranging from 0.06 µg/g (MS3) to
293 22.02 µg/g (DV3) for TeA and from 0.03 µg/g (ROS17) to 19.71 µg/g (ROS3) for AME. The AOH
294 levels varied from 0.04 µg/g (F4B) to 12.0 µg/g (ALTFRC). ALT and ATX-I were on average less
295 abundant compared to the other mycotoxins (from 0.006 µg/g to 0.256 µg/g for ALT and from 0.005
296 µg/g to 0.11 µg/g for ATX-I). The only isolate that produced TEN on inoculated pears was MS3, with
297 a concentration of 0.023 µg/g.
298 Moreover, *A. alternata* isolates showed significantly ($P<0.005$) different ability to produce AOH and
299 ALT compared to AASC isolates, using the Mann-Whitney two-tailed test. For the other mycotoxins
300 no significant differences were found ($P>0.005$).

301

302 ## 4. Discussion

303 *Alternaria*, one of the most common fungal genera, is found in different matrices such as plant tissues,
304 agricultural products, soil and the atmosphere (Woudenberg et al., 2013; Nishikawa and Nakashima,
305 2020), but few publications reported the presence of *Alternaria* section *Alternaria* as a pathogen on
306 European pear in Europe (Thanassoulopoulos, 1990; Gianetto et al., 2013; Wenneker et al., 2019).
307 In this study monitoring was carried out in seven orchards in order to investigate the pathogens
308 responsible of black spot on pear fruits cv. Abate Fétel. All orchards investigated showed the presence
309 of *Alternaria* spp.. In only one orchard we observed co-occurrence of *Alternaria* spp. and, to a lower
310 extent, of *Stemphylium vesicarium* (data not shown). *Stemphylium vesicarium* was the most
311 frequently pathogen normally isolated from brown spots on European pear in Italy since the late 1970s
312 (Alberoni et al., 2008). Unlike from what has been reported in literature and initially expected, in this
313 work we have mostly isolated *Alternaria* spp.. The present work consisted in identifying and
314 characterizing *Alternaria* species associated to black spot on European pear, by evaluating their
315 pathogenicity on pear fruits cv. Abate Fétel and by using molecular and chemical analysis. As
316 described by Peever et al. (2004) and Andrew et al. (2009), most of the species of *Alternaria* section
317 *Alternaria* cannot be distinguished using standard housekeeping genes. In the study of Woudenberg
318 et al. (2015), nine gene regions, 5.8S nrDNA (ITS), the 18S nrDNA (SSU), the 28S nrDNA (LSU),
319 glyceraldehyde-3-phosphate dehydrogenase (gapdh), translation elongation factor 1-alpha (tef1),
320 RPB2, Alt-a1, endoPG and OPA10-2, were used to solve the phylogeny of this section, but they
321 obtained a Bayesian posterior probability lower than 0.75 for the AASC. The phylogeny obtained
322 from our Maximum likelihood concatenated dataset of RPB2, Alt-a1, endoPG and OPA10-2 gene

regions for the isolates isolated from European pear in this study provided an unclear species assignment, with two clades dividing *A. alternata* isolates from AASC isolates, with low bootstrap value, and a few isolates that did not cluster with any reference isolate. Based on single locus phylogeny, a different species assignment for some isolates and a low bootstrap value at major internodes were observed. The only locus showing strong bootstrap support for the AASC clade (74% bootstrap) was OPA 10-2. Based on these observations, we decided species assignment on the congruence between the results of the concatenated dataset and the single OPA 10-2 dataset. This permitted to identify 15 isolates as AASC, 27 as *A. alternata* and four as *Alternaria* sp.. The results showed the inability of the selected genes to clearly distinguish AASC from *A. alternata*. The incongruence observed between tree topology and species assignment was similar to the results of Woudenberg et al. (2015), with a Bayesian Posterior Probabilities, which was lower than 0.75 for the AASC. The branching topology and low bootstrap support found with ML suggest that *A. alternata* could be paraphyletic (DeMers, 2022), although definitive conclusions are not possible at this stage. Both species were isolated from fruits and leaves and were present in all sampled orchards except one where only *A. alternata* was found. The presence of both *A. alternata* and AASC was previously observed in different hosts, such as apple (Rotondo et al., 2012), pistachio (Pryor and Michailides, 2012), basil (Siciliano et al., 2018), pear (Wenneker et al., 2019), and citrus (Garganese et al., 2016; Aiello et al., 2020).

