ABSTRACT

This study investigates the impact of wastewater treatment plant (WWTP) effluent on the toxicity of the recipient water body and the effectiveness of the disinfection treatment applied (sodium hypochloride) to assure the compliance of both microbiological and toxicological emission limits. No toxicity was found in the majority of samples collected from the recipient river, upstream and downstream of the WWTP, using three different toxicity tests (*Vibrio fischeri, Daphnia magna, Pseudokirchneriella subcapitata*). Only three samples presented Toxic Unit (TU) values with *V. fischeri*, and one presented TU with *S. capricornutum*. The influent toxicity ranged from slightly toxic to toxic (TU = 0.68 - 4.47) with *Vibrio fischeri*, while only three samples presented TU values with the other tests. No toxicity was found in the absence of chlorination, while the mean toxicity was 3.42 ± 4.12 TU with chlorination in the effluent. Although no toxicity or very slight toxicity was found in the receiving water, its residual toxicity was higher than the U.S. EPA Quality Standard in two samples. *E. coli* concentration had a lower mean value in the chlorinated effluent: 13,993 ± 12,037 CFU/100 mL vs. 62,857 ± 80,526 CFU/100 mL for the non-chlorinated effluent. This difference was shown to be significant ($p < 0.05$). *E. coli* in ten chlorinated samples was higher than the limit established by European and Italian Legislation. The mean highest Trihalomethanes (THMs) value was found in the influent samples (2.79 ± 1.40 µg/L), while the mean highest disinfection by products (DBPs) was found in the effluent samples (1.85 ± 2.25 µg/L). Significant correlations were found between toxicity, sodium hypochlorite, THMs, DBPs, *E. coli* and residual chlorine.

In conclusion, this study highlighted that the disinfection of wastewater effluents with sodium hypochlorite determines the increase of the toxicity, and sometimes is not enough to control the *E. coli* contamination.

Keywords: Wastewater; Chlorination; Toxicity; Trihalomethanes; *Escherichia coli.*

1. Introduction

Industrial wastewater, effluent of sewage treatment plants and run-off from agriculture are major sources of surface water pollution. Wastewater is a complex mixture of various organic and inorganic compounds; in addition to the unknown products discharged into the wastewater treatment plants, other substances are formed during the treatment processes (Farrè et al. 2001; Ricco et al. 2004). Moreover, in recent years, the incidence of human-use compounds, such as pharmaceuticals and drugs, in aquatic environments has been recognized as an important issue in environmental chemistry. Some of these compounds enter the aquatic environment, mostly via the effluents of municipal sewage treatment plants, unaltered or as slightly transformed metabolites (Huerta-Fontela et al. 2008; Watkinson et al. 2009). Due to the presence of several chemical pollutants, no useful monitoring or screening of surface water can be based only on chemical analysis of a limited number of toxic compounds. Therefore, biological tests prove to be indispensable for the assessment of cytotoxic and genotoxic potential in surface water. Because of the variety of aquatic organisms and the heterogeneous condition in aquatic environments, there is no single biotest for detecting toxic and genotoxic effects. Only a set of bioassays with prokaryotic and eukaryotic organisms can be applied to estimate accurately the effects of toxicants in surface waters (Dizer et al. 2002; Persoone et al. 2003).

One of the objectives of the European Communityôs (EC) environmental regulations is to reduce the pollution of surface water caused by municipal waste (see the Council Directive 91/271/EEC as amended by the Commission Directive 98/15/EEC of 27 February, 1998). This requires the European Union (EU) member states to ensure that discharge of urban wastewater and its effects are monitored (Farrè et al. 2001; Mantis et al. 2005, see also Council Directive 2000/60/EC).

In order to prevent sanitary hazards related to the uses of recipient water bodies, the current Italian regulations prescribe WWTP effluent emission limits for a wide range of chemical compounds, toxicity and bacterial discharge (i.e., *Escherichia coli*). In order to

meet the bacterial discharge limit, WWTPs can introduce a wastewater disinfection step; however, disinfectants may induce chemical reactions, leading to the production of disinfection by-products (Decree Italian Law 152/2006).

The microbiological emission limit of *E. coli* is not stated by the national regulation at a general level, but it should be established by local authorities in each specific discharge licence with respect to the public health situation, and to the foreseen uses of the recipient water body. In the case of the WWTP investigated, the local authority (Piedmont Region) has evaluated the introduction of a concentration limit for *E. coli* of 20,000 CFU/100ml, while the Council Directive 2000/60/EC has introduced a concentration limit for *E. coli* of 5,000 CFU/100ml. In order to respect this limit, many WWTPs apply a wastewater disinfection process, because sometimes the *E. coli* concentration at the end of the purification process is higher than the limit established by the local authorities and by European legislation. However, disinfectants can induce chemical changes in these systems, thus resulting in changes that will not be restricted to the microbial population. One possible outcome of these chemical changes is a change of the effluent toxicity, as demonstrated by Blatchley et al. (1997), Monarca et al. (2000), Wang et al. (2007) and Wu et al. (2010). Chemical disinfectants are effective for killing harmful microorganisms in water, but they are also powerful oxidants, oxidizing the organic matter, anthropogenic contaminants, and bromide/iodide naturally present in most source waters (rivers, lakes, and groundwater). Chlorine, ozone, chlorine dioxide, and chloramines are the most common disinfectants in use today: each produces its own suite of DBPs in water, with overlapping constituents. In the 30 years since the THMs were identified as DBPs in drinking water, significant research efforts have been directed toward increasing the understanding of DBP formation, occurrence, and health effects. Although more than 600 DBPs have been reported in the literature, only a small number has been assessed either in quantitative occurrence or health-effects studies (Richardson et al. 2007). Toxicity of water disinfection and DBPs was studied intensively. Many chlorinated by-products showed doseï response

relationships with DNA and chromosome damage, cytotoxicity and apoptosis in vivo (Lu et al. 2002; Richardson et al. 2007; Yuan et al. 2006) or in vitro (Boorman et al. 1999; Lu et al. 2004; Yuan et al. 2005; Shi et al. 2009).

The aim of the present work was to investigate the impact of a WWTP effluent on the recipient water body, with particular respect to its toxicity, and to verify the effectiveness of disinfection treatment with sodium hypochlorite (NaOCl). This was to ensure the compliance with both microbiological and toxicological emission limits, using three different toxicity tests (*Vibrio fischeri, Daphnia magna, Pseudokirchneriella subcapitata*). Finally, the presence of disinfection by-products (trihalomethanes) and *E. coli* was measured to evaluate the correlation with acute toxicity and the efficiency of the chlorination process.

2. Material and methods

2.1. Features of the sewage treatment plant

The considered WWTP is a consortium plant that treats civil and industrial discharges from the municipal districts of Collegno, Grugliasco, Rivoli and Villarbasse (Torino, Piedmont Region, Italy), a metropolitan area in Northern Italy, with a total population equivalent of about 400,000. The mean treated flow is around 42,000 m^3/day. The plant comprises a water and sludge treatment system. The former includes primary sedimentation, active sludge oxidation with nitrification/denitrification processes, and a section for the recovery and reutilization of treated water. The mean COD of the influent and of the effluent is 844.16 mg/L and 40.5 mg/L. In order to limit and to evaluate microbiological emissions, 15 of the 22 effluent samples were chlorinated with sodium hypochlorite (3 mg/L) at a mean dosage of 34 L/h. The final effluent was then discharged into the Dora Riparia River (one of the tributaries of the Po River, the largest Italian river) which has a mean flow rate of 26 m^3/s.

141 *2.2. Sampling of sewage and water*

142 Twenty-four hour composite samples of the influent (IN) and final WWTP effluent
143 (OUT) were taken during ten different sampling events from February 2005 to
144 November 2005 (first sampling period) and twelve different sampling events from
145 September 2006 to May 2007 (second sampling period). On the same dates, grab
146 samples of water were collected from the recipient river, 2 km upstream (US) and 2 km
147 downstream (DS) of the WWTP. The samples (4 ï 14 L) were divided into four aliquots
148 and stored in brown glass flasks at 4°C. In each sample, an aliquot of 1 L was used for
149 the toxicological analysis, and another 200 mL aliquot was utilised for the
150 microbiological analysis. Another 1 L aliquot was used for trihalomethanes (THMs)
151 analysis (only during the second sampling period), and the remainder was stored at
152 4°C until the end of the analyses. All the analysis were performed within 24 hours from
153 the sampling. Also grab disinfected effluent samples (100 ml) were collected for
154 immediate analysis of the residual chlorine.