The pathogenicity assay on wounded pears cv. Abate Fétel at commercial maturity showed that all isolates of *Alternaria* spp. were pathogenic, with no significant differences in rot development between isolates isolated from fruits or leaves. A second assay, performed on healthy non-wounded fruit, confirmed the pathogenicity on a selection of isolates, representative of fungal species, plant tissue and orchard. The isolates produced a black rot, both on wounded fruit, by conidial inoculation, and on healthy fruit, by contact with a mycelial plug. This demonstrates their pathogenicity either by wound colonization or by direct contact with the pear skin, though black spot symptoms could be obtained on immature fruit. *Alternaria alternata* on European and Japanese pear was previously reported associated to the dead flower buds disease (Wenneker et al., 2019). In Greece (1983) and Italy (2012), severe symptoms of Alternaria black spot caused by virulent *A. alternata* isolates were reported on *Pyrus communis* cv. Abate Fétel, with a disease incidence reaching 80% and 100%, respectively (Thanassoulopoulos, 1990; Gianetto et al., 2013), with figures similar to the present study. During the last years, and in particular during season 2018, high temperature and humidity during summer, together with high precipitation during spring, were recorded. These changes in the average climate parameters could favour the infections of *Alternaria* spp. (Dickinson and Bottomley, 1980), resulting in more serious and severe symptoms, as already reported by Reis et al. (2007) and

Yang et al. (2019). Previously, Gianetto and colleagues (2013) reported similar, but less severe symptoms in northern Italy regions (Piedmont, Trentino, and South Tyrol). This climatic change, and in particular the increase in the average temperature, could affect the pre-harvest development of *Alternaria* spp., as previously demonstrated (Van de Perre et al., 2015).

This study represents the first report of *A. arborescens* species complex as agent of black spot on European pear in Italy, but AASC was previously reported as agent of leaf blotch and premature leaf drop on apple cv. Golden Delicious in the Netherlands (Wenneker et al., 2018), as agent of dead flower buds on European pear in the Netherlands (Wenneker et al., 2019), and on *Pyrus* sp. in Austria (Woudenberg et al., 2015).

In our study, no specific toxins were produced by the two species isolated from European pear, underlining the inability of chemical analyses to differentiate *Alternaria alternata* from AASC. In particular, TeA and AOH (89.1% of the isolates), AME (89.1%), ATX-I (80.4%), ALT (50.0%) and TEN (2.2%) were produced. Accordingly to Zwickel et al. (2018), on rice inoculated with the same species, the main mycotoxins produced were TeA, AOH and AME. Hayashi and colleagues (1990) reported also the production of ATX-I by *A. alternata* isolates isolated from *Pyrus pyrifolia.*

It is well-known that mycotoxin production is influenced by different parameters, such as water activity (a_w), temperature, and carbon and nitrogen sources. Our data showed that TeA, AOH and AME were the most produced mycotoxins (in frequency and amount) on inoculated pears at 24 ± 1 °C. As reported in literature, the optimal temperature for the production of these secondary metabolite is 25 °C, either *in vivo* or in synthetic media (Magan et al., 1984; Oviedo et al., 2009; Oviedo et al., 2010; Meena et al., 2017). Compared to the other Alternaria-toxins, ATX-I, ALT and TEN were produced less in terms of concentration and numbers of isolates able to produce them *in vivo*, different from the study of Li and colleagues (2001) for *A. alternata* isolates on wheat kernels. The great amount of carbon sources in pear fruit could have positively influenced the mycotoxin produced, as already reported by Brzonkalik et al. (2011). Furthermore, Van de Perre et al. (2015) reported that climate change can have an effect on several factors, including biological and environmental factors and a shift in microbiological ecology, which are influencing the pre-harvest development of *Alternaria* spp. and its potential to produce mycotoxins.

Currently, no regulatory limits are established by the European Union for *Alternaria* mycotoxins in food, but European Food Safety Authority (EFSA) classified some secondary metabolites, including AOH, AME, ATXI, ATXIII, and TeA as mycotoxins potentially harmful to human health, due to their genotoxic or mutagenic potential (EFSA, 2011; Arcella et al., 2016). In our study, 98% of the isolates were able to produce at least two mycotoxins and 43.5% produced four mycotoxins with a mean total concentration exceeding 7.58×10^6 ng/kg. There are few or no relevant data on the toxicity

of Alternaria-toxins, however EFSA (EFSA, 2011) considered appropriate to use the threshold of toxicological concern (TTC) approach to assess the relative level of concern for these mycotoxins. For AOH and AME the suggested TTC was 2.5 ng/kg body weight per day (0.15 µg/person per day), while for TeA and TEN it was 1,500 ng/kg body weight per day (90 µg/person per day). The European Union, with the recent Commission Recommendation 2022/553, suggested some limits on Alternaria-toxins, with indicative levels for AOH, AME and TEA in certain foods. This document underlines the need to carry out investigations to identify the factors that influenced the production of these mycotoxins. In our experiments, the average concentration of the six Alternaria-toxins found on inoculated fruits was higher than the values reported in Commission Recommendation 2022/553 for the only fruit derived product reported (10 µg/kg AOH, 5 µg/kg AME and 500 µg/kg TeA), underlining a potential risk for human health.