155

156 *2.3. Microbiological analysis*

157 Determination of *E. coli* was performed using the membrane filter technique (AWWA
158 1998), which is highly reproducible, can be used to test relatively large sample
159 volumes, and yields numerical results more rapidly than the multiple-tube procedure.
160 The results are expressed in Colony Forming Unit (CFU)/100 mL.

161

162 *2.4. Biological assays*

163 Microtox™ test

164 After the screening test, the BASIC test (90%) was applied following the procedure
165 described in the Microtox™ manual (Azur Environmental 1995). The principle of this
166 system is based on the evaluation of the luminous energy naturally emitted by *V.*
167 *fischeri* bacteria (Azur Environmental, Carlsbad, CA, USA). Luminescence was
168 measured at time zero and after 5, 15 and 30 minutes, and compared to the control.

169 The final expression of the toxic potentials of samples is the Effective Concentration at
170 30 minutes, EC50, showing the sample concentration factor which caused a 50%
171 brightness decrease of the bacteria population. Each test was analysed using a
172 MicrotoxÊ reference toxicant (phenol) as quality control.
173
174 *Daphnia magna test*
175 This test is based on the evaluation of the immobilization of 10 organisms in the
176 presence of stress sources against a control. The dormant eggs of the crustacean and
177 stock solution for preparation of the standard freshwater (International Organization for
178 Standardization) medium were taken from the commercial test system, DaphToxkit F™
179 *magna* (MicroBioTests, Nazareth, Belgium). The hatching of ephippia and the
180 preparation of standard freshwater were performed according to the manufacturer's
181 instructions. The ephippia were transferred to hatching petri dishes with 50 mL pre-
182 aerated standard freshwater, thereafter covered and incubated for 72 hours, at 20ï
183 22°C under continuous illumination of 6000 lux. A dilution series of treated and
184 untreated water samples was prepared by serial 1:1 dilution with standard freshwater.
185 Assays were carried out in 24-well plates. Five neonates were transferred into each
186 well, which each contained a 10ml water sample. Freshwater controls were included in
187 every test. Tests were performed in quadruplicate. The plates were covered and
188 incubated at 20°C in the dark. After 24 hours and 48 hours of incubation, the number of
189 dead and immobilized neonates was recorded, and the percent mortality was
190 calculated (Cao et al. 2009). The toxic potential of the sample is expressed with EC50,
191 showing the concentration of the sample which causes the immobilization of the 50% of
192 the organisms against the control (OECD 1984a).
193
194 *Pseudokirchneriella subcapitata test*
195 The algal culture and stock solution for the preparation of growth media were taken
196 from the commercial test system AlgalToxkit F™ (MicroBioTests, Nazareth, Belgium).

Water and wastewater samples were supplemented with mineral nutrients, and incubated with *P. subcapitata* at 23°C ± 2°C under constant uniform illumination (8000 lux) for 72 hours in disposable long cells in polystyrene (volume 25 mL). The test was run in triplicate for both samples and controls. Algal growth was followed by optical density (OD) at 670 nm after 24, 48 and 72 hour exposure to the samples. The algal growth inhibition was calculated from these data by integrating the mean values, from time zero to time 72 hours, for each concentration tested, including control. The toxic potential of the samples is expressed with EC50 (OECD 1984b). The toxicity test is considered acceptable when the number of algae in the control test vials increases at least by a factor of 16 during the 72 hour test period and the pH does not change by more then one unit.

Final expression of the toxicity results

The EC50 values of the three tests were subsequently converted in toxic units (TU) that are proportional to toxicity:

$TU = (1/EC50) \times 100$

Considering the hazard classification system for wastes discharge into aquatic environment described by Persoone et al. (2003) the judgment of toxicity depends on the values shown in Table 1.

Without specific information concerning the persistence of toxicity, it is recommended that effluent toxicity is limited to dilution estimates and that toxicity is assumed to be additive and conservative. For rivers, the following dilution equation should be used, assuming completely mixed conditions:

$$C = (C_s Q_s + C_e Q_e)/(Q_e + Q_s)$$

C = downstream toxicity concentration (TU)

C_s = upstream toxicity concentration (TU)

Q_s = upstream mean flow

C_e= effluent toxicity concentration (TU)

225 Q_e =effluent mean flow (U.S. EPA, 1991).

226 The downstream toxicity concentration (C) was calculated considering the highest TU
227 value of the three tests applied.