The risks for consumers are related to the consumption of fruit-derived products, such as juices, nectars or purees. Often, second-choice fruits or fruits apparently healthy but affected by core rot could be used for the production of fruit-derived products (Moake et al., 2005; Spadaro et al., 2007). Pear juices and nectars are among the most consumed fruit-based products in Italy, and they are highly consumed by infants (Spadaro et al., 2008). The above mentioned factors contribute to create a potential risk for consumers. Gotthardt and colleagues (2019) reported that some apple and pear products for infants were highly contaminated by AOH, TEN and AME. The presence of AOH, AME, TeA and TEN was also reported on juices, tomato, cereal based products and sunflower seed during a European food surveys. Furthermore, in a study of Pan et al. (2017), *A. alternata* was detected on pear juice underlining the risks for human safety linked to the possible production of mycotoxin.

In literature, the main fungal pathogen reported on European pear is *S. vesicarium*, although from the orchards targeted by this study we were able to isolate this fungal species only in one orchard with a very low frequency (data not shown).

Generally, mycotoxins act as virulence factors, without being essential for the pathogenicity, and only few studies reported their implication in *Alternaria* spp. pathogenicity (Graf et al., 2012; Meena et al., 2017). More recently, Wenderoth et al. (2019) demonstrated that the production of AOH was associated to the virulence and colonization ability of *A. alternata* on tomatoes, citrus and apple. In our study, all the *Alternaria* spp. isolates isolated from fruits and leaves were virulent and produced a great amount of AOH and its derivative AME, suggesting that pathogenicity and virulence on European pear could be linked to the production of these mycotoxin.

In conclusion, the presence of different *Alternaria* species pathogenic on European pear suggests that more than one fungal species is responsible for black spot, an important information to plan effective management strategies in the field. The production of different mycotoxins also highlights the

425 possible strong effect on human health due to exposure to multiple toxic effects. Furthermore, the
426 potential involvement of different mycotoxins on pathogenicity should be investigated, including the
427 study of TeA, which is one of the main mycotoxins produced on pear fruits.