228

229 *2.5. Trihalomethanes analysis*

230 Trihalomethanes (THMs), composed of disinfection by-products (DBPs) chloroform,
231 bromoform, chlorodibromomethane, bromodichloromethane and other THMs, 1,1,1-
232 trichloroethane, trichloroethylene, carbon tetrachloride, 1,2-dichloroethane,
233 trichloroethylene, and tetrachloroethene, were analysed by headspace combined with
234 gas chromatography coupled to an electron capture detector (GC-ECD) (Ottavini and
235 Bonadonna 2000), with a detection limit of 0.1 µg/L in the samples collected during the
236 second sampling period (Sep 2006 ï May 2007).

237

238 *2.6. Residual chlorine analysis*

239 The residual chlorine concentrations of the effluent samples were analysed as reported
240 in the Standard Methods for the Examination of Water and Wastewater (AWWA 1998).

241

242 *2.7. Statistical analysis*

243 The statistical analyses were performed with the statistical package SPSS 17.0 (SPSS
244 for Windows, Chicago, IL, USA) using Spearmanôs test, ANOVA, Probit regression
245 analysis and *T*-test.

246

247 **3. Results**

248

249 *3.1. Toxicity*

250 Tables 2 - 5 report the toxicity of the 22 different water samples in the four sampling
251 sites. The samples collected from the Dora Riparia River, upstream (table 2) and
252 downstream (table 5) of the WWTP, were not toxic with the three toxicity tests adopted

(Microtox™, *Daphnia magna, Pseudokirchneriella subcapitata*), not even when the chlorination process of the final effluent was started (June 2005) during the first sampling period. But, during the second sampling period, we found acute toxicity in some samples. The sixteenth sample US, and the sixteenth and eighteenth samples DS exhibited slight acute toxicity with Microtox™. Moreover, the fifteenth sample DS exhibited acute toxicity (TU = 1.55) with *P. subcapitata*. As reported in table 3, all the influent samples exhibited TUs and the toxicity ranged from slight acute toxicity to acute toxicity (TU = 0.68 - 4.47) with *V. fischeri*, while only the eleventh and the twentieth samples presented TUs values with *D. magna* (TU sample 11 = 1.09, TU sample 20 = 2.05), while the twenty-second sample presented TU = 1.18 with *P. subcapitata*. So *V. fischeri* was confirmed to have a different sensitivity in the toxicity evaluation of wastewater (Tiġler and Zagorc-Konļan 1999; Ricco et al. 2004). As reported in table 4, TUs (*V. fischeri*) were often detected in the WWTP effluent samples ranging from 0.40 to 13.83. Using the hazard classification system reported by Persoone et al. (2003), the OUT site was classified from not toxic to hightly toxic. Moreover, four effluent samples presented TUs with *D. magna* ranging from 1.68 to 8.30, and five samples presented TUs with *P. subcapitata* ranging from 1.75 to 4.19. In two cases (the eighth and the tenth samples), the sample concentration and the inhibition of algal growth were inversely proportional. The presence of a high concentration of nutrients for algae in wastewater could have been one of the possible reasons for that. Throughout the 72 hour exposure time, the adverse effects of toxicants could have been masked by the ameliorating effects of the nutrient compounds that stimulate algae growth (Manusadġianas et al. 2003). The mean highest TUs value (*V. fischeri*) was found in the effluent samples (2.27 ± 3.65), and the results of the linear regression analysis (ANOVA) suggested that there were significant differences in the TUs between sites ($F = 7.84$ and $p < 0.001$). The post-hoc Tukey test of the ANOVA results indicated that the difference between effluent and both US and DS TU values was significant, while there was no statistical difference between the US

281 and DS TU values. As shown in Fig. 1, the TUs mean values were higher in the effluent
282 samples then in the influent for the three toxicity tests applied, and this means that the
283 toxicity generally increased in the effluent.
284 The evaluation of the overall toxic concentration following the ecotoxicological
285 approach is shown in Fig. 2 (U.S. EPA 1991). Eight DS samples, taken during the
286 disinfection period, exhibited an appreciable toxicity (C), although only the ninth and
287 the sixteenth samples exceeded the U.S. EPA acceptance limit for acute toxicity (TU =
288 0.3).
289 In relation to the effect of the chlorination process on the toxicity of the effluent, no
290 toxicity was found in the absence of chlorination, while the mean toxicity was 3.42 ±
291 4.12 TU with chlorination, considering the highest TU values of the three tests applied.
292
293 *3.2. Microbiological analyses*
294 Microbiological analyses (Tables 2 - 5) highlighted that there was generally a difference
295 between the four sampling sites (IN: 7,622,700 ± 6,227,340 CFU/100 mL; US: 42,700 ±
296 23,400 CFU/100 mL; OUT: 34,700 ± 67,000 CFU/100 mL; DS: 39,000 ± 29,200
297 CFU/100 mL). The results of the linear regression analysis (ANOVA) suggested that
298 these differences in *E. coli* concentration between sites were significant ($F = 31.629$
299 and $p < 0.0001$). The post-hoc Tukey test of the ANOVA results indicated that the
300 difference between influent and both US and DS samples values was significant, while
301 there was no statistical difference between the *E. coli* concentrations of the other three
302 sites (OUT, US and DS). Microbiological analyses have highlighted the efficiency of
303 the WWTP in the removal of *E. coli* from the influent. The mean removal was 97.83% ±
304 7.03% at the end of the process; however, sometimes this was not sufficient to reduce
305 the *E. coli* concentration below 20,000 CFU/100 mL, which is the concentration limit
306 established by the local authorities, or below 5,000 CFU/100 mL, which is the
307 concentration limit established by the Decree Italian Law 152/2006. In relation to the
308 effect of the chlorination process on the *E. coli* concentration of the WWTP effluent, we

found a lower mean value for the chlorinated effluent: 13,993 ± 12,037 CFU/100 mL vs. 62,857 ± 80,526 CFU/100 mL for the non-chlorinated effluent (Figure 3). This difference was shown to be significant with the *T*-test ($p < 0.05$). However, *E. coli* in ten chlorinated samples was higher than 5,000 CFU/100 mL (Decree Italian Law 152/2006).

3.3. Trihalomethanes concentration

THMs expressed as the sum of disinfection by-products (DBPs) chloroform, bromoform, chlorodibromomethane, bromodichloromethane and other THMs, 1,1,1-trichloroethane, trichloroethylene, carbon tetrachloride, 1,2-dichloroethane, trichloroethylene, and tetrachloroethene (Tables 2 - 5) were detected at all of the sampling sites at concentrations ranging from <0.10 to 7.72 µg/L. The highest mean THMs value was found in the influent samples (2.79 ± 1.40 µg/L), while the mean highest DBPs value was found in the effluent samples (1.85 ± 2.25 µg/L), and the results of the linear regression analysis (ANOVA) suggest that there were significant differences in DBPs mean concentrations between sites ($F = 5.44$ and $p < 0.01$). The post-hoc Tukey test of the ANOVA results determined that the mean DBP concentration of the WWTP effluent differs significantly from the mean DBP concentrations of the US and DS samples; however, the mean DBP concentrations of the US and DS samples are not significantly different from one another. The DBP values of the effluent exhibited a higher mean value (2.52 ± 2.52 µg/L) in the presence of chlorination, as shown in figure 4. Despite this, the t-test performed between the DBP values with and without chlorination showed that this difference was not significant (t-test, $p > 0.05$), which could be a result of the small sample size.

3.4. Residual chlorine concentration

335 The residual chlorine concentrations of the effluent samples (Table 4) ranged from
336 <0.05 mg/L to 1.01 mg/L. In six samples it exceed the limit (≤ 0.2 mg/L) established by
337 the Decree Italian Law 152/2006 for the effluent discharged into surface waters.
338
339 *3.5. Comparison of toxicity, E. coli, NaOCl, residual chlorine and DBPs*
340 Spearman correlations were calculated between toxicity and the other parameters
341 considered in this study. Significant correlations were found for TU vs. DBPs ($r = 0.632$,
342 $p < 0.01$), TU vs. *E. coli* ($r = 0.254$, $p < 0.05$), and DBPs vs. *E. coli* ($r = 0.570$, $p < 0.01$).
343 These relationships become closer if one only considered the effluent site. All the data
344 are reported in table 6.
345
346 **4. Discussion**
347 In the absence of effluent chlorination, the WWTP investigated in this study has a good
348 efficiency in removing the influent toxicity. This evidence is confirmed by the absence
349 of toxicity with all the tests utilized in the recipient water body both downstream and
350 upstream of the plant discharge, except for the fifteenth sample from DS site that
351 presented a TU value with *P. subcapitata*. Whereas, in the second sampling period
352 (2006 - 2007), we found a low toxicity in one US sample and in two DS samples after
353 the effluent treatment with NaOCl; the disinfection of these samples might have used
354 the highest concentrations of sodium hypochlorite (4.58 and 5.00 mg/L). Furthermore,
355 during the first sampling period (2005), the effluent toxicity did not change in summer,
356 even when the disinfection had been applied. However, with the lowering of effluent
357 temperature in October, toxicity increased significantly, showing the maximum value in
358 the eighth sample (October 2005). This was probably due to the high temperatures
359 observed that summer in Northern Italy. This phenomenon probably caused a high
360 evaporation rate of oxidising volatile compounds, and minimised the formation and
361 residence time in the water phase of disinfection by-products, as reported in the study
362 of Matamoros et al. (2007), where it was observed that the THMs production