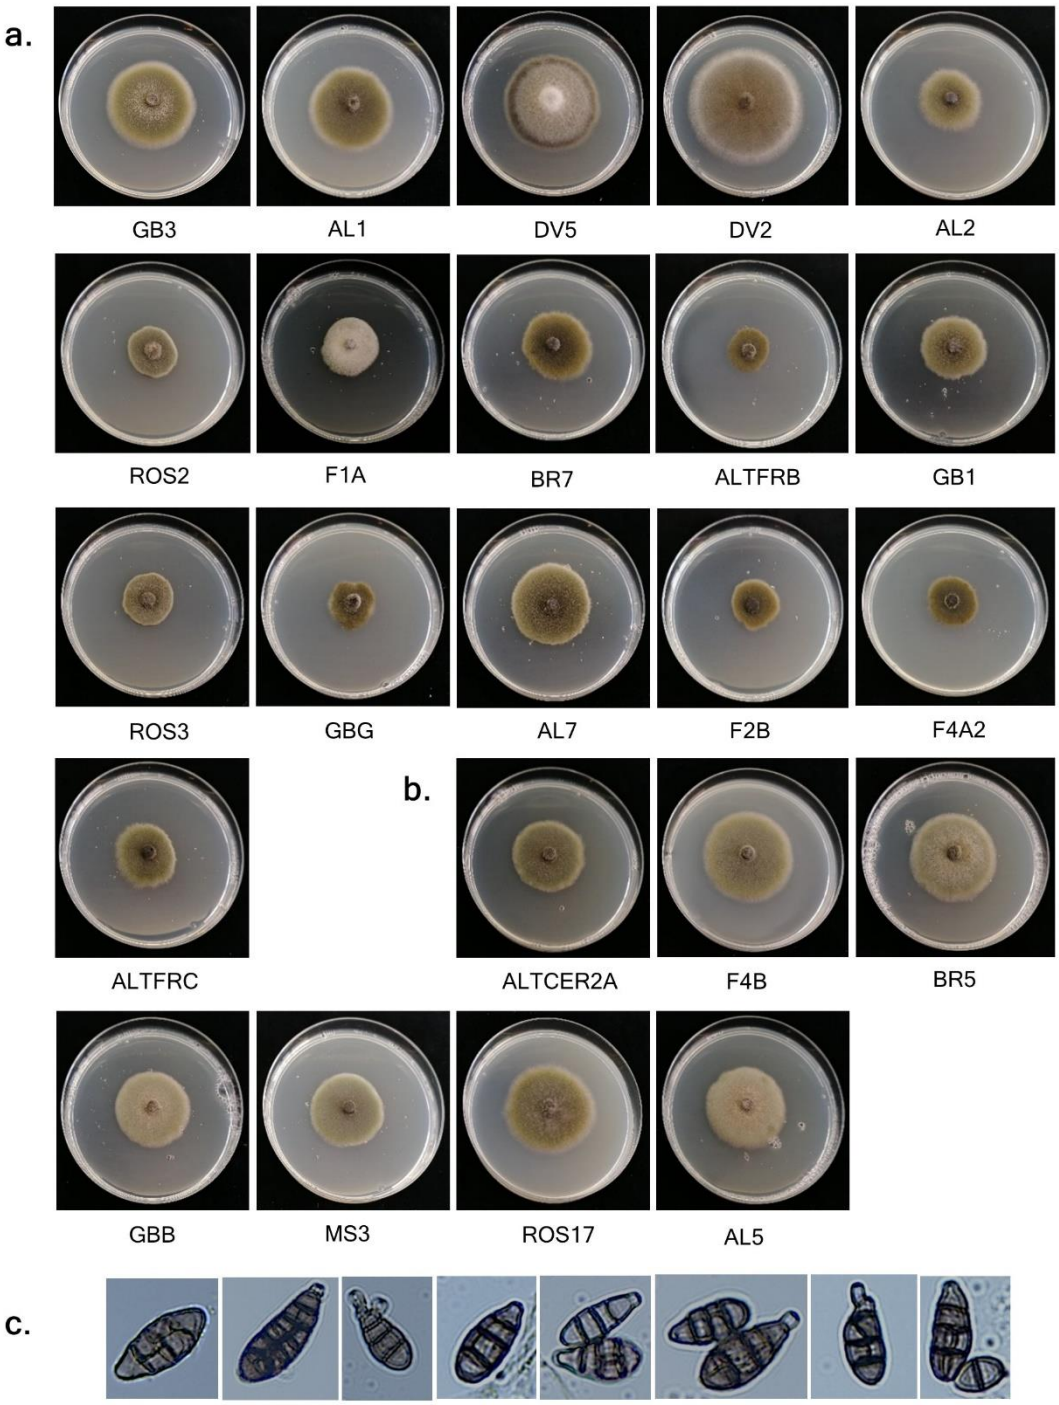
MS6	*A. alternata*	Leaf	7	3.40 ± 0.14

Supplementary Table 4 - Validation parameters for the six *Alternaria* toxins in pear matrix.

Analyte	Recovery %	ME %	LOD ng/g	LOQ ng/g	R^2	Inter-day (RDS %)	Inter-day (RDS %)
TeA	86.8±4.48	39.8	18.1	60.5	0.9977	5.2	7.8
AOH	93.1±13.2	153.9	1.9	6.5	0.9960	6.5	7.1
AME	92.5±7.8	125.5	3.4	11.2	0.9941	2.7	4.0
TEN	78.53±9.7	69.2	8.5	28.4	0.9994	6.4	9.3
ALT	88.7±4.6	120.8	3.3	11.1	0.9962	6.6	7.3
ATX-I	82.3±6.1	77.7	4.2	13.8	0.9938	7.0	9.1

Supplementary Figures

Supplementary Figure 1 - Morphology of some *Alternaria* spp. isolates isolated from fruits and leaves of *Pyrus communis* cv. Abate Fétel. a. Colonies morphology of AASC after 7 days of incubation at 25 ± 1°C on Potato Dextrose Agar medium. b. Colonies morphology of *A. alternata* isolates after 7 days of incubation at 25 ± 1°C on Potato Dextrose Agar medium. c. Conidial obtained from isolates grown on Potato Carrot Agar medium for 20 days.



Supplementary Figure 2 - Bootstrap consensus tree based on the concatenated RPB2, Alt-a1, endoPG and OPA10-2 sequence datasets. The phylogenetic tree was constructed with Maximum Likelihood analysis using Tamura Nei (TN93) plus Gamma distribution (+G) model and by assuming that a certain fraction of sites are evolutionarily invariable (+I). Evolutionary analyses were conducted using MEGA, version 6.