363 decreased with higher temperatures, and that this decrease could be attributed to the
364 increase of ammonia nitrogen concentration observed during summer. Moreover, the
365 increase in the toxicity value from summer to autumn could also depend on the change
366 of quality of wastewater entering the plant. Ra et al. (2007) reported a seasonal
367 variation in the toxicity which was lower in summer compared to winter, but it was due
368 to the rainfall. The calculated toxicity (C) of the Dora Riparia was obtained by taking
369 into account the toxicities and flow rates of both WWTP discharge and its recipient
370 water body, and it resulted in being above the water quality standard established by
371 U.S. EPA (1991) for acute toxicity in two samples. This result was not in accordance
372 with the measured toxicity in the river downstream of the WWTP outlet, but it has to be
373 considered that this was based on grab sampling, so the results are not completely
374 representative. Moreover, the toxicity with *V. fischeri* presented a significant correlation
375 with the NaOCl concentration, the THMs and the DBPs concentration as reported in
376 other studies (Petala et al. 2008; Zouboulis et al. 2007; Monarca et al. 2000), but we
377 did not find correlation with the effects on *D. magna* and *P. subcapitata.* Cao et al.
378 (2009) found an increased mortality of neonates (*D. magna*) after chlorination, but the
379 disinfectant dosages used were higher than 5 mg/L.
380 The WWTP reached a good percentage removal of the bacterial concentration, but the
381 disinfection process applied can be considered less effective: in eight effluent samples
382 (four in absence of chlorination and four in presence of chlorination), *E. coli* exceeded
383 the concentration of 20,000 CFU/100 mL (the limit established by the local authority)
384 and exceeded the concentration of 5,000 CFU/100 mL (Decree Italian Law 152/2006)
385 in all the effluent samples not disinfected and in eleven disinfected samples, even if the
386 *E. coli* concentration in the effluent presented a significant correlation with the
387 disinfectant dosage and with the residual chlorine. It is interesting to highlight that, even
388 if the *E. coli* effluent concentrations were higher than the established limits, we
389 observed no impact on the recipient river because the mean *E. coli* concentration
390 upstream was 42,667 ± 23,422 CFU/100 mL. Also, the study of Gaki et al. (2007)

391 reported that the chlorination applied was unable to produce the required effluent
392 standard.
393 THMs and DBPs in both the chlorinated and the non-chlorinated samples were
394 acceptable under Italian legislation (Decree Italian Law 152/2006), which restricts
395 chlorinated solvents of WWTP effluents to 1 mg/L. THMs and DBPs presented a
396 significant correlation with the disinfectant dosage, residual chlorine and toxicity, as
397 reported in the study by Matamoros et al. (2007), where the concentrations of THMs
398 found were comparable with the ones reported in this study.
399 Regarding the hygienicï sanitary evaluation of the impact of the disinfection practice on
400 the recipient water body, we observed that the chlorination with sodium hypochlorite
401 seems inadequate to comply with the foreseen microbiological emission limit;
402 moreover, it produces an increase in the toxicity of the effluent and the overcoming of
403 the limit established by Italian Law for the residual chlorine concentration. Thompson
404 and Blatchley (1999) studied the toxicity response of wastewater effluent samples
405 exposed to ɔ-radiation compared with chlorinated and municipal wastewater effluent
406 samples not disinfected. The chlorinated effluent samples often showed a statistically
407 significant increase in toxicity as compared to those not disinfected and to the ɔ-
408 irradiated samples. This type of disinfection system is more expensive than
409 chlorination, so it is not as widespread. In another study, Emmanuel et al. (2004)
410 showed that the addition of NaOCl to wastewater can reduce bacterial pollution, but
411 highlighted considerable acute toxicity with *D. magna* (TU = 9.8 ï 116.8) and *V.*
412 *fischeri* (TU = 2.47 ï 4.15). Petala et al. (2008) evaluated different ozone treatments
413 applied to secondary effluents by combination of bioassays (*V. fischeri*) using different
414 end-points and physicochemical parameters. The study of toxicity of pre-concentrated
415 samples showed that ozonation may either increase or decrease the toxic potential of
416 secondary effluents. The application of low ozone doses induced a decrease of toxicity,
417 whereas ozone doses higher than 5.0 mg O_3/L resulted in an increase of toxicity of
418 treated wastewater, and this was due to the formation of ozonation by-products.

Moreover Gagnè et al., (2008) evaluated the immunotoxic potential of a primary treated municipal effluent following enhanced disinfection by ozonation on freshwater mussels. They found that this disinfection process successfully reduced microbial loading, but increased the inflammatory properties of the effluent.

The studies on wastewater effluents indicated that all toxicity tests have a variable role to play in monitoring and control of water quality, and demonstrated that there is no single method that can constitute a comprehensive approach to aquatic life protection. For this reason, toxicity tests containing sensitive microorganisms should be applied in battery form, so the tests can complement each other, in addition to complementing the chemical analysis (Hemming et al. 2002; Sponza 2003).

In conclusion, this study highlighted that the disinfection of wastewater effluents with sodium hypochlorite determines the increase of the toxicity, and sometimes is not enough to control the *E. coli* contamination; the effluent toxicity after the chlorination process seems to be due to the concentration of the DBPs. The toxicity assessment of the wastewater (influent and effluent) and of the surface water provides a real approach to assess the effluent risk, and enables confirmation of the efficiency of the WWTP to remove toxic compounds. The toxicity tests can be considered as useful analytical tools for the screening of chemical analysis, and as an early warning system to monitor the WWTPs (Hernando et al. 2005). The identification of different disinfectants, such as peracetic acid, ozone or UV, and the study of the ideal concentration for reaching the toxicological and the microbiological standard for WWTP effluent seems to be a research issue that could facilitate the management of the surface water bodies.

FIGURE CAPTIONS

Fig. 1 TU mean values of the influent (IN) and effluent (OUT) samples.

Fig. 2 Calculated Toxicity (C) of the recipient water body (Dora Riparia River, Collegno, Torino, Italy) expressed in Toxic Unit (TU) and U.S. EPA acceptance limit.

Fig. 3 *E. coli* concentration in effluent samples chlorinated and not-chlorinated.

Fig. 4 Total THMs, DBPs, and industrial THMs in effluent samples chlorinated and not-chlorinated.

Table 1 Hazard classification system for wastes discharged into the aquatic environment proposed by Persoone et al. (2003).

TU	Class	Toxicity
< 0.4	Class I	No acute toxicity
0.4 < TU < 1	Class II	Slight acute toxicity
1 < TU < 10	Class III	Acute toxicity
10 < TU < 100	Class IV	High acute toxicity
TU > 100	Class V	Very high acute toxicity

Table 2 Toxicity with Microtox™, *D. magna*, *P. subcapitata*, *E. coli*, THMs concentration in the Upstream WWTP (US) sampling point.

Site and sampling	*V. fischeri* (TU)	*D. magna* (TU)	*P. subcapitata* (TU)	*E. coli* (CFU/100 ml)	THMs (µg/L)

N.T. = not toxic; N.D. = not determined

642 Table 6 Comparison of toxicity (TU), *E. coli,* NaOCl, THMs, DBPs and residual chlorine

643 (RCHL) in the effluent site (OUT).

Spearman correlations	r	p
TU vs NaOCl	0.539	< 0.01
TU vs THMs	0.664	< 0.05
TU vs DBPs	0.788	< 0.01
TU vs *E. coli*	0.660	< 0.01
TU vs RCHL	0.657	< 0.01
THMs vs *E. coli*	0.850	< 0.01
THMs vs RCHL	0.865	< 0.01
NaOCl vs *E. coli*	0.631	< 0.01
NaOCl vs THMs	0.676	< 0.05
NaOCl vs DBPs	0.715	< 0.01
NaOCl vs RCHL	0.740	< 0.01
RCHL vs E. coli	0.428	< 0.05
RCHL vs DBPs	0.835	< 0.01
